For all exercises, reinforce the importance of first finding the neutral spine (cervical and lumbar regions), performing the drawing-in maneuver, and then maintaining the neutral spine while superimposing any extremity motions. It is critical to instruct the patient to stop the exercises (or decrease the intensity) as soon as there is a sense that there is loss of control of the stable spinal position. It is important not to progress the patient beyond what he or she is able to control in order to develop the proper muscle response. The emphasis is first on improving the static holding capacity (endurance) of the trunk muscles followed by strengthening. Endurance training of the trunk extensor muscles is related to decreased pain and improving function during the early stages of recovery in patients with subacute low back pain.⁸

- **Emphasis on muscle endurance.** Determine a level of exercise that the patient can perform for several repetitions while maintaining a stable spine in the neutral position. Have the patient exercise at that level with the goal of increasing the number of repetitions or the time. Once the patient can perform repetitions for 1 minute, add weights, decrease the repetitions, and emphasize strength. Progress to the next level of difficulty for muscular endurance.
- **Use of external props.** Use of the Stabilizer™ pressure biofeedback unit to help the patient with learn control while doing the abdominal stabilization exercises was described earlier (see Box 16.5). For exercises in the quadruped position, if the patient has difficulty controlling the trunk rotation, use a prop such as a dowel rod placed along the spine. Have the patient attempt to keep it balanced while performing the arm and leg exercises (Fig. 16.29). It may be helpful to cue the patient to not shift his or her weight as the extremity is moved—this is difficult to do but is effective in bringing in the stabilizing trunk muscles.
- **Extremity loading.** Boxes 16.5 and 16.6 identify a progression of exercises in supine and quadruped/prone positions with extremity loading. Initially have the patient do the motions repetitively; then progress to

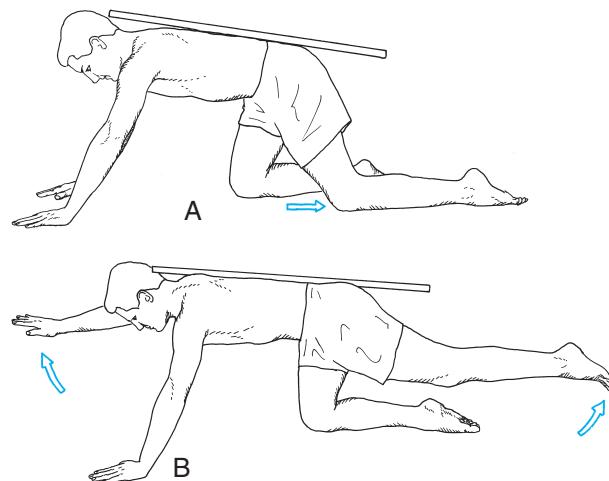

FIGURE 16.29 Balancing a rod on the back while doing quadruped exercises provides reinforcement that the trunk is not twisting. (A) Single leg slides. (B) Lifting the opposite arm and leg simultaneously, then alternating extremities.

alternating the extremities or moving all four extremities simultaneously (Fig. 16.30). This requires the stabilizing musculature to adjust to the shifting loads. Motions begin in the sagittal plane and then progress to the transverse plane and diagonal patterns (unilateral and bilateral), where movement away from the midline adds a rotational component and increases the challenge to the stabilizing musculature.

- **External resistance.** Use weights, elastic resistance, or pulleys for strengthening. Several suggestions are

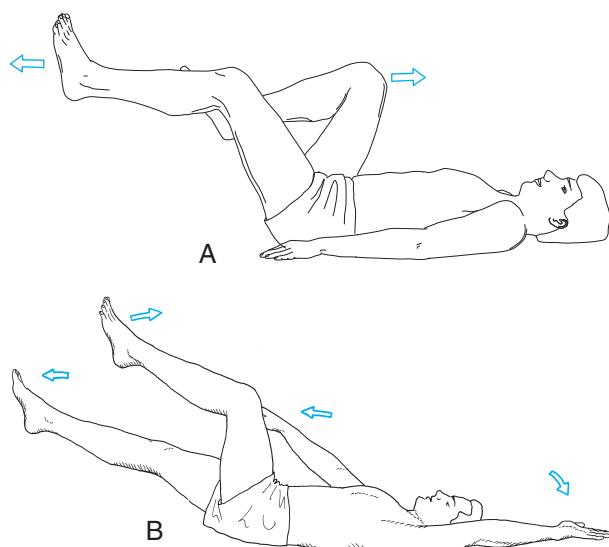

FIGURE 16.30 (A) Alternating lower extremity motions with the "modified bicycle" or (B) reciprocal and alternating patterns using the upper and lower extremities simultaneously require a strong controlling action in the abdominals.

illustrated in Figures 16.31, 16.32, and 16.33. Even though the extremities benefit from the exercises, the primary purpose is to improve performance in the stabilizing muscles of the trunk; therefore, when signs of fatigue occur, such as poor control of spinal stability (seen as movement of the pelvis or lumbar spine), reduce the intensity or stop the exercise and allow recovery.

- **Position changes.** Apply the extremity-loading exercises in the sitting (supported then unsupported), kneeling, and standing positions. Also use modified bridging to challenge the stabilizing function of the trunk musculature. Exercises such as wall slides and partial lunges and bridging with extremity motions use the extremities and trunk during weight bearing and prepare the muscles for functional activities. These exercises are described in the final section under Functional Activities

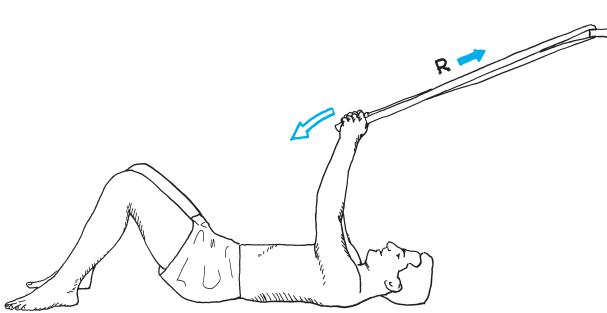

FIGURE 16.31 Developing the stabilizing action of the abdominal muscles by using pull-down activities against a resistive force from pulleys or elastic bands. This exercise can also be done sitting or standing to increase the challenge to the muscles in less stable positions.

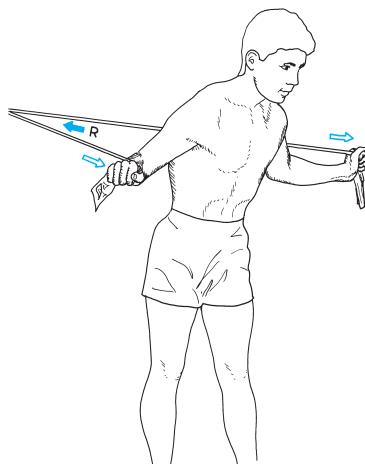

FIGURE 16.32 Using elastic resistance to train and strengthen the abdominal muscles in the upright position. The drawing-in maneuver to set the stabilizing muscles precedes the movement of the arms forward against the resistance.

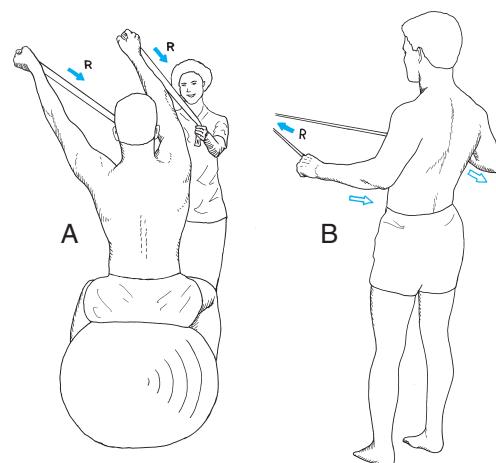

FIGURE 16.33 Using elastic resistance to train and strengthen the back extensor muscles to stabilize in the upright position (A) diagonal patterns while sitting on an unstable surface and (B) while standing.

but also serve the purpose of challenging the stabilizing muscles.

- **Unstable surfaces.** Use a large gym ball, foam roller, or wobble board to challenge the patient's balance and develop the stabilizing musculature. A variety of positions can be used, such as sitting upright on the ball with the feet on the floor, lying supine with the trunk on the ball and feet on the floor or with the feet on a low mat. If a foam roller is used, the patient is supine, with the roller placed longitudinally along the spine. Examples are shown in Figures 16.34 and 16.35. Secure elastic or pulley resistance in front of the patient at various heights and have him or her do pulling motions (see Fig. 16.33A).

FIGURE 16.34 Strength, balance, and coordination are required to maintain spinal stabilization while sitting on a gym ball and moving the extremities. This activity is progressed by adding weights to the extremities.

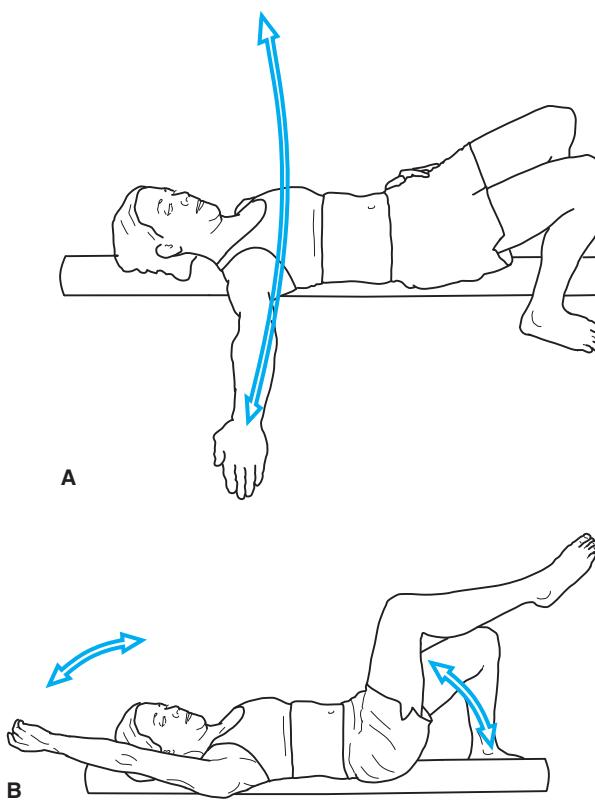

FIGURE 16.35 Activation of the core and global trunk muscles occur to maintain balance on a foam roll while the extremities move in various planes; for example (A) shoulder horizontal abduction/adduction and (B) ipsilateral hip and shoulder flexion/extension.

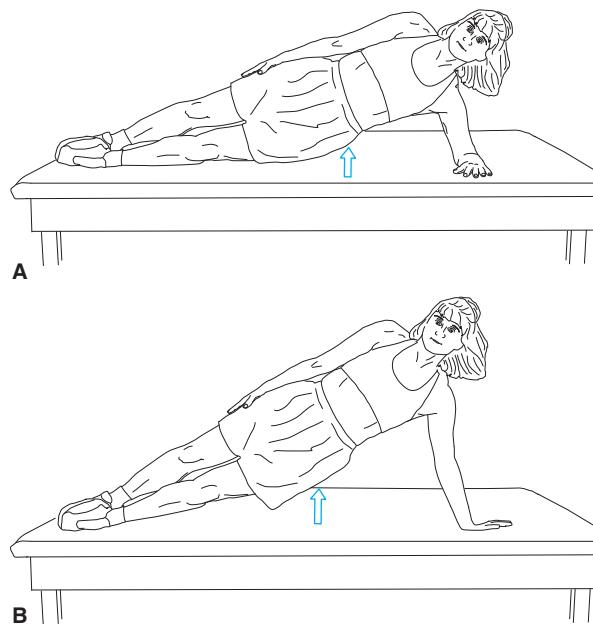

FIGURE 16.36 Quadratus lumborum stabilization training using closed-chain side-propping (A) on the elbow and knee and (B) on the hand and foot.

instruct him or her to incorporate the core activation and stabilization techniques into the activities.

ISOMETRIC AND DYNAMIC EXERCISES

Quadratus Lumborum—Stabilization Exercises

The quadratus lumborum has been identified as an important stabilizer of the spine in the frontal and transverse planes.³³ Strongest activation of this muscle occurs with the side propping position. The external obliques are also activated in this position.³³

Patient position and procedure: Begin side-lying. Have the patient prop up on the elbow and then lift the pelvis off the mat, supporting the lower body with the lateral side of the knee on the downward side. The position can be maintained for an isometric hold or performed intermittently (Fig. 16.36A). Progress by having the patient support the upper body with the hand (with the elbow extended) and lateral aspect of the foot on the downward side (Fig. 16.36B).

Progression to Dynamic Exercises

When the patient has developed control, endurance, and strength in the stabilizing muscles in weight-bearing and non-weight-bearing positions, *dynamic trunk strengthening* exercises are initiated at a low intensity (see following section). The emphasis is on control and safety.

As the patient returns to his or her instrumental activities of daily living (IADLs) and limited work activities,

isometric exercises may be considered stabilizing exercises, as there is little or no movement of the spinal segments. They are included in this section with dynamic exercises, however, because of the method of application of the resistive force; that is, the resistive force is applied directly to the axial skeleton rather than through limb loading, as described in the spinal stabilization section. The decision to use the isometric exercises described in this section must be based on the goals of intervention. The exercises may be combined with the stabilization exercises in a home exercise program.

Dynamic exercises with spinal movement are introduced into the patient's exercise program when the patient demonstrates effective core and global stabilization techniques and has developed endurance in the stabilizing musculature. Dynamic exercises should not be a substitute for stabilization exercises. Because of the load imposed on the spine, they may exacerbate the patient's symptoms if introduced prior to effective stabilization and control. They are important in the total rehabilitation of the individual with neck or low back pain, as dynamic muscle endurance and strength is required for many daily activities as well as manual labor and athletic performance.

Exercises for the Cervical Region

Isometric Exercises—Self-Resistance

The intensity of the isometric exercises can be from light to strong, depending on the patient's symptoms and tolerance.

Patient position and procedure: Sitting.

- **Flexion.** Have the patient place both hands on the forehead and press the forehead into the palms in a nodding fashion while not moving (Fig. 16.37A).

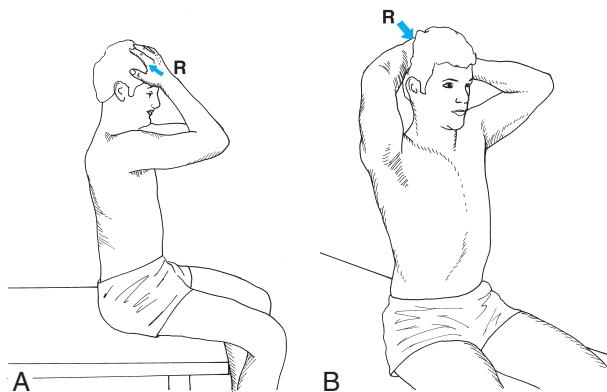

FIGURE 16.37 Self-resistance for isometric (A) cervical flexion and (B) axial extension.

- **Side bending.** Have the patient press one hand against the side of the head and attempt to side-bend, as if trying to bring the ear toward the shoulder but not allowing motion.
- **Axial extension.** Have the patient press the back of the head into both hands, which are placed in the back, near the top of the head.
- **Rotation.** Have the patient press one hand against the region just superior and lateral to the eye and attempt to turn the head to look over the shoulder but not allowing motion.

Isometric Resistance Activities

- *Patient position and procedure:* Standing with a basketball-sized inflatable ball between the forehead and a wall. Have the patient keep the chin tucked and not go into a forward-head posture. The patient maintains the functional position while superimposing arm motions. Progress by adding weights to the arm motions.
- *Patient position and procedure:* Supine with the head over the edge of the mat, the neck maintained in a neutral functional position, and no support to the head. The patient must be able to keep the neck in its safe, functional position to perform this advanced stabilization exercise. He or she holds the position as tolerated. Progress by adding arm motions, then adding weights to the arm motions as tolerated.

Dynamic Cervical Flexion

Often with faulty forward-head postures, the patient substitutes using the sternocleidomastoid (SCM) muscles to lift the head when getting up from the supine position rather than the overstretched, weak, deep cervical flexors. To correct this muscle imbalance, begin training capital flexion as described in the stabilization section (core muscle activation). For home exercise, emphasize “curling” the head and neck, not lifting the head up.

Patient position and procedure: Supine. If the patient cannot tuck the chin and curl the neck to lift the head off the mat, begin with the patient on a slant board or large wedge-shaped bolster under the thorax and head to reduce the effects of gravity (Fig. 16.38). Have the patient practice tucking the chin and curling the head up. Use assistance until the correct pattern is learned. Progress by decreasing the angle of the board or wedge and then adding manual resistance if the patient does not substitute with the SCM.

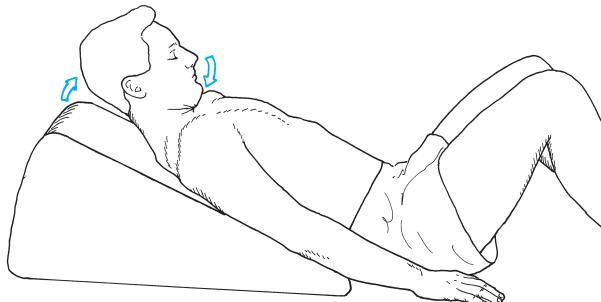

FIGURE 16.38 Training the short cervical flexors while de-emphasizing the sternocleidomastoid for cervical flexion to regain a balance in strength for anterior cervical stabilization.

Manual Resistance—Cervical Muscles

Patient position and procedures: Supine. Stand at the head end of the treatment table, supporting the patient's head for each exercise.

- Place one hand on the patient's head to resist opposite the motion. Do not resist against the mandible lest force be transmitted to the temporomandibular joint. Resistance is given to isolated muscle actions or to general ROMs, whichever best gains muscle balance and function.
- Isometric resistance can be applied with the head in any desired position before applying resistance. Avoid jerking the neck when applying or releasing the resistance by gradually building up the intensity, telling the patient to match your resistance, holding, and then gradually releasing and asking the patient to relax.

Intermediate and Advanced Training

As the patient progresses in the rehabilitation program, greater challenges to the musculature to stabilize and

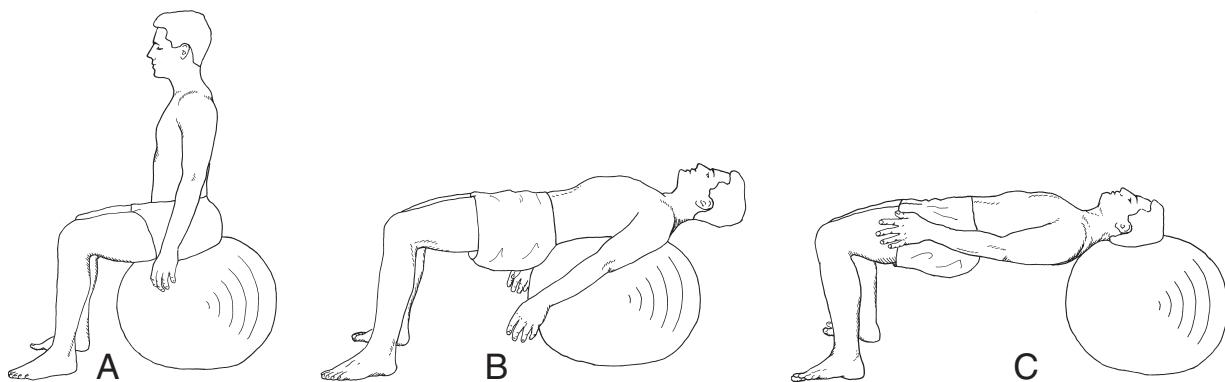

FIGURE 16.39 Advanced exercises for strengthening the cervical and upper thoracic flexors and extensors as stabilizers. Begin by (A) sitting on a large gym ball, then (B) walking forward while rolling the ball up the back. With the ball behind the mid-thoracic area, the cervical flexors must stabilize. Continue walking forward until the ball is (C) under the head; the cervical extensors now must stabilize. Walk back and forth between the two positions (B and C) to alternate control between the flexors and extensors. Progress by adding arm motions or arm motions with weights to increase resistance.

control motion are emphasized, especially for those individuals returning to work, sports, or recreational activities that place greater demands on the cervical structures.

Transitional Stabilization for the Cervical and Upper Thoracic Regions

- *Patient position and procedure:* Standing with a basketball-size inflatable ball between the head and the wall. Have the patient roll the ball along the wall, using the head. This requires the patient to turn the body as he or she walks along.
- *Patient position and procedure:* Sitting on a large gym ball. Have the patient walk the feet forward so the ball rolls up the back and the thorax is resting on the ball (Fig. 16.39 A&B). The head and neck are maintained in neutral position, and the cervical flexors are emphasized. Have the patient then walk the ball farther so it is under the head. The extensors are now emphasized (Fig. 16.39C). The patient walks the feet forward and backward, alternating stabilization between the flexors and extensors. Progress to advanced training by adding arm motions and then arm motions with weights in each of the positions.

NOTE: This activity requires considerable strength in the cervical extensors to support the body weight and should be performed only with advanced training with patients who have been properly progressed to tolerate the resistance.

Functional Exercises

Design exercises that simulate patient-specific functional activities. Identify what activities stress that individual's neck and have the patient practice modifications of those activities with the spine kept in neutral position. Include pushing, pulling, reaching, and lifting (see Functional

Training section later in this chapter). Challenge the patient with increased repetitions and weight and in patterns that replicate functional demands.

Exercises for the Thoracic and Lumbar Regions

Alternating Isometric Contractions and Rhythmic Stabilization

Patient positions and procedures: Begin with the patient supine in the most stable position. Progress to sitting on a stable surface, sitting on an unstable surface such as a large gym ball, kneeling, and then standing. Sitting, kneeling, and standing require stabilizing action in the hip, knee, and ankle musculature, respectively, as well as the spinal muscles. Apply resistance directly against the patient's shoulders or pelvis, against a rod that is held by the patient (see Fig. 17.41), or against the patient's arms.

- Have the patient find the neutral spine position and then activate the stabilizing muscles with the drawing-in maneuver prior to applying the resistive force. Then instruct the patient to "meet my resistance" while applying a force to stimulate isometric contractions. Apply the resistance in alternating directions at a controlled speed while the patient learns to maintain a steady position.
- Initially, provide verbal cues, such as "hold against my resistance, but do not overpower me. Feel your abdominal muscles contracting. Now I'm pulling in the opposite direction. Match the resistance and feel your back muscles contracting."
- Progress by shifting the directions of resistance without the verbal cues and then by increasing the speed.
- Begin with alternating resistance in the sagittal plane; progress to side-to-side and then transverse plane resist-

ance. Isometric resistance to trunk rotation (transverse plane resistance) has been shown to be the most effective in stimulating the oblique abdominals, transversus abdominis, and deep spinal extensor muscles.⁴³

- Alternating resistance to pelvic rotation can also be done by having the patient assume a modified bridge position. Apply resistance directly to the pelvis to stimulate rotation while the patient isometrically holds the pelvis and spine in a stable position.

Dynamic Strengthening—Abdominal Muscles

NOTE: Dynamic exercises of the trunk musculature are not initiated until late during the rehabilitation process and not until after the patient has learned to activate the drawing-in maneuver automatically for stabilization in all functional activities.

No one abdominal exercise challenges all of the abdominal muscles³³; therefore, a variety of exercises should be included in the patient's exercise program to include the entire region.

Focus on Evidence

EMG studies have looked at abdominal muscle recruitment with various abdominal exercises.^{3,29,33,54} In summary:

- Curl-ups (various types) recruit primarily the rectus abdominis, with low activity in the obliques, transversus abdominis, and psoas.
- Sit-ups (straight-leg and bent-knee) show high rectus and external oblique activity, high psoas activity, and high low-back compression. Heel press sit-ups increase psoas activity.
- Hanging-leg raises show high external oblique and high spinal compression.
- Supine single-leg lifts show negligible global abdominal muscle activity (opposite lower extremity provides stability). These exercises are primarily used early in the stabilization exercise routines to train the deep stabilizing muscles under progressive extremity loading.
- Supine bilateral-leg lifts show increased activity in the RA, EO, and IO during the first part of the range of hip flexion and increased load on the spine.
- Curl-ups on a labile surface doubled the activity of the rectus abdominis and increased the activity of the external obliques fourfold compared with curl-ups on a stable surface.⁵⁴

Rectus abdominis. There is no clinically significant selective difference between the upper and lower rectus abdominis function.²⁹ Both portions contract strongly in all trunk curl-type and leg lift exercises.^{29,33}

External obliques. External obliques contract strongest in sit-ups and diagonal sit-ups to the opposite side.³²

Internal obliques. Internal obliques contract strongest in diagonal sit-ups to the same side and horizontal side propping (see Fig. 16.36).³³

Trunk Flexion

Patient position: Supine or hook-lying with the lumbar spine neutral. McGill³³ suggested supporting the low back with the hands to maintain slight lordosis. The spine should not be allowed to go into an increased lordosis during the exercise—this indicates weakness of the abdominals and consequently lifting of the trunk occurs from hip flexor action only.²⁷ When training the abdominals, curl-up exercises should be performed at a slow, controlled rate to activate the stabilizing function of the abdominals.⁵⁵

PRECAUTIONS: Patients with conditions such as intervertebral disk lesions or osteoporosis should not do dynamic trunk flexion exercises because of the increased intra-abdominal pressure and increased compression forces on the vertebral bodies. Similarly, if a patient experiences pain with trunk flexion, these exercises should not be done. Use the stabilization exercises, as described in the previous section, with the spine maintained in a neutral position (slight lordosis).

Procedures

Curl-ups. First, instruct the patient to perform the drawing-in maneuver to cause a stabilizing contraction of the abdominal muscles (see section on Stabilization Training—Core Muscle Activation) and then lift the head. Progress by lifting the shoulders until the scapulae and thorax clear the mat, keeping the arms horizontal (Fig. 16.40). A full sit-up is not necessary because once the thorax clears the mat the rest of the motion is performed by the hip flexor muscles.

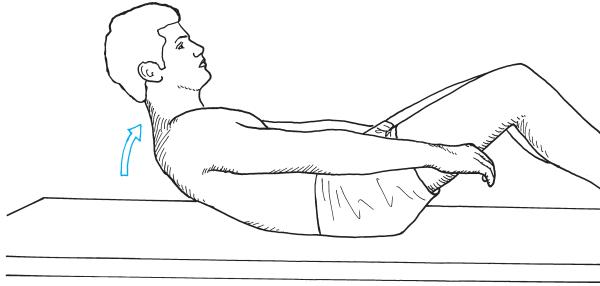

FIGURE 16.40 The curl-up exercise to strengthen the abdominal muscles. The thorax is flexed on the lumbar spine. The arms are shown in the position for least resistance. Progress by crossing the arms across the chest and then behind the head.

- Further progress the difficulty of the curl-up by having the patient change the arm position from horizontal to folded across the chest and then to behind the head.
- During all these activities, the low back should not arch; if it does, reduce the progression until the abdominals are strong enough to maintain lumbar flexion.

Curl-downs. If the patient is unable to perform the curl-up, begin with curl-downs by having the patient start in the hook-sitting or long-sitting position and lower the trunk only to the point where he or she can maintain a flat low back and then return to the sitting position.

- Once the patient can curl-down full range, reverse and perform a curl-up.

Diagonal curl-ups. Have the patient reach one hand toward the outside of the opposite knee while curling up; then alternate. Reverse the muscle action by bringing one knee up toward the opposite shoulder; then repeat with the other knee. Diagonal exercises emphasize the oblique muscles.

Double knee-to-chest. To emphasize the lower rectus abdominis and oblique muscles, have the patient set a posterior pelvic tilt; then bring both knees to the chest and return. Progress the difficulty by decreasing the angle of hip and knee flexion (Fig. 16.41).

Pelvic lifts. Have the patient begin with the hips at 90° and knees extended; then lift the buttocks upward off the mat (small motion). The feet move upward toward the ceiling (Fig. 16.42). The patient should not push against the mat with the hands.

Bilateral straight-leg raising

- Have the patient begin with legs extended; then perform a posterior pelvic tilt followed by flexing both hips,

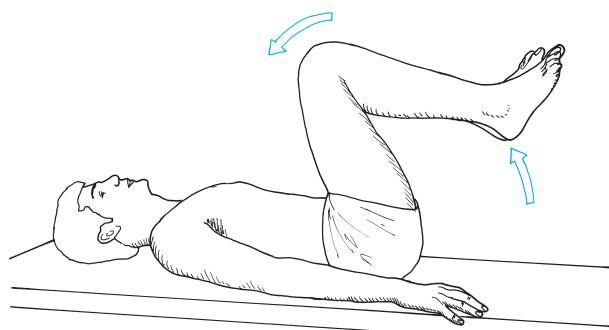

FIGURE 16.41 Strengthening the abdominal muscles by flexing the hip and pelvis on the lumbar spine. The legs are shown in the position for least resistance. Progress by decreasing the angle of hip flexion until the legs can be lifted with the knees extended, as in the pelvic lift.

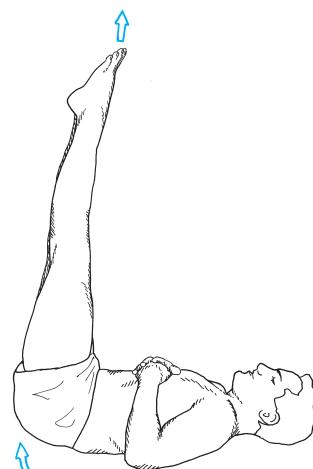

FIGURE 16.42 Pelvic lifts. Elevating the legs upward toward the ceiling by raising the buttock off the floor emphasizes strengthening the lower abdominal muscles.

keeping the knees extended. If the pelvis and spine cannot be kept stable, the knees should be flexed to a degree that allows control.

- If the hips are abducted before initiating this exercise, greater stress is placed on the oblique abdominal muscles.

PRECAUTION: The strong pull of the psoas major causes shear forces on the lumbar vertebrae. Also this bilateral straight-leg raise (SLR) causes increased spinal compression loads. If there is any low-back pain or discomfort, especially with spinal hypermobility or instability, this exercise should not be performed even if the abdominals are strong enough to maintain a posterior pelvic tilt.

Bilateral straight-leg lowering. Bilateral straight-leg lowering can be performed if the bilateral SLR is difficult. Have the patient begin with the hips at 90° and knees extended; then lower the extremities as far as possible while maintaining stability in the lumbar spine (should not increase the lordosis), followed by raising the legs back to 90°. See precaution under the bilateral SLR exercise.

Trunk Flexion (Abdominals)—Sitting or Standing

Patient position and procedures: Sitting or standing. Pulleys or elastic material are secured at shoulder level behind the patient. Progress the resistance as the patient's abdominal strength increases.

- Have the patient hold the handles or ends of the elastic material with each hand and then flex the trunk, with emphasis on bringing the rib cage down toward the pubic bone and performing a posterior pelvic tilt, rather than flexing at the hips (Fig. 16.43).
- Have the patient perform diagonal motions by bringing one arm down toward the opposite knee with emphasis on moving the rib cage down toward the opposite side of the pelvis. Repeat the diagonal motion in the opposite direction.

FIGURE 16.43 Standing trunk flexion against elastic material to strengthen the abdominal muscles. The patient performs a posterior pelvic tilt and approximates the ribs toward the pubis.

Trunk Flexion (Abdominals)—Unstable Surfaces

Patients with chronic, unilateral low back pain have been shown to have impaired balance.² Use of unstable surfaces, such as a gym ball (Fig. 16.44) or a balance board, while doing abdominal curl-up exercises has been shown to increase activity in the internal and external obliques and the rectus abdominis.⁴⁹ The presumption is that these muscles generate increased activity to maintain balance on the unstable surfaces. Other suggestions include balancing on a foam roll or a biomechanical ankle platform system (BAPS) board while performing arm and leg activities or curl-up exercises.

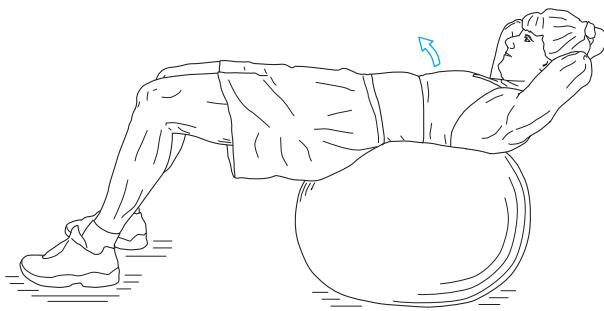

FIGURE 16.44 Curl-ups on an unstable surface. The unstable surface increases activity in the oblique and rectus abdominis muscles.

Dynamic Strengthening—Erector Spinae and Multifidus Muscles

Focus on Evidence

Strengthening the extensor muscles and an improved extensor/flexor ratio has been found to be important in decreasing symptoms in patients with chronic low back pain (LBP).⁵² Lee et al.²⁸ determined that the trunk extensor/flexor ratio is a sensitive parameter for predicting LBP. After following 67 asymptomatic individuals for 5 years, they found an increased incidence of LBP in those who had lower extensor than flexor muscle strength. Danneels et al.⁹ demonstrated that intensive lumbar resistance training (isometric or dynamic) is necessary to develop paravertebral muscle strength and bulk. The following is a summary of specific exercise outcomes studies.

- Prone arch, isometric trunk extension, and isometric leg extensions: high activity in both the multifidus and erector spinae.³⁶
- Isolated training of multifidus: requires a low-intensity focus, as described in the stabilization section—techniques for core muscle activation.⁴⁰

Resistance can be applied to any of the following recumbent exercises by having the patient hold weights in the hands or by strapping weights around the patient's legs.

Extension Exercises in Prone Position

PRECAUTIONS: Extension exercises in the prone position are performed at the end of the ROM in spinal extension and therefore may not be appropriate for individuals with symptoms from conditions such as arthritis or nerve root compression. Patients with spondylosis or other flexion bias conditions or patients who develop symptoms under loaded conditions (e.g., with disk lesions) may experience increased symptoms and therefore should not do dynamic end-range extension exercises. If symptoms occur, modify the positioning toward more neutral spinal positions, such as the quadruped position, and emphasize stabilization with isometric holds rather than moving into full extension (see Figs. 16.28, 16.29, and 16.33).

Thoracic elevation. Begin with the arms at the side, progress to behind the head or reaching overhead as strength improves. Have the patient tuck in the chin and lift the head and thorax. The lower extremities must be stabilized (Fig. 16.45).

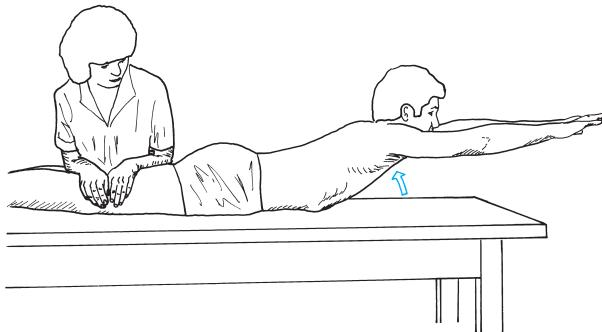

FIGURE 16.45 Strengthening the back extensors with the arms in position to provide maximal resistance. Additional resistance can be provided by holding weights in the hands.

Leg lifts. Initially have the patient lift only one leg, alternate with the other leg, and finally lift both legs and extend the spine. Stabilize the thorax by having the patient hold onto the side of the treatment table.

“Superman.” Progress the extension exercises by having the patient lift both upper and lower extremities simultaneously (Fig. 16.46).

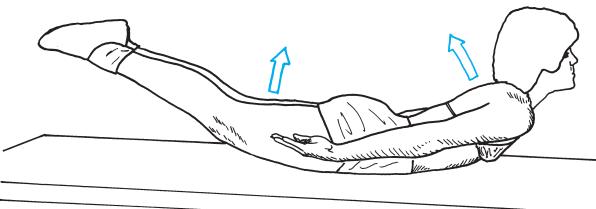

FIGURE 16.46 Strengthen the trunk and hip extensors by lifting the trunk and legs off the mat simultaneously. Greater resistance can be provided by abducting the shoulders to 90° or by elevating them to 180° (“Superman”).

Extension Exercises Sitting or Standing

Elastic resistance or weighted pulleys. Secure pulleys or elastic resistance in front of the patient at shoulder level. Have him or her hold onto the ends of the material or handles and extend the spine (Fig. 16.47).

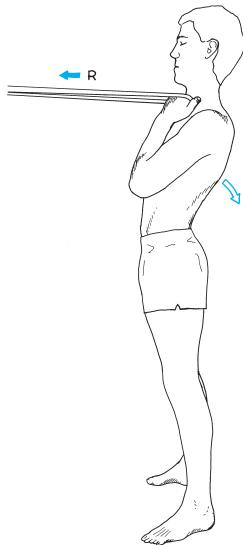

FIGURE 16.47 Using elastic resistance for concentric eccentric back extension.

For trunk rotation, use a pulley or elastic resistance secured under the foot or to a stable object opposite to the side being exercised. Have the patient pull against the resistance, extending and rotating the back. Change the angle of pull of the resistance to recreate functional patterns specific to the patient's needs (Fig. 16.48).

FIGURE 16.48 Rotation with extension strengthens the back extensors in functional patterns.

Trunk Side Bending (Lateral Abdominals, Erector Spinae, Quadratus Lumborum)

Trunk side-bending exercises are used for general strengthening of the muscles that side-bend the trunk.

Focus on Evidence

McGill³³ identified the quadratus lumborum as one of the most important stabilizers of the spine and documented the isometric horizontal side support as an effective exercise to strengthen this muscle (see discussion in the stabilization section and Figure 16.36).

Side-bending exercises are also used if there is scoliosis, although exercise alone has not been shown to halt or change the progression of a structural scoliosis curve. Exercise in conjunction with other methods of correction, such as bracing, is often employed.^{5,7} When there is a lateral curve, the muscles on the convex side are usually stretched and weakened. The following exercises are described for use as strengthening exercises on the side of the convexity, although they may be used bilaterally for symmetrical strengthening.

Stabilization exercises for spinal control, as previously described, may be beneficial for strengthening and conditioning when there is scoliosis.

● **Patient position and procedure:** Standing. Place elastic resistance under the foot or have the patient hold a weight in the hand on the side of the concavity; then have him or her side-bend the trunk in the opposite direction.

● **Patient position and procedure:** Side-lying on the concave side of the curve with the apex at the edge of the table or mat so the thorax is lowered. If you have access to a split table with one end that can be lowered, begin with the apex of the curve at the bend of the table. Have the patient place the lower arm folded across the chest and upper arm along the side of the body and side-bend the trunk up against gravity. Progress by having the patient clasp both hands behind the head (Fig. 16.49). Stabilization of the pelvis and lower extremities must be provided.

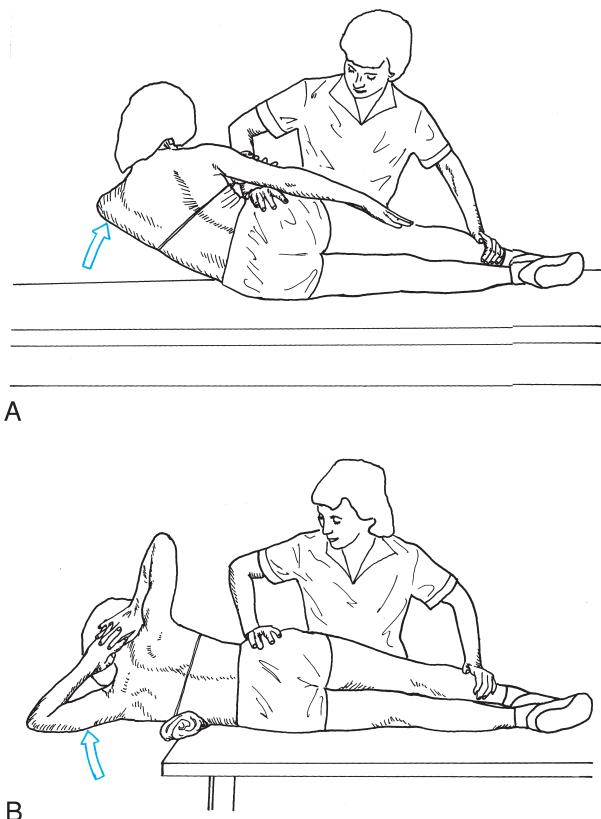

FIGURE 16.49 (A, B) Antigravity strengthening of the lateral trunk musculature. There is less resistance if the top arm is at the side and the bottom arm is folded across the chest.

CARDIOPULMONARY ENDURANCE

Goal. To develop cardiopulmonary fitness for overall endurance and well-being.

Aerobic conditioning exercises provide many benefits for the patient with spinal symptoms. The activity not only improves cardiopulmonary endurance but stimulates feelings of well-being and relief of symptoms.³⁵ Chapter 7 describes cardiopulmonary conditioning principles and procedures. Specific precautions and suggestions for medical conditions are also explained. For patients recovering from spinal injuries, surgery, or postural dysfunction, aerobic exercises may be initiated once signs of inflammation no longer exist. Begin with low to moderate intensity and work with the patient to choose activities that do not place added stress on the recovering spinal structures. If a particular spinal bias has been identified (see Chapter 15), choose aerobic exercises that emphasize that spinal bias. A brief summary of the principles is reviewed in Box 16.6. Guidelines for safe application of common conditioning exercises when there are spinal impairments are described in this section.

BOX 16.6 Summary of Aerobic Conditioning Principles

1. Establish the target heart rate and maximum heart rate.
 - The maximum heart rate is generally 220 minus the individual's age or may be the symptom-limiting heart rate (the rate at which cardiovascular symptoms appear).
 - Target heart rate is between 60% and 80% of the maximum heart rate.
2. Perform warm-up exercises for 10 to 15 minutes, including active movements of the neck and trunk.
3. Individualize the program of exercise.
 - Select activities that emphasize the patient's spinal bias if necessary (see information in the text).
 - Not all people are at the same fitness level and therefore cannot perform the same exercises. Any one exercise has the potential to be detrimental if attempted by someone not able to execute it properly.
 - To avoid overuse syndromes to structures of the musculoskeletal system, appropriate equipment, such as correct footwear, should be used for biomechanical support with weight-bearing exercises.
4. Increase the pace of the activity to reach the target heart rate and maintain it for 20 to 30 minutes.
5. Cool down for 5 to 10 minutes with slow, total body, repetitive motions and stretching activities.
6. Frequency of aerobic exercise should be three to five times per week.
7. Always stay within the tolerance of the individual. Overuse commonly occurs when there is an increase in time or effort without adequate rest (recovery) time between sessions. Increase repetitions or time by no more than 10% per week.³⁰ If pain begins while exercising, heed the warning and reduce the stress.

COMMON AEROBIC EXERCISES AND EFFECTS ON THE SPINE

Some aerobic exercises place the spine in end-range positions. They are reviewed so the reader understands why some activities may be inappropriate for patients with specific conditions. If modifications are possible, they should be considered.

Cycling

Road bikes place the thoracolumbar spine in flexion and the upper cervical spine in hyperextension. Use this exercise for patients who have a flexion bias in the lumbar region so long as there are no upper cervical symptoms. Modifications include using a bike that positions the body in a more upright posture, such as a mountain bike or

hybrid bike. Many stationary bikes also position the individual in upright postures and therefore are less likely to precipitate cervical problems.

Walking and Running

The upright posture emphasizes normal spinal curves, and lumbar extension is emphasized with walking and running (terminal stance). Emphasize the importance of identifying the neutral spine, activating the drawing-in maneuver, and stabilizing the spine while walking or running. Because conscious control is not possible during the entire exercise time, coach the patient to check his or her posture and muscle control frequently, such as each time he or she is crossing an intersection, or when passing another individual, or if symptoms develop in the spinal region. Walking or running with the cervical spine in retraction (axial extension) and the scapulae comfortably adducted, along with a rhythmic arm swing, reinforces cervical stabilization. Easy access to treadmills, tracks, or roads and trails make these activities popular. Running is a high-impact activity and may not be tolerated by individuals with intervertebral disk lesions or degenerative joint conditions.

Stair Climbing

Commercial devices that replicate stepping with various grades of resistance are used for strengthening and aerobic conditioning. Regular steps can also be used for aerobic conditioning. This activity requires pelvic control of the reciprocating lower extremities because lifting the leg on one side emphasizes spinal flexion while the contralateral lower extremity and spine are extending. Coach the patient to maintain the neutral spine with the stabilizing muscles against the rotational forces.

Cross-Country Skiing and Ski Machines

Cross-country skiing, whether out in the cold or on a commercial machine, is a high-intensity aerobic activity. The kicking motion that accompanies the backward motion of the leg emphasizes spinal extension. It is important to coach the patient to maintain the neutral spine and contract the stabilizing abdominal muscles.

Swimming

When swimming, the breaststroke emphasizes extension in the cervical and lumbar spinal regions when taking a breath. Coach the patient to not extend the neck full range but to keep it neutral and lift the head out of the water as a “solid” unit with the thorax just enough to clear the mouth for the breath.

The freestyle stroke may exacerbate cervical problems because of the repetitive cervical rotation while taking a breath; this stroke also emphasizes lumbar extension with the flutter kick. Teach the patient to breathe using a “log-roll” technique where the whole body rolls toward one side

while breathing and then rolls back to the face-down position for the stroke. This requires good spinal stabilization.

The backstroke emphasizes spinal extension via kicking the lower extremities and the arm motions. The butterfly stroke moves the spine through a full ROM; emphasis is placed on controlling the range with the stabilizing muscles.

Upper Body Ergometry Machines

Ergometry machines provide upper extremity resistance and can also be used for aerobic training. Forward motions emphasize spinal flexion and shoulder girdle protraction; backward motions emphasize spinal extension and shoulder girdle retraction. Coach the patient to assume the neutral spinal posture and use the stabilizing muscles prior to and during the use of the ergometer to enhance postural responses. If the machine can be used standing, progression to the standing position stimulates a total body response.

Step Aerobics and Aerobic Dancing

Stepping is similar to using stairs or a stair machine except for the jumping and bouncing that is usually added to the more advanced step aerobic programs.

Dancing moves take on many forms, and classes are taught that address various fitness levels and age groups. If possible, review safe movement patterns and help the patient recognize the safe limits of his or her spinal range and abilities.

"Latest Popular Craze"

People like variety and may be attracted to charismatic and energetic figures who demonstrate “new” workout techniques and routines or new exercise machines. Patients may ask for advice as to the value of the activities and techniques. Knowledge and skill in analyzing the biomechanics of the activity and the forces that are imposed through the spine should be used to provide advice about exercise safety. End-of-range postures and high-velocity stresses (such as vigorous kicking and ballistic motions) may be damaging to vulnerable tissues in the spine and should not be attempted by patients recovering from spinal problems.

FUNCTIONAL ACTIVITIES

Goal. To progress to independence safely.

N O T E : Achieving the maximum level of independence underlies all the goals of therapeutic exercise. The patient develops core and global stability; develops flexibility, muscle endurance, and strength; learns how exercise and posture correction relieves stress; and develops cardiopul-

monary endurance—all to be able to function safely in daily activities, including work, recreation, and athletic pursuits.

EARLY FUNCTIONAL TRAINING— FUNDAMENTAL TECHNIQUES

Early functional training consists of teaching basic maneuvers needed for ADLs such as how to roll over safely, go from lying down to sitting (and reverse), and go from sitting to standing (and reverse). These techniques follow the early kinesthetic training instruction in which the patient learns to find his or her neutral spine and experiences the effect that simple arm and leg motions have on the spine, as well as early muscle performance training in which the patient learns how to activate the core musculature for segmental stabilization. If the examination reveals problems with basic ADL activities, the following are included in the early training program.

Rolling. Rolling with a neutral spine requires that the patient first find the neutral spine, perform the drawing-in maneuver, and then roll the trunk as a unit.

- It may be helpful to suggest that the patient “imagine a solid rod connecting the shoulders and pelvis so as not to twist” or suggest that he or she “roll like a log.”
- Encourage the patient to use the arms and top leg to assist the roll.

Supine to sit/sit to lying down. Have the patient use the log roll maneuver (as described above) to roll from supine to side-lying while simultaneously flexing the hips and knees and pushing up with the arms.

- Help the patient focus on stabilizing the trunk with commands such as “push up your trunk as if it is a board; do not allow it to twist or bend.”
- The reverse is practiced by coaching the patient to lower oneself to the side-lying position as a unit first onto the elbow and then shoulder. Once down, the patient can roll to supine or prone-lying using the log-roll technique.

Sit to stand/stand to sit. The patient’s level of function dictates how much assistance from the upper extremities is needed to accomplish “sit to stand” or “stand to sit.” If the hip and knee extensors are not strong enough to elevate the body, the patient requires a chair with armrests so there is some leverage for pushing up; alternatively, an elevated seat may be necessary.

- To use the stable spine technique, instruct the patient to find the neutral spine by rolling the pelvis forward and backward, activate the drawing-in maneuver, and then bend forward at the hips while maintaining the neutral spine position.
- Help the patient focus on the hip motion while keeping the spine “solid like a board.” The reverse is also practiced.

In and out of a car. Getting in and out of a car is often symptom-provoking for patients with low back pain. Once

sit to stand can be safely performed, have the patient practice the following.

- Approach the open car door and seat with the back toward the seat; stabilize the spine in its neutral position with the drawing-in maneuver, then bend at the hips and sit down.
- Once seated, flex both hips and knees and pivot the whole body around as a unit, maintaining a stable spine.
- When exiting a car, keep both knees together and pivot the legs and trunk outward as a unit. Once the feet are on the ground, bend at the hips and elevate the trunk as a unit.

Walking. For some patients walking may provoke symptoms.

- Remind the patient to use the neutral spine and drawing-in maneuvers to stabilize the spine while walking.
- It is not possible to maintain conscious control for long, so remind the patient to check the spinal posture and reactivate the drawing-in maneuver whenever the symptoms recur.

PREPARATION FOR FUNCTIONAL ACTIVITIES—BASIC EXERCISE TECHNIQUES

Once the patient has learned to manage his or her symptoms and the symptoms of inflammation diminish, exercises are initiated that prepare the extremities and trunk for functional activities such as safely lifting, carrying, pushing, pulling, and reaching in various directions. In the subacute or controlled motion phase of rehabilitation, emphasis is placed on strengthening the extremities in functional patterns while maintaining a stable spine. The patient should be able to perform IADLs and limited work activities at this stage. Evaluate the patient’s performance and modify what he or she is doing to include safe spinal postures and correct stabilization. Use the activities in this section to prepare for or advance the patient’s function.

Many of the strengthening exercises described in the extremity chapters are appropriate to use in preparation for functional training. With postural problems and recovery from back or neck injuries, it is critical to emphasize the neutral (functional) spinal posture before and during total body exercises. Many of the stabilization and movement patterns described earlier in this chapter can also be progressed in intensity, repetitions, speed, and coordination to prepare for return to functional activities.

Weight-Bearing Exercises

Modified Bridging Exercises

Modified bridging exercises require stabilization with the trunk flexor and extensor muscles in conjunction with strengthening the gluteus maximus and quadriceps muscles in preparation for lifting activities. The abdominals function with the gluteus maximus to control the pelvic tilt, and

the lumbar extensors stabilize the spine against the pull of the gluteus maximus.

Patient position and procedures: Begin with the patient hook-lying. Have the patient concentrate on maintaining the neutral spinal position while raising and lowering the pelvis (flexing and extending at the hips) (see Fig. 20.21). Hold the bridge for isometric control.

- Alternate arm motions; progress by adding weights to the hands.
- Alternate lifting one foot and then the other by marching in place (Fig. 16.50A); progress by extending the knee as each leg is lifted. When the patient tolerates greater resistance, add ankle weights and coordinate with arm motions (Fig. 16.50B).
- Abduct and adduct the thighs without letting the pelvis sag. Progress by placing the feet on a stool, chair, or large gym ball and repeating the bridging activities.

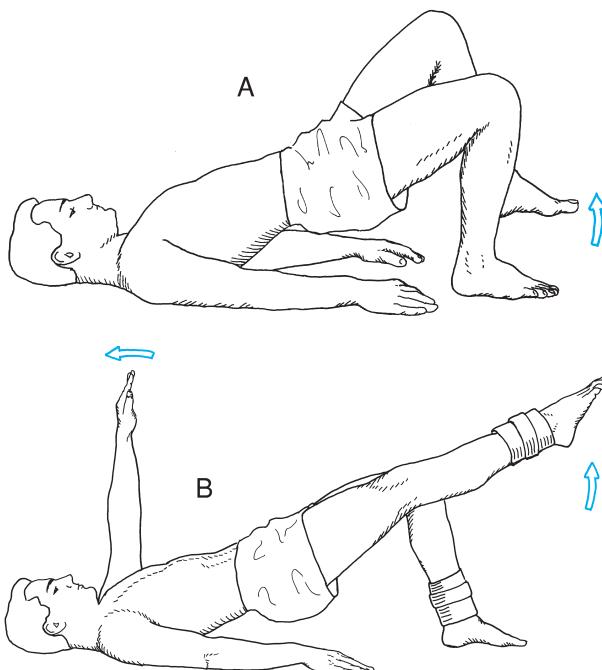

FIGURE 16.50 Holding a bridge to develop trunk control and gluteus maximus strength while superimposing extremity motions by (A) marching in place and (B) progressing to extending the extremities. Adding weights to the arms or legs requires greater strength and control.

Push-Ups with Trunk Stabilization

Push-ups use the body weight to strengthen the triceps and shoulder girdle musculature in preparation for pushing activities. The trunk musculature must stabilize against the pull of the shoulder girdle musculature as well as control the neutral spinal position as the body is raised and lowered.

Patient positions and procedures: Standing facing a wall or prone-lying with hands placed against the wall or floor in front of the shoulders. Remind the patient to find and maintain the neutral spinal position while performing the exercise.

- These exercises may begin as wall push-ups if the patient is not strong enough to push up from the floor.
- Prone-lying on the floor the patient may push up with the pivot point being the knees or may perform full body push-ups with the pivot point being the feet.
- To challenge the patient on an unstable surface, he or she begins prone on a large gym ball. Have the patient walk forward with the hands on the floor until just the thighs are supported by the ball, maintain a stable spinal posture, and perform push-ups with the arms. To progress, walk out farther with the hands until just the legs are supported by the ball (Fig. 16.51).

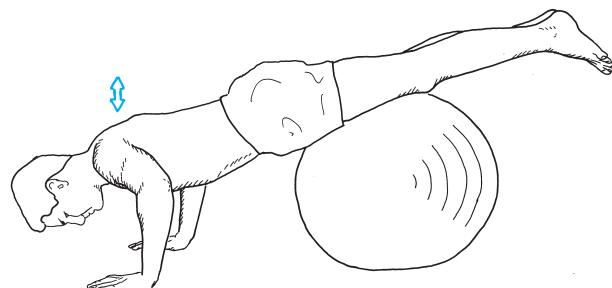

FIGURE 16.51 Push-up activities with the lower extremities balanced on a gym ball for strengthening the arms and developing trunk control.

Wall Slides

Wall slides develop strength in the hip and knee extensor muscles to prepare the lower extremities for squatting activities and training in safe body mechanics.

Patient position and procedure: Standing with the back to a wall and the spine held in its neutral position. Place a towel behind the back so it slides easier along the wall. The exercise is more challenging if a large gym ball is placed between the back and the wall (Fig. 16.52). Have

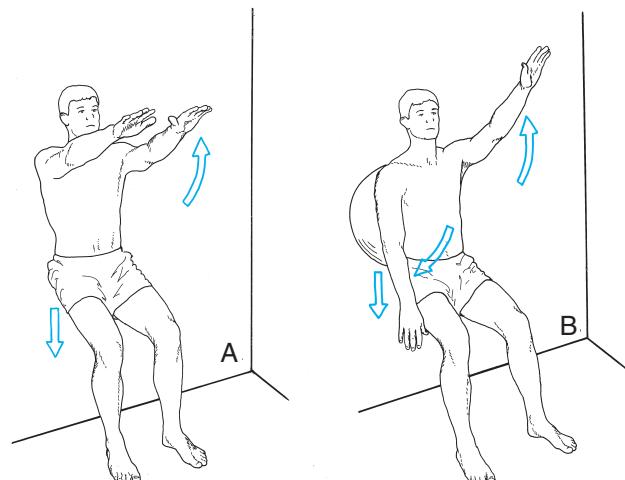

FIGURE 16.52 Wall slides/partial squats to develop lower extremity strength and coordinate with trunk stability in preparation for training body mechanics. (A) The back sliding down a wall, with bilateral arm motion for added resistance. (B) Rolling a gym ball down the wall, with antagonistic arm motion to develop coordination.

the patient slide his or her back down the wall into a partial squat and hold the position for isometric strengthening of the hip and knee extensors or move up and down for concentric/eccentric strengthening.

- Superimpose arm motions such as alternating or bilateral shoulder flexion/extension.
- Use handheld weights to add resistance for upper and lower extremity strengthening.

Partial Lunges and Partial Squats

Partial lunges and squats are described in Chapters 20 and 21. They are beneficial for strengthening total body movement in preparation for learning body mechanics. If necessary, begin by having the patient balance by holding onto the side of a treatment table or other stable object and then progress to balancing with a cane (see Fig. 20.23). Once able to perform multiple repetitions without holding on, add weights to the upper extremities for resistance.

Progress by adding arm motions that are synchronized with the leg motions, such as reaching forward and downward to develop coordination and control.

Walking Against Resistance

Secure a weighted pulley or elastic resistance around the patient's pelvis with a belt, or the patient can hold the handles. Have the patient walk forward, backward, or diagonally against the resistive force. Emphasis is placed on spinal control (see Fig. 20.25).

Progress by having the patient push and pull weighted objects, such as a cart or a box on a table. Place emphasis on maintaining a stable spinal position while the extremities are loaded (see Figs. 17.56 and 18.20A).

Transitional Stabilization Exercises

Exercises that cause movement into spinal flexion and extension challenge the patient to control the neutral spine position. The patient learns to stabilize the spine against alternating trunk motions.

Quadruped Forward/Backward Shifting

Patient position and procedure: Quadruped. Have the patient rock back to rest the buttocks on the heels, then shift the body forward onto the hands in the press-up position. The patient concentrates on controlling the pelvis in its neutral position rather than allowing full spinal flexion when shifting toward the heels or full spinal extension when shifting forward toward the press-up position.

Squatting and Reaching

Patient position and procedure: Begin standing. Have the patient reach downward while partially squatting. The tendency is for the spine to flex, so have the patient concentrate on maintaining a neutral spinal position with the spinal extensors. The patient then stands up and reaches overhead. This causes the spine to extend, so have the patient concentrate on using the trunk flexors to stabilize in

the neutral position. Progress by lifting and reaching with weights while controlling the neutral posture of the spine.

Shifting Weight and Turning

Have the patient practice shifting weight forward/backward and side to side while maintaining the neutral spinal position and absorbing the forces with the hip and knee muscles. Practice turning using small steps and rotating at the hips rather than the back. Instruct the patient to imagine two rigid poles connecting each shoulder to each hip that do not allow the spine to twist. Even though some movement in the spine occurs, the activity helps the patient focus on a stable spine rather than rotating full range. Progress by using weights and having the patient lift, turn, and then place the weight at a new location.

● BODY MECHANICS AND ENVIRONMENTAL ADAPTATIONS

Principles of Body Mechanics—Instruction and Training

When teaching safe body mechanics it is advisable to not overwhelm the patient with too many instructions. Most people "know" they are to lift with their legs rather than their back, but still have faulty techniques. Initiate training by suggesting that the patient find his or her neutral spine, perform the drawing-in maneuver then lift. Observe the technique they use and suggest modifications if needed. Squatting is often taught as the preferred method, yet not all patients are able to squat if they have impairments such as knee pain or weakness. Under some circumstances, an individual may be more stable lifting with a lunge technique rather than the squat technique.

Lumbar Spine Position

The position of the lumbar spine, whether it is flexed, extended, or in mid-range, raises several issues. Of the three postures, lifting with a neutral spinal posture provides greater stability of the spine¹² and uses both the ligamentous and muscular system for stabilization and control.⁵⁰ After a back injury, the preferred lifting posture may have to be adapted, depending on the type of injury and the response of the tissues when stressed.⁵⁰

Spinal flexion. When lifting with a flexed lumbar spine (posterior pelvic tilt), support for the spine is primarily from inert structures (ligaments, lumbodorsal fasciae, posterior annulus fibrosus, and facets); there is little muscle activity.

- Flexion occurs when stooping to the floor. Some have suggested that it may also be the posture of choice for a patient who has injured the back muscles because the muscles are "quiet" when the spine is in flexion.⁵⁰
- Lifting with the lumbar spine in flexion may pose some problems. When lifting slowly with a flexed spine, the load is maintained on the ligaments, and creep of the

inert tissues occurs; this increases the chance of injury if the tissue is already weakened. In addition, with the muscles lengthened and relaxed, they may be at an unfavorable length-tension relationship to respond quickly with appropriate force to resist a sudden change in load. There is greater chance of ligamentous strain when a person lifts with a flexed spine.²²

Spinal extension. When lifting with an extended (lordotic) lumbar spine, the muscles supporting the spine are more active than when flexed, which increases the compressive forces on the disk. Also, the facets are approximated (close-pack position). This posture relieves stress on the ligaments; but for an individual whose back muscles are in poor condition and fatigue quickly, this posture may jeopardize the spine when repeated lifts are performed because the ligaments are not providing support.³²

Load Position

Reinforce the concept of lifting and carrying objects as close to the center of gravity as possible.

- Have the patient practice carrying objects close to his or her center of gravity and draw attention to the feel of balance and control, as well as less stress on the neck and back, compared to the feel when carrying objects in more stressful positions. Point out that, when lifting, the closer the object is held to the center of gravity, the less stress is placed on the supporting structures.
- Have the patient practice shifting the load from side to side and turning. Have the patient practice turning with hip rotation and minimal trunk rotation. The action should be directed by the legs while the spine is kept stable.
- Replicate the mechanics of the patient's job setting and practice safe mechanics.

Environmental Adaptations

Ergonomic assessment and modification of the home and working environments are necessary to correct stresses as well as prevent future recurrence of symptoms.

Home, Work, and Driving Considerations

- Chairs and car seats should have lumbar support to maintain slight lordosis. Use a towel roll or lumbar pillow if necessary.
- Chair height should allow knees to flex to take tension off the hamstring muscles, support the thighs, and allow the feet to rest comfortably on the floor.
- Arm rests should be used if prolonged sitting is required in order to take the stress off shoulders and the cervical spine.
- Desk or table height should be adequate to keep the person from having to lean over the work.
- Work and driving habits should allow frequent changing of posture. If normally sedentary, the patient should get up and walk every hour.

Sleeping Environment

- The mattress needs to provide firm support to prevent any extreme stresses. If it is too soft, the patient sags and stresses ligaments; if it is too firm, some patients cannot relax.
- Pillows should be of a comfortable height and density to promote relaxation but should not place joints in an extreme position. Foam rubber pillows tend to cause increased tension in muscles because of the constant resistance they provide.
- Whether the person should sleep prone, side-lying, or supine is something that must be analyzed for each individual patient. Ideally, a comfortable posture is one that is in the mid-range and that does not place stress on any supporting structure. Pain that is experienced when waking up in the morning is often related to sleeping posture; if this is the case, listen carefully to the patient's description of postures when sleeping and see if it relates to the pain. Then attempt to modify the sleep position accordingly. Remind the patient that it takes several weeks to change habits.

INTERMEDIATE TO ADVANCED EXERCISE TECHNIQUES FOR FUNCTIONAL TRAINING

As the patient learns spinal control while doing the exercises, repetitions are increased to develop muscular endurance, and resistance is added to develop strength. If speed and balance are required, they are emphasized. By this stage it is recognized that the individual already knows the basic spinal stabilization techniques and is habitually assuming the neutral spinal position and activating the drawing-in maneuver. Reinforce the importance of this when doing the following exercises. It is also recognized that the patient should be able to control greater spinal ROM without experiencing symptoms. Adapt the exercises to replicate return to work or sport-related activities. Examples follow.

Repetitive Lifting

The ability to do repetitive lifting throughout the workday is necessary for many jobs and may result in symptom recurrence. To prepare for returning to work, progressively increase the repetitions of lifting activities the patient must do to improve muscle endurance. Marras and Granta³¹ demonstrated that with repetitive lifting (over a 5-hour period) subjects had a significant change in their lifting pattern and in the muscle recruitment patterns so there was a decrease in spine stabilization (decreased compression) and an increase in anterior/posterior shear in the lumbar spine. To reduce the risk of recurrence of low-back disorders, a patient needs to learn to monitor these changes and

be conscious of correcting faulty patterns. Help the patient modify and adapt the stable spine body mechanics that were initiated under basic techniques to replicate the type of lifting he or she will be doing at home or on the job. Include variations in the lifting tasks to prepare for unexpected situations.

Repetitive Reaching

Repetitive reaching requires that the patient learn to assume a comfortable stride and then practice shifting his or her weight forward and backward on the lower extremities rather than bending forward and backward with the spine. Preparatory exercises should include partial lunging forward, sideways, and backward. During practice have the patient use a weight comparable to that in the real-life situation and go through the action on a repetitive basis, concentrating on spinal control and resting only when control is no longer possible.

Repetitive Pushing and Pulling

Repetitive pushing and pulling require strong upper extremities and a stable spine. Preparatory activities should include pushing and pulling against elastic resistance or pulley resistance set at heights that replicate the work environment. Progress to pushing and pulling a weighted cart or a weighted box across a table. Reinforce the importance of activating the spinal stabilizers.

Rotation or Turning

Turning with a load is a component of most work activity. A person may rotate the spine to reach around to place a load to the side or behind. Rotation may create an unstable situation or may be damaging to the spinal structures. Therefore, it is important to take the rotation out of turning. Have the patient practice a “stable spine turn,” which requires motion and control in the hips, or taking steps into the direction of the turn rather than twisting and rotating the back.

Transitional Movements

Most functional activities require *transitional motions*, such as reaching downward to pick up something (spinal flexion), then reaching overhead to place it on a high shelf (spinal extension). In sports activities the activity may

require moving quickly from a forward-bent position to an extended position with arms overhead (such as dribbling a basketball, then shooting). Set up drills that replicate the speed and movements of the desired outcome; have the patient practice moving through the patterns while attempting to maintain control of his or her functional spinal position and range.

Transfer of Training

Ideally, each patient is progressed through rehabilitation to the level of being able to *transfer skills* learned to closely related but new situations. Provide variable learning opportunities from simple to complex and then help the patient analyze successful adaptations to each new experience. (See Figure 1.6 and accompanying text in Chapter 1 for examples of how to vary tasks from simple to complex.)

EDUCATION FOR PREVENTION

Education occurs on a continual basis. Before discharge, review the following relationships of posture and pain with the patient.

- When experiencing pain or the recurrence of symptoms, check posture. Avoid any one posture for prolonged periods.
- If sustained postures are necessary, take frequent breaks and perform appropriate ROM exercises at least every half hour. Finish all exercises by assuming a well balanced posture.
- Avoid hyperextending the neck or being in a forward-head posture or forward-bent position for prolonged periods. Find ways to modify a task so it can be accomplished at eye level or with proper lumbar support.
- If in a tension-producing situation, perform conscious relaxation exercises.
- Use common sense and follow good safety habits.

Develop and progress a safe home exercise program.

- Teach flexibility, muscle endurance, and strengthening exercises appropriate for the patient to maintain ROM, muscle endurance, and strength.
- Address any misconceptions the patient may have about exercise.

Reinforce the importance of maintaining cardiopulmonary endurance and its effect on managing symptoms.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Observe a homemaker or worker doing an activity that requires pushing, pulling, reaching, lifting, or some other repetitive pattern. Analyze what component motions are part of the total pattern and decide if strength, range, endurance, balance, or coordination (or a combination) is necessary in the upper extremities, lower extremities, and trunk. Decide what is necessary to make the spine safe while doing this activity and design an exercise program that encompasses all the components.
2. Go to a health club or exercise class and observe how individuals are performing the exercises. Note the activities that cause stress to the spine. How would you modify each exercise? Consider safe use of the equipment, safe biomechanics, and appropriate instruction for the audience. Can you tell the purpose of each exercise (strength, stretch, endurance)? Are the directions appropriately given for the level of participants?

● Laboratory Practice

1. With a laboratory partner practice the kinesthetic training techniques and core muscle activation techniques for the cervical spine and the lumbar spine until you become proficient at performing them and recognizing when they are done correctly. Then practice teaching them to a family member or friend and see how well they understand what they are to do.
2. Practice the progression of spinal stabilization exercises described in the muscle performance section. Start at the easiest level and progress the leg and arm movements

until you feel you are at your maximum resistance for stabilization. After resting, time yourself for 1 minute, beginning at the most difficult level of movement. The idea is to keep the spine stable during the entire minute. If you begin to feel you are losing control, decrease the amount of extremity resistance (e.g., going from moving both lower extremities in a reciprocal pattern to moving just one extremity while the other is on the floor). This can also be done for 3 minutes. Were you able to meet the challenge yet keep the spine stable? Did you feel your stabilizing muscles “working?”

3. Practice doing wall slides, partial squats, and partial lunges with a stable spine. When you can do the squat comfortably with a stable spine, practice lifting a box from the floor to table height, then from the floor to shoulder height, then place it on a shelf at each height. Feel what is happening to your spine. Then repeat the maneuvers with a stable spine, and see if you can control the spinal position with the drawing-in maneuver. When you can do the lunge comfortably, practice lifting small objects from the floor with a lunging technique and stable spine. Finally, practice lifting objects from the floor and turning (using legs and hips to change direction, not spinal rotation) to place the objects on a table or shelf. Feel what is happening to the spine and repeat the activities with a stable spinal posture.

● Case Studies

Review the cases described in Chapter 14 and 15 and modify your answers based on information you studied in this chapter.

The design of the shoulder girdle allows for mobility of the upper extremity. As a result, the hand can be placed almost anywhere within a sphere of movement, being limited primarily by the length of the arm and the space taken up by the body. The combined mechanics of its joints and muscles provide for and control the mobility. When establishing a therapeutic exercise program for impaired function of the shoulder region, as with any other region of the body, the unique anatomical and kinesiologic features must be taken into consideration as well as the state of pathology and functional limitations imposed by the impairments. This chapter is divided into three major sections. The first section briefly reviews the structure and function of the shoulder girdle complex. The second section describes common disorders and guidelines for conservative and postsurgical management. The last section describes exercise techniques commonly used to meet the goals of treatment during the stages of tissue healing and phases of rehabilitation.

STRUCTURE AND FUNCTION OF THE SHOULDER GIRDLE

The shoulder girdle has only one bony attachment to the axial skeleton (Fig. 17.1). The clavicle articulates with the sternum via the small sternoclavicular joint. As a result, considerable mobility is allowed in the upper extremity. Stability is provided by an intricate balance between the scapular and glenohumeral muscles and the structures of the joints in the shoulder girdle.

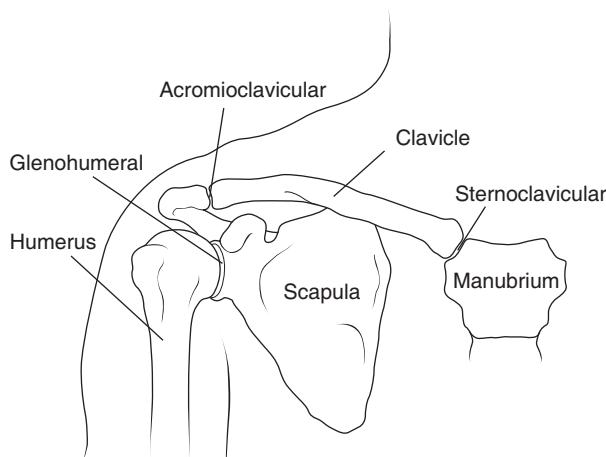

FIGURE 17.1 Bones and joints of the shoulder girdle complex.

JOINTS OF THE SHOULDER GIRDLE COMPLEX

There are three synovial joints (glenohumeral, acromioclavicular, sternoclavicular) and two functional articulations (scapulothoracic, suprhumeral) that make up the shoulder girdle complex.

Synovial Joints

Glenohumeral Joint

The glenohumeral (GH) joint is an incongruous, ball-and-socket (spheroidal) triaxial joint with a lax joint capsule. It is supported by the tendons of the rotator cuff and the glenohumeral (superior, middle, inferior) and coracohumeral ligaments (Fig. 17.2). The concave bony partner, the glenoid fossa, is located on the superior-lateral margin of the scapula. It faces anteriorly, laterally, and upward, which provides some stability to the joint. A fibrocartilaginous lip, the glenoid labrum, deepens the fossa for greater congruity and serves as the attachment site for the capsule. The convex bony partner is the head of the humerus. Only a small portion of the head comes in contact with the fossa at any one time, allowing for considerable humeral movement and potential instability.¹³³

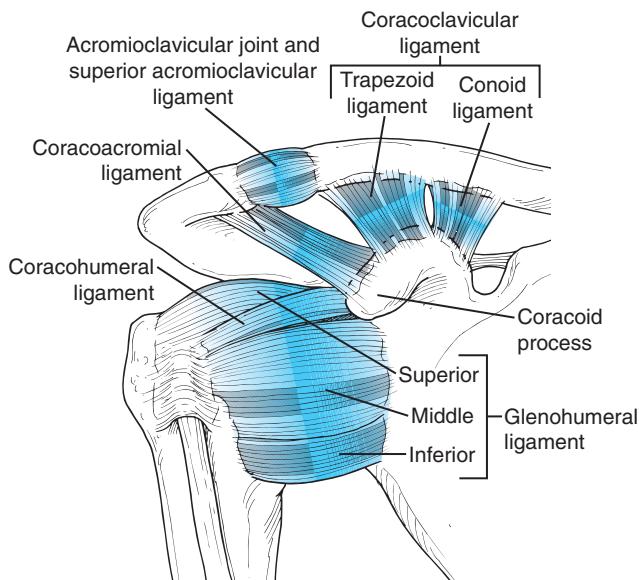

FIGURE 17.2 Ligaments of the glenohumeral and acromioclavicular joints.

Arthrokinematics

According to the convex-concave theory of joint motion (see Chapter 5), with motions of the humerus (physiologi-

BOX 17.1 Summary of Joint Arthrokinematics of the GH Joint

Extension	Posterior	Anterior
Horizontal abduction	Posterior	Anterior
External rotation	Posterior	Anterior
Abduction	Superior	Inferior

cal motions) the convex head rolls in the same direction and slides in the opposite direction in the glenoid fossa (Box 17.1).

Focus on Evidence

Of interest and apparent contradiction of this theory, one study reported that through the mid-range of the arc of passive motion there is minimal displacement of the humeral head. However, beyond mid-range the overall displacement of the head in normal joints is anterior with shoulder flexion and posterior with shoulder extension.⁶⁹ This cadaveric study demonstrated that the integrity of the capsular ligamentous system influenced the displacement and that both hyper- and hypomobility of the capsule changed the overall

displacement of the humeral head with passive range of motion (ROM).

In another study, Howel et al.,⁸⁴ using radiographs, measured humeral head displacement in normal and unstable shoulders. These investigators reported posterior displacement of the humeral head during end-range horizontal abduction with the humerus at 90° and in full external rotation in normal subjects, yet anterior displacement in subjects with anterior instability. These studies support the importance of joint mobility testing to examine restricted accessory motions to determine if interventions with joint mobilization techniques should be used and the direction of the mobilization force, rather than just using the convex-concave rule, to determine the direction of mobilizations.

Stability

Static and dynamic restraints provide joint stability (Table 17.1).^{31,44,162,199,202} The structural relationship of the bony anatomy, ligaments, and glenoid labrum and the adhesive and cohesive forces in the joint provide static stability. The tendons of the rotator cuff blend with the ligaments and glenoid labrum at their sites of attachment so when the muscles contract they provide dynamic stability by tightening the static restraints (Fig. 17.3). The coordinated response of the muscles of the cuff and tension in the ligaments provide varying degrees of support depending on the position and motion of the humerus.^{151,162,184} In addition, the long head of the biceps and the long head of the

TABLE 17.1 Static and Dynamic Stabilizers of the Scapula and Glenohumeral Joint

Description	Static Stabilizers	Dynamic Stabilizers
Scapula Weight of upper extremity creates downward rotation and forward tipping moment on the scapula	• Cohesive forces of subscapular bursa	Upper trapezius and serratus anterior middle trapezius and rhomboids
Glenohumeral joint In dependent position: if scapula is in normal alignment, weight of arm creates an adduction moment on the humerus	• Superior capsule and suprahumeral ligament are taut • Adhesive and cohesive forces of synovial fluid and negative joint pressure hold surfaces together • Glenoid labrum deepens fossa and improves congruency	Rotator cuff, deltoid, and long head of biceps brachii
When the humerus is elevating and the scapula is rotating upward	• Tension placed on static restraints by the rotator cuff • Glenohumeral ligaments provide inferior translation of humeral head	Rotator cuff and deltoid; elbow action brings in two-joint muscle support • Long head of biceps stabilizes against humeral elevation • Long head of triceps stabilizes against inferior translation

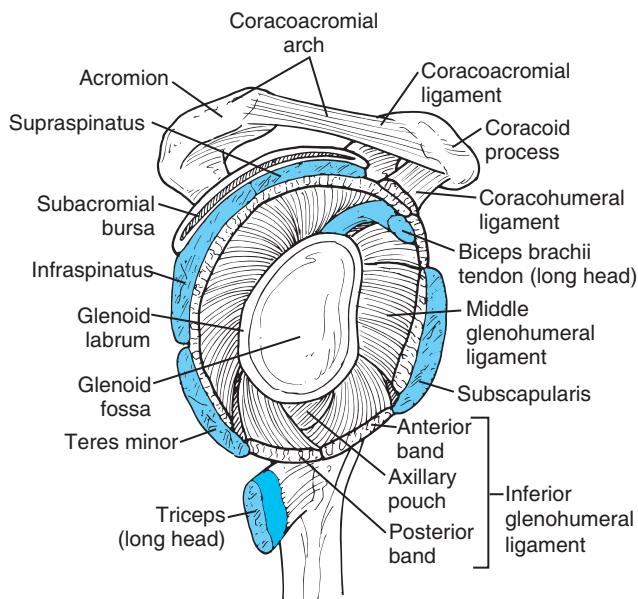

FIGURE 17.3 Lateral aspect of the glenoid fossa (interior view), showing attachments of the glenoid labrum, capsule, ligaments, and their relationship to the rotator cuff and long head of the biceps brachii musculature.

triceps brachii reinforce the capsule with their attachments and provide superior and inferior shoulder joint support, respectively, when functioning with elbow motions.⁹⁶ The long head of the biceps in particular stabilizes against humeral elevation⁹⁶ and contributes to anterior stability of the glenohumeral joint by resisting torsional forces when the shoulder is abducted and externally rotated.^{11,151} Neuromuscular control, including movement awareness and motor response, underlies coordination of the dynamic restraints.^{199,202}

Acromioclavicular Joint

The acromioclavicular (AC) joint is a plane, triaxial joint that may or may not have a disk. The weak capsule is reinforced by the superior and inferior AC ligaments (see Fig. 17.2). The convex bony partner is a facet on the lateral end of the clavicle. The concave bony partner is a facet on the acromion of the scapula.

Arthrokinematics

With motions of the scapula, the acromial surface slides in the same direction in which the scapula moves because the surface is concave. Motions affecting this joint include upward rotation (the scapula turns so the glenoid fossa rotates upward), downward rotation, winging of the vertebral border, and tipping of the inferior angle.

Stability

The AC ligaments are supported by the strong coracoclavicular ligament. No muscles directly cross this joint for dynamic support.

Sternoclavicular Joint

The sternoclavicular (SC) joint is an incongruent, triaxial, saddle-shaped joint with a disk. The joint is supported by

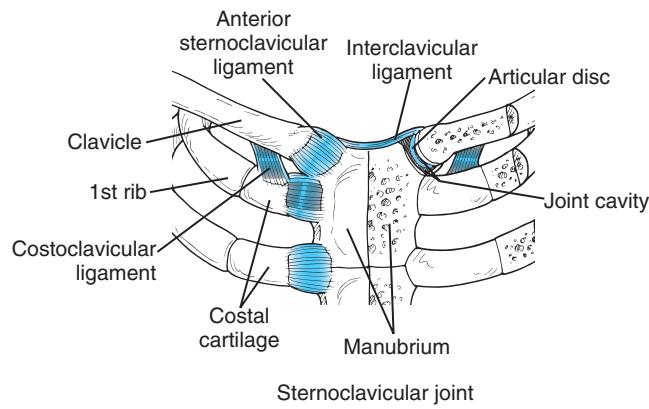

FIGURE 17.4 Ligaments of the sternoclavicular joint.

the anterior and posterior SC ligaments and the interclavicular and costoclavicular ligaments (Fig. 17.4). The medial end of the clavicle is convex superior to inferior and concave anterior to posterior. The joint disk attaches to the upper end. The superior-lateral portion of the manubrium and first costal cartilage is concave superior to inferior and convex anterior to posterior.

Arthrokinematics

The motions of the clavicle occur as a result of the scapular motions of elevation, depression, protraction (abduction), and retraction (adduction) (Box 17.2). Rotation of the clavicle occurs as an accessory motion when the humerus is elevated above the horizontal position and the scapula upwardly rotates; it cannot occur as an isolated voluntary motion.

Stability

The ligaments crossing the joint provide static stability. There are no muscles crossing the joint for dynamic stability.⁴¹

Functional Articulations

Scapulothoracic Articulation

Normally there is considerable soft tissue flexibility, allowing the scapula to slide along the thorax and participate in all upper extremity motions.

Motions of the Scapula

Motions of the scapula are:

BOX 17.2 Summary of Arthrokinematics of the SC Joint

Physiological Motion of the Clavicle	Roll	Slide
Protraction	Anterior	Anterior
Retraction	Posterior	Posterior
Elevation	Superior	Inferior
Depression	Inferior	Superior

- Elevation, depression, protraction (abduction), and retraction (adduction), seen with clavicular motions at the SC joint (Fig. 17.5 A&B). They are also component motions when the humerus moves.
- Upward and downward rotation, seen with clavicular motions at the SC joint and rotation at the AC joint, occurs concurrently with motions of the humerus (Fig. 17.5C). Upward rotation of the scapula is a necessary component motion for full ROM of flexion and abduction of the humerus.
- Winging and tipping, seen with motion at the AC joint concurrently with motions of the humerus (Fig. 17.5D). Winging is a transverse plane motion where the medial border lifts away from the rib cage; it normally occurs with horizontal adduction of the humerus. Forward tipping of the scapula occurs in conjunction with internal rotation and extension of the humerus when reaching the hand behind the back.

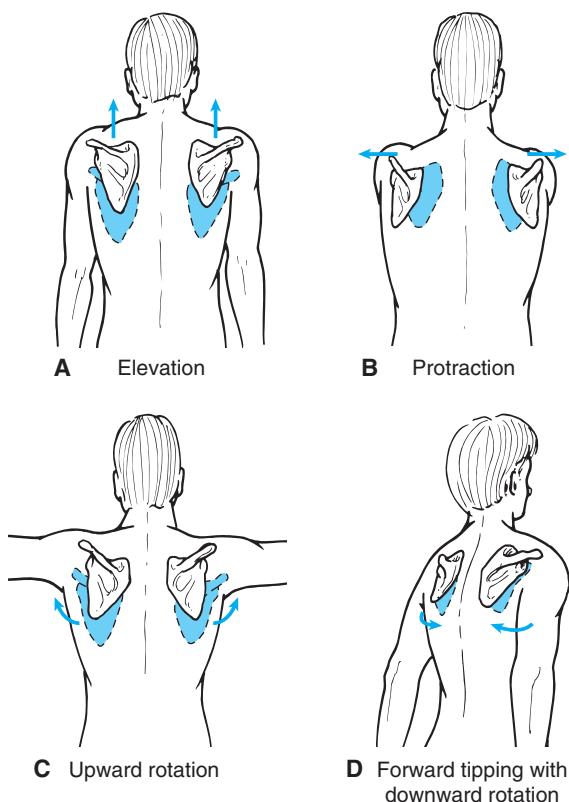

FIGURE 17.5 Scapular motions. (A) Elevation occurs with clavicular elevation at the SC joint when shrugging. (B) Protraction (abduction) occurs with clavicular abduction at the SC joint when reaching forward. (C) Upward rotation occurs with clavicular rotation at the SC and AC joints when flexing and abducting the shoulder. (D) Forward tipping (along with downward rotation) occurs at the AC joint when extending and internally rotating the shoulder.

Scapular Stability

Postural relationship. In the dependent position, the scapula is stabilized primarily through a balance of forces. The weight of the arm creates a downward rotation, abduction, and forward tipping moment on the scapula. The

downward rotation is balanced by the dynamic support of the upper trapezius and serratus anterior. The forward tipping and abduction is balanced by the dynamic support of the rhomboids and middle trapezius^{98,163} (see Table 17.1).

Active arm motions. With active arm motions, the muscles of the scapula function in synchrony to stabilize and control the position of the scapula so the scapulohumeral muscles can maintain an effective length-tension relationship as they function to stabilize and move the humerus. Without the positional control of the scapula, the efficiency of the humeral muscles decreases. The upper and lower trapezius with the serratus anterior upwardly rotate the scapula whenever the arm abducts or flexes, and the serratus anterior abducts (protracts) the scapula on the thorax to align the scapula during flexion or pushing activities. During arm extension or during pulling activities, the rhomboids function to downwardly rotate and adduct (retract) the scapula in synchrony with the latissimus dorsi, teres major, and rotator cuff muscles. These stabilizing muscles also eccentrically control acceleration motions of the scapula in the opposite directions.¹³⁵

Faulty posture. With a faulty scapular posture, muscle length and strength imbalances occur not only in the scapular muscles but also in the humeral muscles, altering the mechanics of the glenohumeral joint. A forward tilt of the scapula (seen with a forward head posture and increased thoracic kyphosis) is associated with decreased flexibility in the pectoralis minor, levator scapulae, and scalenus muscles and weakness in the serratus anterior or trapezius muscles. This scapular posture changes the posture of the humerus in the glenoid, which assumes a relatively abducted and internally rotated position with respect to the scapula (Fig. 17.6). The glenohumeral internal rotators may become less flexible, and external rotators may weaken, affecting the mechanics of the joint.

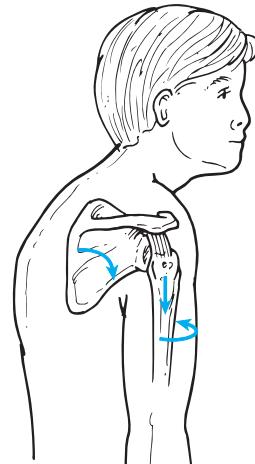

FIGURE 17.6 Faulty forward head, thoracic kyphosis, and shoulder girdle posture results in a forward tilt and downward rotation of the scapula with relative abduction and internal rotation of the humerus when the arm is in a dependent position.

Focus on Evidence

A study by Borstad and Ludewig,¹⁹ which looked at the effect of pectoralis minor resting length on scapular kinematics in subjects without shoulder pain, documented that those individuals with a short pectoralis minor ($n = 25$) had greater scapular internal rotation (protraction) and less posterior tipping during arm elevation in flexion, abduction, and scaption than those with a longer pectoralis minor ($n = 25$), thus providing evidence for altered pectoralis minor muscle length and altered scapular movement. In a related study by the same author,²⁰ a correlation between the postural impairments of increased thoracic kyphosis, scapular internal rotation and forward tipping, and decreased pectoralis minor length was found to be significant, thus further supporting the relationship between muscle length and posture.

Supr humeral (Subacromial) Space

The coracoacromial arch, composed of the acromion and coracoacromial ligament, overlies the subacromial/subdeltoid bursa, the supraspinatus tendon, and a portion of the muscle (Fig. 17.7).⁹⁸ These structures allow for and participate in normal shoulder function. Compromise of this space from faulty muscle function, faulty postural relationships, faulty joint mechanics, injury to the soft tissue in this region, or structural anomalies of the acromion lead to impingement syndromes.^{19,27,30,99,103,113} After a rotator cuff tear, the bursa may communicate with the glenohumeral joint cavity.⁴⁴

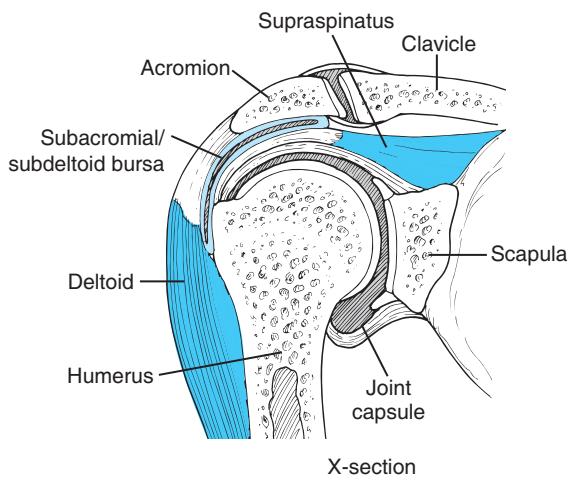

FIGURE 17.7 The supraspinatus and subacromial/subdeltoid bursa lie in the suprhumeral space.

SHOULDER GIRDLE FUNCTION

Scapulohumeral Rhythm

Motion of the scapula, synchronous with motions of the humerus, allows for 150° to 180° of shoulder ROM into

flexion or abduction with elevation. The ratio has considerable variation among individuals but is commonly accepted to be 2:1 (2° of glenohumeral motion to 1° of scapular rotation) overall motion. During the setting phase (0° to 30° abduction, 0° to 60° flexion), motion is primarily at the glenohumeral joint, whereas the scapula seeks a stable position. During the mid-range of humeral motion, the scapula has greater motion, approaching a 1:1 ratio with the humerus; later in the range, the glenohumeral joint again dominates the motion.^{39,98,170}

- During humeral elevation, the synchronous motion of the scapula allows the muscles moving the humerus to maintain an effective length-tension relationship throughout the activity and helps maintain congruency between the humeral head and fossa while decreasing shear forces.^{39,98,170}
- Muscles causing the upward rotation of the scapula are the upper and lower trapezius and the serratus anterior. Weakness or complete paralysis of these muscles results in the scapula being rotated downward by the contracting deltoid and supraspinatus as abduction or flexion is attempted. These two muscles then reach active insufficiency, and functional elevation of the arm cannot be reached, even though there may be normal passive ROM and normal strength in the shoulder abductor and flexor muscles.¹⁷⁰
- During elevation of the humerus, the pectoralis minor is lengthened as the scapula upwardly rotates, retracts, and tips posteriorly. Restricted scapular movement during humeral elevation from a shortened pectoralis minor results in patterns similar to those seen in patients with impingement symptoms and could be a risk factor for development of the syndrome.¹⁹

Clavicular Elevation and Rotation With Humeral Motion

It is commonly accepted that initially the first 30° of upward rotation of the scapula occurs with elevation of the clavicle at the SC joint. Then, as the coracoclavicular ligament becomes taut, the clavicle rotates 38° to 55° about its longitudinal axis, which elevates its acromial end (because it is crank-shaped). This motion allows the scapula to rotate an additional 30° at the AC joint.⁹⁸ Loss of any of these functional components decreases the amount of scapular rotation and thus the ROM of the upper extremity.

Focus on Evidence

A recent three-dimensional study of clavicular motion during humeral flexion, scaption, and abduction to 115° using surface electromagnetic sensors on 30 asymptomatic subjects and 9 individuals with shoulder pathology documented 11° to 15° of clavicular elevation, 15° to 29° of retraction, and 15° to 31° of posterior long axis rotation, showing similar patterns but different ranges from previously reported studies.¹⁰⁴ Ranges of clavicular motion

above 115° were not reliable owing to movement of the clavicle under the skin.¹⁰⁴

External Rotation of the Humerus With Full Elevation

During abduction of the arm in the frontal plane, for the greater tubercle of the humerus to clear the coracoacromial arch, the humerus must externally rotate as it is elevated above the horizontal. Weak or inadequate external rotation results in impingement of the soft tissues in the suprhumeral space, causing pain, inflammation, and eventually loss of function.

Internal Rotation of the Humerus With Full Elevation

Medial rotation begins at around 50° of passive shoulder flexion when all structures are intact.¹³⁶ With full range of shoulder flexion and elevation, the humerus medially rotates 90°, and the medial epicondyle faces anteriorly.^{17,18,136}

- As the arm elevates above the horizontal position in the sagittal plane, the anterior capsule and ligaments become taut, causing the humerus to rotate medially. The bony configuration of the posterior aspect of the glenoid fossa contributes to the inward rotation motion of the humerus as the shoulder flexes.¹⁷⁰ Most of the shoulder flexor muscles are also medial rotators of the humerus.¹⁷⁰
- The infraspinatus and teres minor stabilize the humeral head against the inward rotating forces, helping to maintain alignment and stability of the head in the fossa. Weakness in these muscles may contribute to excessive anterior translation and instability.³¹

Elevation of the Humerus Through the Plane of the Scapula—Scaption

The plane of the scapula is described as 30° anterior to the frontal plane. Motion of the humerus in this plane is popularly called *scaption*^{181,198} or scapular plane abduction.⁴² In this range there is less tension on the capsule, and greater elevation is possible than with pure frontal or sagittal plane elevation. Neither internal nor external rotation of the humerus is necessary to prevent greater tubercle impingement during elevation in scaption.^{42,181} Many functional activities occur with the shoulder oriented in this plane.

Deltoid–Short Rotator Cuff and Supraspinatus Mechanisms

- Most of the force of the deltoid muscle causes upward translation of the humerus; if unopposed, it leads to impingement of the soft tissues in the suprhumeral space between the humeral head and the coracoacromial arch.

- The combined effect of the short rotator muscles (infra-spinatus, teres minor, subscapularis) causes stabilizing compression and downward translation of the humerus in the glenoid.
- The combined actions of the deltoid and short rotators result in a balance of forces that abduct the humerus and control the humeral head.
- The supraspinatus muscle has a significant stabilizing, compressive, and slight upward translation effect on the humerus; these effects, combined with the effect of gravity, lead to abduction of the arm.
- Interruption of function leading to fatigue or poor coordination of any of these muscles can cause microtrauma and eventual dysfunction in the shoulder region.

REFERRED PAIN AND NERVE INJURY

For a detailed description of referred pain patterns, peripheral nerve injuries in the shoulder, thoracic outlet syndrome, and complex regional pain syndromes (including reflex sympathetic dystrophy) and their management, see Chapter 13.

Common Sources of Referred Pain in the Shoulder Region

Cervical Spine

- Vertebral joints between C3 and C4 or between C4 and C5
- Nerve roots C4 or C5

Referred Pain from Related Tissues

- Dermatome C4 is over the trapezius to the tip of the shoulder.
- Dermatome C5 is over the deltoid region and lateral arm.
- Diaphragm: pain perceived in the upper trapezius region.
- Heart: pain perceived in the axilla and left pectoral region.
- Gallbladder irritation: pain perceived at the tip of shoulder and posterior scapular region.

Nerve Disorders in the Shoulder Girdle Region

Brachial plexus in the thoracic outlet. Common sites for compression are the scalene triangle, costoclavicular space and under the coracoid process, and pectoralis minor muscle.¹⁰²

Suprascapular nerve in the suprascapular notch. This injury occurs from direct compression or from nerve stretch, such as when carrying a heavy book bag over the shoulder.

Radial nerve in the axilla. Compression occurs from continual pressure, such as when leaning on axillary crutches.

MANAGEMENT OF SHOULDER DISORDERS AND SURGERIES

To make sound clinical decisions when managing patients with shoulder disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting impairments, functional limitations, and possible disabilities. In this section, common pathologies and surgeries are presented and are related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*² (Table 17.2). Conservative and postoperative management of these conditions are described in this section.

TABLE 17.2 Shoulder Pathologies/Surgical Procedures and Preferred Practice Patterns

PATHOLOGY/SURGICAL PROCEDURE	PREFERRED PRACTICE PATTERNS AND ASSOCIATED IMPAIRMENTS ²
<ul style="list-style-type: none"> • Abnormal posture (protracted scapula, kyphosis, forward head) • Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis) • Synovitis • Postimmobilization arthritis (stiff shoulder) • Idiopathic frozen shoulder • Adhesive capsulitis • Joint instability, subluxation, dislocation (nontraumatic/recurrent) • Rotator cuff syndrome and allied disorders • Labral lesion 	<ul style="list-style-type: none"> • Pattern 4B—Impaired posture • Pattern 4D—Impaired joint mobility, motor function, muscle performance, and range of motion (ROM) associated with connective tissue dysfunction

JOINT HYPOMOBILITY: NONOPERATIVE MANAGEMENT

Glenohumeral Joint

Restricted mobility of the glenohumeral joint may occur as a result of pathology such as rheumatoid arthritis or osteoarthritis, from prolonged immobilization, or from unknown causes (idiopathic frozen shoulder). Associated impairments in mobility and muscle performance also occur in the muscles and other connective tissues in the area.

Related Pathologies and Etiology of Symptoms

Rheumatoid arthritis and osteoarthritis. These disorders follow the clinical picture described in Chapter 11.

Traumatic arthritis. This disorder occurs in response to a fall or blow to the shoulder or to microtrauma from faulty mechanics or overuse.

Postimmobilization arthritis or stiff shoulder. This disorder occurs as a result of lack of movement or secondary effects from conditions such as heart disease, stroke, or diabetes mellitus.

Idiopathic frozen shoulder. This disorder, which is also called *adhesive capsulitis* or *periarthritis*, is characterized by the development of dense adhesions, capsular thickening, and capsular restrictions, especially in the dependent folds of the capsule, rather than arthritic changes in the cartilage and bone, as seen with rheumatoid arthritis or osteoarthritis. The onset is insidious and usually occurs between the ages of 40 and 60 years; there is no known cause (primary frozen shoulder), although problems already mentioned in which there is a period of pain and/or restricted motion, such as with rheumatoid arthritis, osteoarthritis, trauma, or immobilization, may lead to a frozen shoulder (secondary frozen shoulder). With primary frozen shoulder, the pathogenesis may be a provoking chronic inflammation in musculotendinous or synovial tissue such as the rotator cuff, biceps tendon, or joint capsule.^{41,66,122,125} Consistent with this is a faulty posture and muscle imbalance predisposing the suprhumeral space to impingement and overuse syndromes.¹

Clinical Signs and Symptoms

Glenohumeral joint arthritis. The following characteristics are associated with glenohumeral (GH) joint pathologies that lead to hypomobility.

- **Acute phase.** Pain and muscle guarding limit motion, usually external rotation and abduction. Pain is frequently experienced radiating below the elbow and may disturb sleep. Joint swelling is not detected owing to the depth of the capsule, although tenderness can be elicited by palpating in the fornix immediately below the edge of the acromion process between the attachments of the anterior and middle deltoid.
- **Subacute phase.** Capsular tightness begins to develop. Limited motion is detected, consistent with a capsular pattern (external rotation and abduction are most limited, and internal rotation and flexion are least limited). Often, the patient feels pain as the end of the limited range is reached. Joint-play testing reveals limited joint play. If the patient can be treated as the acute condition begins to subside by gradually increasing shoulder motion and activity, the complication of joint and soft tissue contractures can usually be minimized.^{117,122}
- **Chronic phase.** Progressive restriction of the GH joint capsule magnifies the signs of limited motion in a capsular pattern and decreased joint play. There is significant loss of function with an inability to reach overhead, outward, or behind the back. Aching is usually localized to the deltoid region.

Idiopathic frozen shoulder. This clinical entity follows a classic pattern*.

- “Freezing.” Characterized by intense pain even at rest and limitation of motion by 2 to 3 weeks after onset. These acute symptoms may last 10 to 36 weeks.
- “Frozen.” Characterized by pain only with movement, significant adhesions, and limited GH motions, with substitute motions in the scapula. Atrophy of the deltoid, rotator cuff, biceps, and triceps brachii muscles occurs. This stage lasts 4 to 12 months.
- “Thawing.” Characterized by no pain and no synovitis but significant capsular restrictions from adhesions. This stage lasts 2 to 24 months or longer. Some patients never regain normal ROM.

Some references indicate that spontaneous recovery occurs, on average, 2 years from onset,⁶⁶ although others have reported long-term limitations without spontaneous recovery.¹⁵⁶ Inappropriately aggressive therapy at the wrong time may prolong the symptoms.¹⁵ Management guidelines are the same as for acute (maximum protection during the freezing stage), subacute (controlled motion during the frozen stage), and chronic (return to function during the thawing state) joint pathology described in this section.

Common Impairments

- Night pain and disturbed sleep during acute flares
- Pain on motion and often at rest during acute flares
- Mobility: decreased joint play and ROM, usually limiting external rotation and abduction with some limitation of internal rotation and elevation in flexion
- Posture: possible faulty postural compensations with protracted and anteriorly tipped scapula, rounded shoulders, and elevated and protected shoulder
- Decreased arm swing during gait
- Muscle performance: general muscle weakness and poor endurance in the glenohumeral muscles with overuse of the scapular muscles leading to pain in the trapezius and posterior cervical muscles
- Guarded shoulder motions with substitute scapular motions

Common Functional Limitations/Disabilities

- Inability to reach overhead, behind head, out to the side, and behind back; thus, having difficulty dressing (such as putting on a jacket or coat or women fastening undergarments behind their back), reaching hand into back pocket of pants (to retrieve wallet), reaching out a car window (to use an ATM machine), self-grooming (such as combing hair, brushing teeth, washing face), and bringing eating utensils to the mouth
- Difficulty lifting weighted objects, such as dishes into a cupboard
- Limited ability to sustain repetitive activities

*See references 41, 66, 122, 125, 153, 189

Glenohumeral Joint Hypomobility:

Management—Protection Phase

See general guidelines for management when symptoms are acute in Chapter 10 and Box 10.1.

Control Pain, Edema, and Muscle Guarding

- The joint may be immobilized in a sling to provide rest and minimize pain.
- Intermittent periods of passive or assisted motion within the pain free/protected ROM and gentle joint oscillation techniques are initiated as soon as the patient tolerates movement in order to minimize adhesion formation.

Maintain Soft Tissue and Joint

Integrity and Mobility

- *Passive range of motion* (PROM) in all ranges of pain-free motion (see Chapter 3). As pain decreases, the patient is progressed to active ROM with or without assistance using activities such as rolling a small ball or sliding a rag on a smooth table top in flexion, abduction, and circular motions. Be sure the patient is taught proper mechanics and avoids faulty patterns, such as scapular elevation or a slumped posture.
- *Passive joint distraction and glides, grade I and II* with the joint placed in a pain-free position (see Chapter 5).
- *Pendulum (Codman's) exercises* are techniques that use the effects of gravity to distract the humerus from the glenoid fossa.^{30,34} They help relieve pain through gentle traction and oscillating movements (grade II) and provide early motion of joint structures and synovial fluid. No weight is used during this phase of treatment (see Fig. 17.22).

PRECAUTION: If there is increased pain or irritability in the joint after use of these techniques, either the dosage was too strong or the techniques should not be used at this time.

CONTRAINDICATION: Stretching (grade III) techniques. If there are mechanical restrictions causing limited motion, appropriate stretching can be initiated only after the inflammation subsides.

- *Gentle muscle setting* to all muscle groups of the shoulder, including scapular and elbow muscles because of their close association with the shoulder. Instructions are given to the patient to gently contract a group of muscles while slight resistance is applied—just enough to stimulate a muscle contraction. It should not provoke pain. The emphasis is on rhythmic contracting and relaxing of the muscles to help stimulate blood flow and prevent circulatory stasis.

Maintain Integrity and Function of Associated Areas

- Reflex sympathetic dystrophy (complex regional pain syndrome type I) is a potential complication after shoulder injury or immobility. Therefore special attention is given to the hand with additional exercises, such as having the patient repetitively squeeze a ball or other soft object.

- The patient is advised of the importance of keeping the joints distal to the injured site as active and mobile as possible. The patient or family member is taught to perform ROM exercises of the elbow, forearm, wrist, and fingers several times each day while the shoulder is immobilized. If tolerated, active or gentle resistive ROM is preferred to passive ROM for a greater effect on circulation and muscle integrity.
- If edema is noted in the hand, instruct the patient to elevate the hand, whenever possible, above the level of the heart.

NOTE: Conditions in which there is potentially a prolonged acute/inflammatory stage, such as with rheumatoid arthritis and during the freezing stage of idiopathic frozen shoulder, it is critical to teach the patient active-assistive exercises to maintain muscle and joint integrity and as much mobility as possible without exacerbating the symptoms.

GH Joint Hypomobility: Management—Controlled Motion Phase

When symptoms are subacute, follow the guidelines as described in Chapter 10, Box 10.2, emphasizing joint mobility, neuromuscular control, and instructions to the patient for self-care.

NOTE: For normal shoulder joint mechanics, there must be good scapular posture and control, and the humerus must be able to externally rotate. To avoid suprhumeral impingement, passive stretching above 90° should be avoided until there is adequate glenohumeral external rotation. With a traumatic injury that involves the AC or SC joints, these joints tend to become hypermobile with improper stretching. Care should be taken to provide stabilization to the scapula and clavicle so as not to stretch these joints when mobilizing the glenohumeral joint.

Control Pain, Edema, and Joint Effusion

- *Functional activities.* It is important to carefully monitor increasing activities. If the joint was splinted, the amount of time the shoulder is free to move each day is progressively increased.
- *Range of motion.* ROM is progressed up to the point of pain, including all shoulder and scapular motions. The patient is instructed in the use of self-assistive ROM techniques, such as the wand exercises or hand slides on a table.

PRECAUTION: With increased pain or decreased motion, the activity may be too intense or the patient may be using faulty mechanics. Reassess the technique and modify it if faulty joint mechanics exist.

Progressively Increase Joint and Soft Tissue Mobility

- *Passive joint mobilization techniques.* Stretch grades (grade III sustained or grade III and IV oscillation) using techniques that focus on the restricting capsular tissue at the end of the available ROM are used to increase joint capsule mobility^{89,127,187} (see Box 17.1 and Figs. 5.15 through 5.20 in Chapter 5). End-of-range techniques

include rotating the humerus and then applying either a grade III distraction or a grade III glide to stretch the restrictive capsular tissue or adhesions (see Figs. 5.17, 5.21, and 17.20).

Use a grade I distraction with all gliding techniques. If the joint is highly irritable and gliding in the direction of restriction is not tolerated, glide in the opposite direction. As pain and irritability decrease, begin to glide in the direction of restriction.⁸⁹

Focus on Evidence

Evidence supporting joint mobilization techniques is limited. A multiple-subject case study, using seven subjects with adhesive capsulitis of the glenohumeral joint (mean disease duration 8.4 months, range 3–12 months) treated with end-range mobilization techniques twice a week for 3 months, showed increased active and passive range and increased capacity of the joint capsule at the end of treatment and at the 9-month follow-up. No control groups were used; therefore the natural course of the disease could not be excluded as the explanation for improvement.¹⁸⁷

A follow-up study by the same author randomly assigned 100 subjects with stage II adhesive capsulitis to a group receiving high-grade mobilization techniques (end-range stretching using Maitland grade III or IV) or a group receiving low-grade mobilization techniques (Maitland grade I or II in nonstressful positions). After 3 months of treatment, both groups exhibited clinically significant improvement, with the group receiving the high-grade mobilization techniques showing greater improvement than the low-grade mobilization group. Because there was no control group, natural progression could not be ruled out.¹⁸⁸

- Pendulum exercises can also be used for joint stretching by adding a cuff weight to the wrist or a weight to the hand to cause a grade III joint distraction force (see Fig. 17.22). To direct the stretch force to the glenohumeral joint, stabilize the scapula against the thorax manually or with a belt.

PRECAUTION: Carefully monitor the joint reaction to the mobilization stretches; if irritability increases, vigorous stretching should not be undertaken until the chronic stage of healing.

- ***Self-mobilization techniques.*** The following self-mobilization techniques may be used for a home program.
 - **CAUDAL GLIDE.** *Patient position and procedure:* Sitting on a firm surface and grasping the fingers under the edge. The patient then leans the trunk away from the stabilized arm (Fig. 17.8).
 - **ANTERIOR GLIDE.** *Patient position and procedure:* Sitting with both arms behind the body or lying supine supported on a solid surface. The patient then leans the body weight between the arms (Fig. 17.9).
 - **POSTERIOR GLIDE.** *Patient position and procedure:* Prone, propped up on both elbows. The body weight shifts downward between the arms (Fig. 17.10).

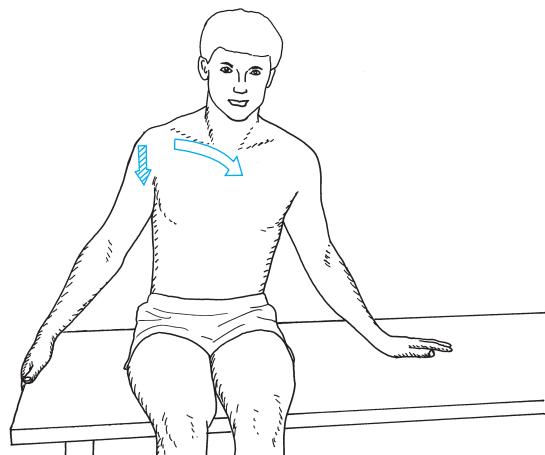

FIGURE 17.8 Self-mobilization. Caudal glide of the humerus occurs as the person leans away from the fixed arm.

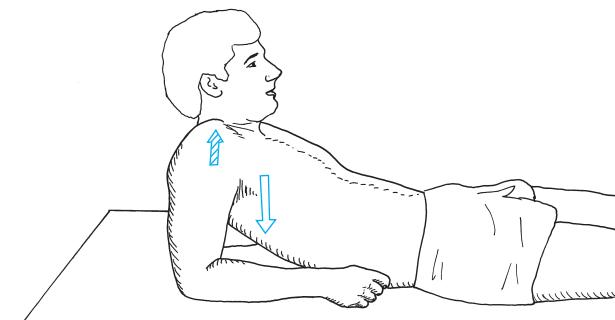

FIGURE 17.9 Self-mobilization. Anterior glide of the humerus occurs as the person leans between the fixed arms.

FIGURE 17.10 Self-mobilization. Posterior glide of the humerus occurs as the person shifts his weight downward between the fixed arms.

- **Manual stretching.** Manual stretching techniques are used to increase mobility in shortened muscles and related connective tissue.
- **Self-stretching exercises.** As the joint reaction becomes predictable and the patient begins to tolerate stretching, self-stretching techniques are taught (see Figs. 17.24 through 17.29 in the exercise section).

Inhibit Muscle Spasm and Correct Faulty Mechanics

Muscle spasm may lead to a faulty deltoid–rotator cuff mechanism and scapulohumeral rhythm when the patient attempts abduction (Fig. 17.11). The head of the humerus may be held in a cranial position in the joint, making it difficult and/or painful to abduct the shoulder because the greater tuberosity impinges on the coracoacromial arch. In this case, repositioning the head of the humerus with a caudal glide is necessary before proceeding with any other form of shoulder exercise. The patient also needs to learn to avoid “hiking the shoulder” when abducting or flexing the arm. The following techniques may address these problems and faulty mechanics. See also mobilization with movement techniques in the next section.

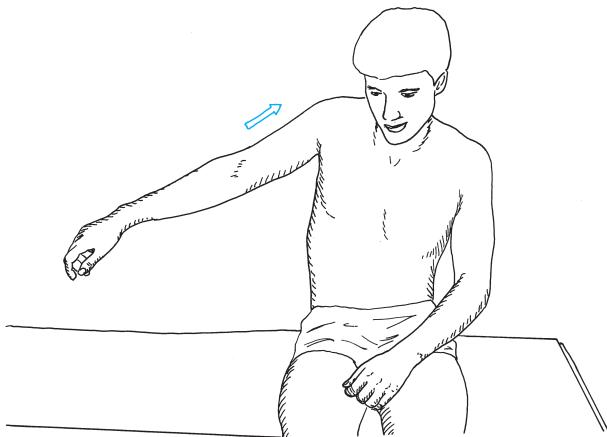

FIGURE 17.11 Poor mechanics with patient hiking the shoulder while trying to abduct the shoulder, thus elevating rather than depressing the humeral head.

- Gentle joint oscillation techniques to help decrease the muscle spasm (grade I or II).
- Sustained caudal glide joint techniques to reposition the humeral head in the glenoid fossa.
- Protected weight bearing, such as leaning hands against a wall or on a table, to stimulate co-contraction of the rotator cuff and scapular stabilizing muscles. If tolerated, gentle rocking forward/backward and side to side requires the muscles to begin controlling motion. Because weight bearing causes joint compression, the benefits of intermittent compression stimulates synovial fluid motion. Techniques are progressed within the tolerance of the joint.
- External rotation exercises to help to depress the humeral head (see Fig. 17.50).

Improve Joint Tracking

Mobilization with movement (MWM) techniques may assist with retraining muscle function for proper tracking of the humeral head.¹¹⁶

- **Shoulder MWM for painful restriction of shoulder external rotation** (Fig. 17.12).
 - **Patient position:** Supine lying with folded towel under the scapula; the elbow is near the side and flexed to 90°. A cane is held in both hands.
 - **Therapist position and procedure:** Stand on the opposite side of the bed facing the patient and reach across the patient's torso to cup the anteromedial aspect of the head of the humerus with reinforced hands. Apply a pain-free graded posterolateral glide of the humeral head on the glenoid. Instruct the patient to use the cane to push the affected arm into the previously restricted range of external rotation. Sustain the movement for 10 seconds and repeat in sets of 5 to 10. It is important to maintain the elbow near the side of the trunk and ensure that no pain is experienced during the procedure. Adjust the grade and direction of the glide as needed to achieve pain-free function.

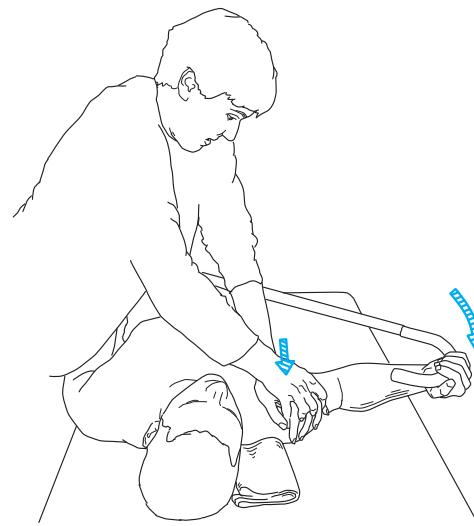

FIGURE 17.12 Mobilization with movement (MWM) to improve external rotation. A posterolateral glide is applied to the humeral head while the patient pushes the arm into the end-range of external rotation with a cane.

- **Shoulder MWM for painful restriction of internal rotation and inability to reach the hand behind the back** (Fig. 17.13).
 - **Patient position:** Standing with a towel draped over the unaffected upper trapezius and affected hand at current range of maximum pain-free position behind back. The patient's hand on the affected side grasps the towel behind the back.
 - **Therapist position and procedure:** Stand facing the patient's affected side. Place the hand closest to the patient's back high up in the axilla with the palm facing outward to stabilize the scapula with an upward

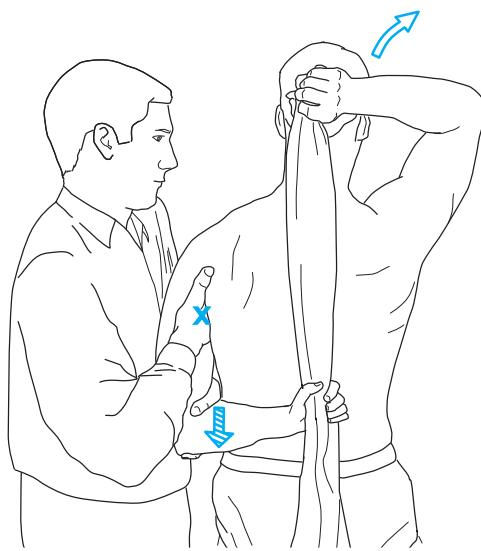

FIGURE 17.13 MWM to improve internal rotation. An inferior glide is applied to the humerus while the patient pulls the hand up the back with a towel.

and inward pressure. With the hand closest to the patient's abdomen hook the thumb in the cubital fossa and grasp the lower humerus to provide an inferior glide. Your abdomen is in contact with the patient's elbow to provide an adduction force to the arm. Have the patient pull on the towel with the unaffected hand to draw the affected hand up the back while the mobilization force is being applied in an inferior direction. Ensure that no pain is experienced during the procedure. Adjust the grade and direction of glide as needed to achieve pain-free function. Maximal glide should be applied to achieve end-range loading.

- **Shoulder MWM for painful arc or impingement signs.** If impingement signs are present in addition to the capsular restrictions, the MWM active elevation technique may be appropriate; see description in the impingement section and Figure 17.17

Improve Muscle Performance

- Any faulty postures or shoulder girdle mechanics the patient displays when moving the upper extremity in various functional patterns should be identified and exercises to correct the muscle imbalances initiated. Stabilization, flexibility, and strengthening exercises for the shoulder-girdle musculature are described in the last section of this chapter. Emphasis is on developing control in the weak musculature. As the patient learns to activate the weak muscles, progress to strengthening functional patterns of motion.
- Exercises to manage faulty spinal posture are described in Chapter 16.
- Once proper mechanics are restored, the patient should perform active ROM of all shoulder motions daily and return to functional activities to the extent tolerated.

GH Joint Hypomobility: Management—

Return to Function Phase

For joint impairments in the chronic stage, follow the guidelines described in Chapter 10, Box 10.4.

Progressively Increase Flexibility and Strength

- Stretching and strengthening exercises are progressed as the joint tissue tolerates. The patient should be actively involved in self-stretching and strengthening by this time, so emphasis during treatment is on correct mechanics, safe progressions, and exercise strategies for return to function.
- If capsular tissue is still restricting ROM, vigorous manual stretching and joint mobilization techniques are applied.

Prepare for Functional Demands

If the patient is involved in repetitive heavy lifting, pushing, pulling, carrying, or reaching, when joint range and strength allow, exercises are progressed to replicate these demands. See the last section of this chapter for suggestions.

GH Joint Management—Postmanipulation

Under Anesthesia

Occasionally, no progress is made, and the physician chooses to perform manipulation under anesthesia. Following this procedure, there is an inflammatory reaction and the joint is treated as an acute lesion. If possible, joint-play and passive ROM techniques are initiated while the patient is still in the recovery room. Surgical intervention with incision of the dependent capsular fold may be used if the adhesions are not broken with the manipulation. Postoperative treatment is the same with the following considerations.¹²⁵

- The arm is kept elevated overhead in abduction and external rotation during the inflammatory reaction stage; treatment principles progress as with any joint lesion.
- Therapeutic exercises are initiated the same day while the patient is still in the recovery room, with emphasis on internal and external rotation in the 90° (or higher) abducted position.
- Joint mobilization procedures are used, particularly a caudal glide, to prevent readherence of the inferior capsular fold.
- When sleeping, the patient may be required to position the arm abducted for up to 3 weeks after manipulation.

Acromioclavicular and Sternoclavicular Joints

Related Pathologies and Etiology of Symptoms

Overuse Syndromes. Overuse syndromes of the AC joint are frequently arthritic or post-traumatic conditions. The causes may be from repeated stressful movement of the joint with the arm at waist level, such as with grinding, packing assembly, and construction work,⁶⁷ or repeated diagonal extension, adduction, and internal rotation motions, as when spiking a volleyball or serving in tennis.

Subluxations or Dislocations. Subluxations or dislocations of either joint are usually caused by falling against the shoulder or against an outstretched arm. In the AC joint, the distal end of the clavicle displaces posteriorly and superiorly on the acromion; the ligaments supporting the AC joint may rupture.¹²⁴ Clavicular fractures may result from the fall.¹²⁴ After trauma and associated overstretching of the capsules and ligaments of either joint, hypermobility is usually permanent because there is no muscle support to restrict movement.

Hypomobility. Decreased clavicular mobility may occur with sustained faulty postures involving clavicular and scapular depression or retraction. Restricted mobility may contribute to a thoracic outlet syndrome (TOS) with a compromise of space for the neuromuscular bundle as it courses between the clavicle and first rib (described in Chapter 13).

Common Impairments

- Pain localized to the involved joint or ligament
- Painful arc with shoulder elevation
- Pain with shoulder horizontal adduction or abduction
- Hypermobility in the joints if trauma or overuse is involved
- Hypomobility in the joints if sustained posture or immobility is involved
- Neurological or vascular symptoms if TOS is present

Common Functional Limitations/Disabilities

- Limited ability to sustain repeated loaded movements related to forward/backward motions of the arm, such as with grinding, packing, assembly, and construction work.⁶⁷
- Inability to reach overhead without pain.
- Inability to serve effectively at tennis or spike a volleyball.
- See also limitations/disabilities from TOS if present (see Chapter 13).

Nonoperative Management of AC or SC Joint Strain or Hypermobility

- Rest the joint by putting the arm in a sling to support the weight of the arm.
- Cross-fiber massage to the capsule or ligaments.
- ROM to the shoulder and grade II traction and glides to the glenohumeral joint to prevent glenohumeral restriction.
- Instructions in self-application of cross-fiber massage if joint symptoms occur after excessive activity.

Nonoperative Management of AC or SC Joint Hypomobility

Joint mobilization techniques are used to increase joint mobility (see Figs. 5.22 through 5.24).

GLENOHUMERAL JOINT SURGERY AND POSTOPERATIVE MANAGEMENT

Severe deterioration of one or both surfaces of the GH joint, causing significant pain and loss of upper extremity function, or an acute or nonunion fracture of the proximal humerus often must be addressed with surgical intervention. Underlying pathologies, causing advanced joint destruction, include late-stage osteoarthritis (OA), rheumatoid arthritis (RA), traumatic arthritis, cuff tear arthropathy, and osteonecrosis (avascular necrosis) of the head of the humerus as the result of a fracture of the anatomical neck of the humerus or long-term use of steroids for systemic disease.

The most common surgical procedure used to treat advanced shoulder joint pathology is *glenohumeral arthroplasty*, often simply referred to as *shoulder arthroplasty*.³⁶ In rare situations, *arthrodesis* (surgical ankylosis) of the GH joint may have to be selected as an alternative to arthroplasty or as a salvage procedure.¹⁰⁹

The goals of these surgical procedures and postoperative rehabilitation are to (1) relieve pain, (2) improve shoulder mobility or stability, and (3) restore or improve strength and functional use of the upper extremity. The extent to which these goals are achieved is predicated on the patient's participation in postoperative rehabilitation, the distinguishing features and severity of the underlying pathology, the prosthetic design and surgical techniques, the integrity of the rotator cuff mechanism and other soft tissues, and the age, overall health, and anticipated activity level of the patient.^{36,109,161,168}

Glenohumeral Arthroplasty

Arthroplasty of the GH joint falls into several categories, the most common of which are *total shoulder replacement arthroplasty*,^{109,119,161,168} in which the glenoid and humeral surfaces are replaced (Fig. 17.14), and *hemireplacement arthroplasty (hemiarthroplasty)*, in which one surface, the humeral head, is replaced.^{6,57,109,121,161} Other categories of shoulder arthroplasty include interpositional and resurfacing arthroplasties, which involve less extensive removal of bone.^{109,161,168,182}

Indications for Surgery

The following impairments associated with these pathologies are widely accepted indications for GH arthroplasty.*

- The primary indication is persistent and incapacitating pain (at rest or with activity) secondary to GH joint destruction.

*See references 6, 36, 47, 108, 109, 119, 121, 161, 168, 173, 174, 195.

FIGURE 17.14 Postoperative anterior-posterior view of the shoulder showing a Neer II type of cemented humeral prosthesis and a nonmetal backed polyethylene glenoid. (From Tovin, BJ, Greenfield, BH: Evaluation and Treatment of the Shoulder—An Integration of the Guide to Physical Therapist Practice. FA Davis, Philadelphia, 2001, p 266, with permission.)

- Secondary indications include loss of shoulder mobility or stability and upper extremity strength leading to inability to perform functional tasks with the involved upper extremity.

Procedures

Background

Implant design, materials, and fixation. Since the pioneering work of Neer during the 1960s and 1970s^{119,121} and many other investigators,²⁸ prosthetic designs and surgical techniques for replacing the shoulder joint have continued to evolve. The designs of current-day total shoulder replacement (TSR), composed of a high-density polyethylene glenoid component (usually all plastic) and a modular humeral component made of an inert metal, closely approximate the biomechanical characteristics of the human shoulder.²⁰⁶

Fixation of the prosthetic components is achieved with a press fit, bio-ingrowth, or cement. The type of fixation selected by the surgeon depends on the component (glenoid or humeral), the underlying pathology, and the quality of the bone stock. Cement fixation is most often necessary in patients with osteoporosis.[†]

[†]See references 36, 108, 109, 173, 206.

BOX 17.3 Designs of Prosthetic Implants for Total Shoulder Replacement

Unconstrained

- Anatomical design with a small, shallow glenoid component combined with a stemmed humeral component
- The most frequently used prosthetic design
- Provides the greatest freedom of shoulder motion but no inherent stability
- Indicated when the rotator cuff mechanism is intact or can be repaired to provide dynamic stability to the GH joint

Semiconstrained

- A larger glenoid component that is hooded or cup-shaped
- Some degree of joint stability inherent in the design
- Indicated when erosion of the glenoid fossa can be compensated for by reaming the fossa and rotator cuff function; although deficient preoperatively, can be improved by repair

Reversed ball and socket

- Small humeral socket that slides on a larger ball-shaped glenoid component
- Couples some degree of stability with mobility for rotator cuff-deficient shoulders that cannot be repaired
- Provides an alternative to standard semiconstrained and total shoulder replacement (TSR) and hemiarthroplasty

Constrained

- Fixed fulcrum, ball-in-socket designs with congruity of the glenoid and humeral components
- Greatest amount of inherent joint stability but less mobility than less constrained designs
- Once thought to be an alternative to hemiarthroplasty for the selected patient with a deficient rotator cuff or cuff tear arthropathy or chronic/recurrent GH joint dislocation after a previous TSR
- Rarely used today owing to high rate of loosening or failure of the components

The designs of total shoulder replacements, ranging from *unconstrained* to *semiconstrained* (including *reverse ball-and-socket*) to *constrained*, provide varying amounts of mobility and stability of the GH joint. Box 17.3 summarizes the characteristics of each of these designs.^{36,108,109,159,161,168,182}

NOTE: The description of constrained designs is included in Box 17.3 for historical purposes and for a comparison with less constrained designs. Because of the high rate of complications that occurred with constrained designs, these implant systems are rarely, if ever, used today.^{36,109}

Selection of procedure. Controversy exists over the specific criteria for selection of TSR versus hemiarthroplasty,

but in general it depends on the etiology and severity of the joint deterioration and the condition of the periarticular soft tissues, particularly the rotator cuff mechanism.^{109,169} Several examples that follow underscore the complexity of the clinical decision-making process involved in the choice of operative procedure and prosthetic design.

In patients with late-stage primary OA, the most common pathology associated with shoulder arthroplasty, the GH joint typically exhibits loss or thinning of the articular cartilage of the head of the humerus and the posterior portion of the glenoid fossa. In addition, the rotator cuff is intact in approximately 90% to 95% of these patients, making them good candidates for either TSR or hemiarthroplasty.^{36,108,139,159,161,168} However, opinions vary on whether selection of an unconstrained TSR yields results that are better than or equal to hemiarthroplasty for shoulders with these characteristics.^{36,109,134,161,171}

Chronic synovitis, associated with RA and other types of synovium-based arthritis, tends to erode periarticular soft tissues in addition to the articular surfaces of a joint. As a consequence, a rupture or full-thickness tear of a rotator cuff tendon (typically the supraspinatus) develops in 25% to 40% of these patients and a rupture of the biceps tendon in an even greater percentage.^{57,159,168,173,182} If the soft tissues can be repaired and their functions improved, a semiconstrained TSR (standard or possibly a reverse ball-and-socket design) that may include bone grafting at the glenoid to improve prosthetic fixation may be indicated. If an effective cuff repair cannot be achieved or if there is insufficient bone stock owing to osteoporosis for fixation of a glenoid implant, hemiarthroplasty is usually the procedure of choice.^{57,109,159,161,169,173,182}

Hemiarthroplasty is often used when the articular surface and underlying bone of the humeral head have deteriorated but the glenoid fossa is reasonably intact, as seen with osteonecrosis of the head of the humerus.^{36,109,168,169} A patient with severe, chronic pain and loss of function as the result of a massive, irreparable cuff tear and subsequent development of a *cuff tear arthropathy* is typically a candidate for hemiarthroplasty.^{57,159,212} (The term “cuff tear arthropathy,” first used by Neer, refers to deterioration and eventual collapse of the head of the humerus, an infrequent but debilitating long-term result of a primary, massive and irreparable tear of the rotator cuff.^{109,159,195}) Chronic deficiency of the rotator cuff mechanism leads to superior migration of the head of the humerus in the glenoid fossa. If a glenoid component is inserted under these conditions, the superior migration creates an incongruous articulation that accentuates the risk of loosening and premature wear of the glenoid implant.^{35,73,159}

Operative Procedures

Total shoulder replacement and hemiarthroplasty are open surgical procedures performed with the patient in a semi-reclining position. The operative procedure involves the following components*: anterior approach using a deltopectoral incision that extends from the AC joint to the deltoid

*See references 6, 36, 57, 109, 161, 168.

insertion for adequate surgical exposure; release (tenotomy) of the subscapularis tendon from its proximal attachment on the lesser tuberosity; anterior capsulotomy; exposure of the humeral head for a humeral osteotomy; and preparation of the humeral canal for insertion of the prosthetic implant. The glenoid fossa is débrided and for a TSR is precisely contoured so the glenoid implant can be placed flush within the fossa.

Reconstruction and balancing of soft tissues is critical for optimal function after TSR and hemiarthroplasty. “Balancing” refers to the intraoperative lengthening or tightening of soft tissues to restore as near-normal resting tension in the tissues as possible, particularly in the rotator cuff, biceps, and deltoid muscle-tendon units.

Concomitant procedures that may be necessary during shoulder arthroplasty include:

- Repair of a deficient rotator cuff if the quality of the cuff tissue is sufficient
- Repair (reattachment) of the subscapularis and lengthening (medial advancement or Z-plasty) if a contracture significantly limits external rotation
- Capsular plication and tightening for chronic subluxation or dislocation (usually posterior) of the GH joint
- Anterior acromioplasty for a history of impingement syndrome
- Bone graft of the glenoid if bone stock is insufficient for fixation of the glenoid implant

After implantation of the prosthetic component(s) and repair of soft tissues but before closure of the skin incision, the shoulder is passively moved through all planes of motion to visually evaluate the stability of the prosthetic joint and the integrity of the repaired soft tissues. This determines the anatomical ROM possible after surgery and how aggressive the postoperative program can be.^{36,109}

Complications

Complications that can occur after a wide variety of orthopedic surgeries are summarized in Chapter 12 (see Box 12.6). Although the incidence of intraoperative and postoperative complications after current-day arthroplasty is low, even a single complication can adversely affect the functional outcome. The incidence of complications tends to be higher in patients with a deficient rotator cuff mechanism, osteoporosis, and a preoperative history of chronic GH joint instability.⁷² Aside from medical complications, such as infection or a deep vein thrombosis, complications specific to shoulder arthroplasty are noted in Box 17.4.^{35,72}

Postoperative Management

NOTE: Effective patient education and close communication among the therapist, surgeon, and patient are the basis of an effective and safe rehabilitation program individualized to address the specific surgical procedures used to meet the unique needs of each patient.

Special Considerations

Integrity of the rotator cuff. Regardless of the underlying cause of late-stage glenohumeral arthritis, the goals,

BOX 17.4 Complications Specific to Glenohumeral Arthroplasty
Intraoperative

- Insufficient lengthening of a tight subscapularis muscle-tendon unit
- Intraoperative damage to the axillary or suprascapular nerves, affecting the deltoid and supraspinatus/infraspinatus muscles, respectively
- Fracture of the humerus

Soft Tissue-Related Postoperative Complications

- Re-tearing a repaired rotator cuff mechanism
- Postoperative disruption of the repaired subscapularis (detached from the lesser tuberosity for the surgical approach and reattached medially on the cut surface of the neck of the humerus)
- Chronic instability of the GH joint
- Progressive erosion of the articular surface of the glenoid fossa (after hemiarthroplasty)

Implant-Related Postoperative Complications

- After TSR mechanical (aseptic) loosening or premature wear or fracture of the polyethylene glenoid implant
 - Most often seen in a rotator cuff-deficient shoulder
 - Due to excessive stresses at the bone-prosthesis interface
 - Low incidence with unconstrained designs but higher with early-generation constrained designs
- Loosening of the humeral prosthesis after hemiarthroplasty

components, and rate of progression of a rehabilitation program after TSR or hemiarthroplasty are influenced by the pre- and postoperative integrity of the rotator cuff mechanism. A deficient rotator cuff compromises the dynamic stability and kinematics of the GH joint, as demonstrated by upward riding of the humeral head leading to increased shear forces at the joint during active elevation of the arm.⁴³ The rehabilitation program for a patient with an intact rotator cuff prior to shoulder arthroplasty can be progressed more rapidly than the program for a patient with coexisting rotator cuff deficiency requiring a concomitant cuff-tendon repair at the time of shoulder arthroplasty. The postoperative program for a patient with an irreparable rotator cuff or a tenuous repair due to poor tendon quality must be progressed even more cautiously.^{43,47,92,109,161,195}

If the rotator cuff was intact prior to surgery, the emphasis of postoperative rehabilitation is to restore shoulder mobility and functional use of the arm as soon as possible while protecting soft tissues as they heal. In contrast, with an irreparable rotator cuff, a tenuous repair, or a preoperative history of recurrent GH dislocation, rehabilitation must place greater emphasis on improving or maintaining joint stability for functional use of the arm than on increasing shoulder mobility.^{43,47,51,92,109}

Intraoperative ROM. In the operating room before closing the incision, the surgeon determines the extent of shoulder

ROM available, particularly elevation and external rotation, that does not place undue stress on periarticular soft tissues or compromise GH joint stability. Subsequent goals for safe, stable postoperative ROM are based on these measurements. For a patient with an unconstrained TSR and sufficient postoperative shoulder stability (static and dynamic), the goal at the conclusion of rehabilitation is to achieve active ROM equal to intraoperative ROM—ideally, 140° to 150° of shoulder elevation and 45° to 50° of external rotation.^{43,109} For a patient with more constrained TSR, a deficient rotator cuff mechanism, or capsuloligamentous laxity, intraoperative ROM is typically less, and postoperative goals focus more on developing dynamic stability and less on shoulder mobility.

Posture. Many patients undergoing shoulder arthroplasty are elderly. Therefore, the postural changes associated with aging⁹⁵ (increased thoracic kyphosis and scapular protraction) cause malalignment (excessive downward rotation) of the glenoid fossa, which predisposes the patient to shoulder impingement and pain particularly during overhead shoulder motions. Accordingly, it is important to emphasize an erect sitting or standing posture during elevation of the arm and to incorporate spinal extension and scapular retraction exercises into the postoperative program.

Immobilization and Postoperative Positioning

At the close of the surgical procedure the operated arm is placed in some type of shoulder immobilizer, usually a sling or sometimes a splint, to protect reattached and repaired soft tissues and for comfort.^{6,36,109,159,168,174} Early postoperative positioning that protects the operated shoulder is detailed in Box 17.5.

Initially, the sling or splint is removed only for exercise and bathing. A patient who did not require repair of

BOX 17.5 Positioning After Shoulder Arthroplasty: Early Postoperative (Maximum Protection) Phase
Supine

- Arm immobilized in sling, which is worn continuously
 - Elbow flexed to 90°
 - Forearm and hand resting on abdomen
- Arm supported at the elbow on a folded blanket or pillow slightly away from the side and anterior to the midline of the trunk
 - Forward flexion (10° to 20°), slight abduction, and internal rotation of the shoulder
 - Head of bed elevated about 30°

Sitting

- Arm supported in sling or resting on a pillow in the patient's lap or on the armrest of a chair

With Tenuous Rotator Cuff Repair

- In some cases if a sling does not provide adequate protection of a repaired cuff, an abduction splint must be worn

the rotator cuff is weaned from the sling during the day as quickly as possible to prevent postoperative stiffness. However, a patient who underwent a cuff repair or other soft tissue reconstruction may need to wear a sling or splint while out in crowded areas or during sleep for approximately 4 to 6 weeks to protect the repaired tissues until sufficient healing has occurred.^{23,26,36,43,47,48,92,109,174}

Exercise

The guidelines for progression of exercises during each phase of rehabilitation after shoulder arthroplasty (TSR or hemiarthroplasty) presented in this section are drawn from the limited number of published protocols available, all of which are based on clinical experience rather than evidence from controlled studies and none of which has been shown to be more effective than another.* Also, almost all of these protocols are time-based, with few criteria reported for advancing a patient from one phase of rehabilitation to the next.

Recently, however, several resources have suggested such criteria.^{37,47,195} Criteria from these resources are identified for the phases of rehabilitation after shoulder arthroplasty described below. It is important to note that these criteria and suggested timelines for progression of exercises and functional activities are typically adjusted for each patient based on periodic evaluations of the patient's status and ongoing communication between the therapist and the surgeon.

NOTE: The exercise guidelines in this section are for patients *without* preoperative rotator cuff deficiency and who *did not* undergo a cuff repair during TSR or hemiarthroplasty. For a complete picture, modifications in guidelines are noted throughout this section for patients with a poor quality rotator cuff mechanism. Remember, pain relief is the primary goal of shoulder arthroplasty, with improvement in functional mobility a secondary goal. Although improvements in surgical techniques and implant technology now allow more accelerated progression of postoperative rehabilitation than several decades ago, it is still important to proceed judiciously during each phase of rehabilitation to avoid excessive muscle fatigue or irritation or any damage of the healing soft tissues.

Exercise: Maximum Protection Phase

The maximum protection phase of rehabilitation begins on the first postoperative day and extends for up to 6 weeks. The emphasis of this first phase is patient education, pain control, and initiation of ROM exercises to prevent adhesions and restore shoulder mobility as early as possible to the ranges achieved during surgery. Early motion is permissible after uncemented and cemented shoulder arthroplasty.

While the patient is hospitalized (usually for 3 to 4 days after surgery), patient education includes reviewing early postoperative precautions and teaching the initial exercises in the patient's home program. Precautions during the first 6 weeks after surgery, when protection of soft

*See references 23, 26, 37, 43, 47, 91, 92, 95, 109, 174, 195.

BOX 17.6 Precautions for the Maximum Protection Phase of Rehabilitation After Shoulder Arthroplasty

Exercise

- Short but frequent exercise sessions (four or five times per day).
- Low number of repetitions per exercise.
- Only *passive* or *assisted* shoulder ROM exercises and only within the "safe" limits of ranges noted during surgery. Absolutely no end-range stretching.
 - Passive external rotation to neutral or to less than 30° to avoid excessive stress to the subscapularis muscle, which was incised for surgical exposure and then repaired or lengthened if a preoperative contracture limited external rotation.
 - During passive or assisted shoulder rotation with the patient lying supine, position the humerus slightly anterior to the midline of the body (by placing the arm on a folded towel) to avoid excessive stress to the anterior capsule and suture line.
 - No hyperextension or horizontal abduction (beyond neutral) of the shoulder to avoid stress to the anterior capsule.
 - If an overhead rope-pulley system is used for assisted elevation of the arm, initially *have the patient face the doorway and pulley apparatus* so shoulder elevation occurs only within a limited range.
 - Maintain an erect trunk during passive or assisted elevation of the arm while sitting or standing to avoid subacromial impingement of soft tissues.
 - In most instances no active (unassisted), antigravity, dynamic shoulder exercises, particularly resisted internal rotation.
 - No resistance (strengthening) exercises.
 - In general, a more gradual progression of exercises for a patient with a severely damaged and repaired or an irreparable rotator cuff mechanism than a patient with a preoperatively intact cuff.

Activities of Daily Living

- Limit activities to those that can be performed with the elbow at waist level, such as eating or writing.
- Avoid reaching behind the back.
- Avoid weight bearing (leaning) on the operated extremity, such as pushing during transfers or when moving in bed, especially the first week after surgery.
- Avoid lifting objects.
- Support the arm in a sling during extended periods of standing or walking.
- Wear the sling while sleeping or outside in crowded areas.
- No driving for several weeks.

tissues as they heal is crucial, are summarized in Box 17.6. A patient's adherence to these precautions is of the utmost importance during this phase of rehabilitation.

Goals and interventions. The first phase of rehabilitation includes the following.^{23,26,37,43,47,48,91,92,109,174}

● **Control pain and inflammation.**

- Use of a sling or splint for comfort.
- Use of prescribed analgesic and anti-inflammatory medication.
- Use of cryotherapy, especially after exercise.

● **Maintain mobility of adjacent joints.**

- Active movements of the neck and scapula (while wearing the shoulder immobilizer and after it can be removed for exercise) to maintain normal motion and minimize muscle guarding and spasm. Incorporate “shoulder rolls” by elevating, adducting, and then relaxing the scapulae to reinforce an erect posture of the trunk. Emphasize active scapular retraction and spinal extension.
- Active ROM of the hand, wrist, and elbow when the arm can be removed from the sling.

● **Restore shoulder mobility.**

- Passive or therapist-assisted shoulder motions *within the safe limits determined during surgery*. With the patient lying supine and the arm slightly away from the side of the trunk on a folded towel and the elbow flexed, perform forward elevation of the arm in the plane of the scapula to tolerance, external rotation to no more than 30° to 45°, and internal rotation until the forearm rests on the chest.
- Pendulum (Codman’s) exercises with the elbow flexed (for a shorter moment arm). Encourage the patient to periodically remove the sling and gently swing the arm during ambulation at home.
- Later during this phase, progress to *self-assisted* shoulder ROM (elevation and rotation) in the *supine position* initially by assisting with the sound hand and later using a wand or dowel rod. Add horizontal abduction to neutral and adduction across the chest holding a wand.
- Self-assisted shoulder ROM in a *sitting* position or *standing* with a wand by performing “gear shift” exercises (see Fig. 17.23), resting the arm on a table and sliding it forward (see Fig. 17.25), or use of an overhead rope-pulley system to lessen the weight of the arm. Remind the patient to maintain an erect trunk when performing assisted shoulder motions while seated or standing.
- Self-assisted reaching movements (to the nose, forehead, or over the head as comfort allows) to simulate functional movements.
- In selected patients, transition to *active* (unassisted) shoulder ROM is often possible by 4 weeks.
- Functional activities with the elbow at waist level, such as hand to face and writing, are permissible.

● **Minimize muscle inhibition, guarding, and atrophy.**

- Gentle muscle-setting of shoulder musculature (excluding the internal rotators) with the elbow flexed and the shoulder in the plane of the scapula or neutral. Teach these exercises prior to discharge from the hospital by having the patient practice isometrically contracting the muscles of the *sound* shoulder. Postpone setting exercises (light isometrics) of the operated shoulder until about 4 to 6 weeks after surgery.

- Scapular stabilization exercises in non-weight-bearing positions. Target the serratus anterior and trapezius muscles.

NOTE: For a patient who underwent repair of a large tear or rupture of a rotator cuff tendon or other soft tissue reconstruction, it may not be permissible to begin ROM exercises immediately after surgery. When the sling or splint can be removed for exercise, perform only passive or assisted ROM throughout the first phase of rehabilitation. The range of shoulder elevation and external rotation initially permitted may be less than for shoulders that did not require cuff repair. Postpone active (unassisted), antigravity ROM and light isometrics until the next phase (until about 6 weeks postoperatively, when repaired soft tissues are reasonably well healed).

Exercise: Moderate Protection/

Controlled Motion Phase

Although suggested timelines vary from one resource to another, the moderate protection/controlled motion phase of rehabilitation, which typically begins at about 4 to 6 weeks and extends to at least 12 to 16 weeks or longer postoperatively, focuses on gradually establishing active (unassisted) control, dynamic stability, and strength of the shoulder while continuing to increase ROM.^{23,26,43,47,91,92,109,174,195}

Criteria for progression. Criteria to advance to the second phase of rehabilitation are:

- ROM: At least 90° of passive elevation, at least 45° degrees of external rotation, and 70° of internal rotation in the plane of the scapula with minimal pain¹⁹⁵ or *almost* full, passive shoulder motion based on intraoperative measurements with little to no pain.^{37,92}
- When testing the subscapularis, no tendon pain during resisted, isometric internal rotation.³⁷
- Ability to perform most waist-level activities of daily living (ADLs) without pain.⁹²

PRECAUTIONS: During this phase of rehabilitation, although it is safe to place increasing stresses (stretching or resistance) on periarticular soft tissues, it is important to do so gradually so as not to irritate these tissues, which are continuing to heal. Therefore, continue with short but frequent exercise sessions (preceded by application of heat and followed by cold) and avoid vigorous stretching or resistance exercises or overuse of the involved shoulder during functional activities.

Goals and interventions. The goals and exercises for this next phase of rehabilitation are as follows.

● **Continue to increase passive ROM of the shoulder.**

- Transition from passive or assisted ROM to low-intensity, pain-free stretching in all anatomical and diagonal planes of motion to achieve full, intraoperative ROM.
- Gentle joint mobilization techniques for specific capsular restriction.

- To increase shoulder elevation: arm-sliding exercises on the surface of a table and wall-climbing exercises, emphasizing overhead reaching.
- To increase external rotation: With the arm at the side, elbow flexed to 90°, and grasping a doorframe, rotate the trunk away from the involved arm.
- To increase shoulder extension and internal rotation: Add wand exercises behind the back. (This exercise also involves scapular winging and tipping, both necessary for reaching behind the back.)
- To increase horizontal adduction: Cross-body stretch with arm at shoulder level.

● Develop active control and dynamic stability and improve muscle performance (strength and endurance) of the shoulder.

- Continue or gradually transition to *active* shoulder ROM exercises, avoiding antigravity abduction until the patient can initiate the movement without first shrugging the operated shoulder.
- Scapular and GH joint stabilization exercises (alternating isometrics and rhythmic stabilization) in a variety of positions initially in non-weight-bearing positions, progressing to light weight bearing.
- Pain-free, low-intensity (submaximal) resisted isometrics of shoulder muscles, including the subscapularis or any other repaired muscle-tendon units.
- Dynamic resistance exercises for the scapula and shoulder musculature (from 0° to 90° of shoulder elevation) using light weights or light-grade elastic resistance. Begin in the supine position to support and stabilize the scapula. Progress to the sitting position. Place emphasis on improving control of the rotator cuff to prevent superior translation of the humerus during shoulder elevation.¹⁶⁶
- Upper extremity ergometry with stationary ergometer or a portable reciprocal exerciser on a table. Emphasize progressive repetitions to increase muscular endurance.

**Exercise: Minimum Protection/
Return to Functional Activity Phase**

The minimum protection/return to functional activity phase usually begins around 12 to 16 weeks postoperatively (depending on rotator cuff tissue quality and function) and typically extends for several more months.^{47,92,195} There is a continued effort during this phase to restore full, active ROM for functional activities so long as there is adequate stability of the GH joint. Consequently, pain-free strengthening of the shoulder girdle for dynamic stability and functional use of the upper extremity for progressively more demanding tasks is the primary focus of this phase. For optimal results, the home exercise program may need to be continued for 6 months or longer, and functional and recreational activities may need to be modified.

Criteria for progression. To advance to the final phase of rehabilitation and gradually return to necessary and desired functional activities, a patient should meet the following criteria.

- Full, passive ROM of the shoulder (based on intraoperative ranges)^{37,92} or at least 130° to 140° of pain-free, passive or assisted shoulder flexion and 120° of abduction.¹⁹⁵
- In the plane of the scapula, at least 60° pain-free, passive external rotation and 70° internal rotation.¹⁹⁵
- Active (unassisted), antigravity elevation of the arm to at least 100° to 120° in the plane of the scapula while maintaining joint stability and using appropriate shoulder mechanics, particularly no shoulder shrugging prior to elevating the arm.¹⁹⁵
- Strength of rotator cuff and deltoid muscles: 4/5.^{47,92}

Goals and interventions. Goals and activities for the final phase of rehabilitation include the following.^{23,26,37,47,48,91,92,195}

- **Continue to improve or maintain shoulder mobility.**
 - End-range self-stretching.
 - Grade III joint mobilization and self-mobilization, if appropriate.^{23,26,37,92}
- **Continue to improve active control and muscle performance of the shoulder.**
 - Pain-free, low-load, high-repetition progressive resistive exercise (PRE) of shoulder musculature in anatomical and diagonal planes and in patterns of movement that replicate functional tasks throughout the available ROM. Position the patient in a variety of gravity-resisted positions.
 - Closed-chain, resisted shoulder exercises, gradually increasing weight bearing through the upper extremity.
 - Use of the involved upper extremity for lifting, carrying, pushing, or pulling activities against increasing loads.
- **Return to most functional activities.**
 - Use of the operated upper extremity for progressively more advanced functional activities.
 - Recreational activities, such as swimming and golf are possible.
 - Modification of high-demand, high-impact work-related or recreational activities to avoid imposing excessive forces on the GH joint that could lead to loosening or premature wear of prosthetic implants.

NOTE: For the patient whose rotator cuff was irreparable or continues to be significantly deficient because of a tenuous repair and who has limited but pain-free shoulder ROM, modification of the environment and use of assistive devices may be necessary for independence in functional activities.

Outcomes

Over the past 30 years, as patient selection criteria, prosthetic designs, and surgical techniques have been refined, postoperative outcomes after shoulder arthroplasty have improved. As noted at the beginning of this section on glenohumeral arthroplasty, numerous resources suggest that outcomes after TSR or hemiarthroplasty are influenced by many factors, including the type and severity of the underlying pathology, the status of soft tissues (espe-

cially the rotator cuff mechanism and subscapularis), the type and quality of the surgical procedure(s) performed, and patient-related factors, such as participation in a postoperative rehabilitation program.^{32,36,195} The outcomes most often measured in follow-up studies using a variety of quantitative scales are pain relief and other parameters of quality of life, passive and active shoulder ROM, and the ability to perform functional activities.

Despite the emphasis in numerous resources that a patient's participation in postoperative rehabilitation is crucial for successful outcomes, there are no studies to support this opinion because all patients undergoing shoulder arthroplasty are given some form of postoperative exercise instruction. Furthermore, published protocols are routinely modified to meet the needs of individual patients and consequently have not been compared to determine if one protocol yields better outcomes than another.¹⁹⁵

Pain relief. A decrease in pain is the most dramatic result of glenohumeral arthroplasty. Almost all patients—regardless of the underlying pathology, the type of arthroplasty (TSR or hemireplacement), or the design of the prosthetic implants—report complete or substantial relief of shoulder pain and improved functional use of the arm.^{36,108,109,117,119,121,130,134,171}

The extent of pain relief has been shown to be associated with the underlying cause(s) of glenohumeral arthritis. Neer et al.,¹¹⁹ Matsen,¹⁰⁸ and more recently Norris and Iannotti¹³⁰ reported that 90% of patients with primary OA or osteonecrosis had complete or near-complete pain relief after TSR. Similar results have been reported for patients with OA who underwent hemiarthroplasty.^{101,109,121} Patients with RA or other synovium-based diseases also report substantial pain relief after TSR or hemiarthroplasty, although not quite to the extent reported by patients with OA or osteonecrosis.^{36,159,182}

Whether TSR is more effective than hemiarthroplasty for pain relief has also been studied. In a prospective follow-up study over a mean of 4.3 years when patients with OA having TSR were compared to those having hemiarthroplasty, postoperative pain scores were reported to be similar in the two groups, with patients in the TSR group demonstrating more improvement because of a higher level of pain preoperatively.¹³⁴ In another study, patients with OA were randomly assigned to undergo either TSR or hemiarthroplasty and were evaluated postoperatively over a 24-month period. Results of this study indicated that both groups of patients reported significant pain relief and improvements in other quality-of-life parameters, with no significant differences between the TSR and hemiarthroplasty groups.¹⁰¹ Whether TSR versus hemiarthroplasty is more effective for pain relief in patients with RA has not been clearly established.^{109,182}

ROM and functional use of the upper extremity. Despite the emphasis placed on improving ROM and use of the arm for function activities during rehabilitation after shoulder arthroplasty, improvements in these

outcomes are less predictable than pain relief, with the functional status improving more consistently than ROM.* In general, patients with primary OA or osteonecrosis demonstrate greater improvement in active ROM (forward elevation and shoulder rotation) than patients with RA, in part because of a higher incidence of cuff deficiency associated with RA or the use of more constrained prosthetic designs.^{159,182,195} For example, in patients with OA or osteonecrosis, the mean active forward elevation of the shoulder (reported in reviews of a number of studies) changed from 105° to 161°. In patients with RA means ranged from 75° to 105°.^{171,195}

Significant improvement in functional status has been reported for patients with OA or osteonecrosis. Although functional improvement after arthroplasty has been reported for patients with RA, many studies used nonstandardized measurement tools, making it difficult to compare their results with those of other studies.¹⁹⁵ Regardless of the underlying pathology, resources agree that a well functioning rotator cuff mechanism is the basis for significant postoperative gains in active ROM and functional abilities.^{36,168,195}

Arthrodesis of the Shoulder

Indications for Surgery

The following are generally accepted indications for arthrodesis of the GH joint.^{109,145,146,196}

- Incapacitating pain (at rest or with movement)
- Gross instability of the GH joint
- Complete paralysis of the deltoid and rotator cuff muscles
- Severe joint destruction due to infection
- Failed shoulder arthroplasty in a young, active patient who is not a candidate for revision arthroplasty
- Sufficient compensatory scapular motion and strength of the serratus anterior and trapezius muscles

Procedure

The GH joint is fused with pins and bone grafts in a position of 15° to 30° flexion and abduction and up to 30° to 45° internal rotation so the hand can reach the middle of the body or the mouth.^{109,145,146,174,196} The shoulder is immobilized in a shoulder spica cast or a thoracobrachial (airplane) splint that extends across the elbow joint. The immobilizer is worn for 3 to 5 months.

Postoperative Management

Place emphasis on maintaining mobility of peripheral joints (wrist and hand) while the shoulder and elbow are immobilized. If a splint with a hinged elbow joint is used, begin elbow flexion and extension when permis-

*See references 57, 109, 130, 134, 161, 171, 195.

sible, often as early as the day after surgery. After the immobilization device may be removed for exercise, begin active scapulothoracic ROM. Strengthen the scapulothoracic musculature to maximize control and stability of the scapula.

Outcomes

A patient may expect to achieve 90° to 130° of active elevation of the arm because of scapulothoracic mobility.^{109,145,146,196} After bony and soft tissue healing is complete, the shoulder is stable and pain-free for activities that require strength or weight bearing at the shoulder. Patients are able to bring the hand to the mouth, behind the head, and to the hip.^{145,174,196} Over time, excessive stress may be placed on the AC joint, resulting in AC joint hypermobility and pain.^{145,146,174}

PAINFUL SHOULDER SYNDROMES (ROTATOR CUFF DISEASE, IMPINGEMENT SYNDROMES, SHOULDER INSTABILITIES): NONOPERATIVE MANAGEMENT

Mechanical compression and irritation of the soft tissues (rotator cuff and subacromial bursa) in the suprhumeral space (see Fig. 17.7) is called *impingement syndrome* and is the most common cause of shoulder pain.^{99,105} Various etiologic factors have been identified and therefore have led to several classification systems, which are summarized in Box 17.7.

Related Pathologies and Etiology of Symptoms

The cause of impingement is multifactorial, involving both structural and mechanical impairments. Impingement syndrome is often used as the diagnosis when the patient's signs and symptoms are related to pain with overhead reaching, a painful arc mid-range, and positive impingement tests. Other test results may more specifically identify the tissue involved, the faulty mechanics associated with the condition, or the degree of instability or injury. Symptoms that derive from impingement are usually brought on with excessive or repetitive overhead activities that load the shoulder joint, particularly in the mid-range. Impingement syndromes are generally classified as *primary* or *secondary*.

Other types of musculotendinous strain in the shoulder region may result from overuse or trauma, such as in the anterior pectoral region from racket sports or in the long head of the triceps and serratus anterior from impact trauma such as holding onto a steering wheel in an automobile accident.

BOX 17.7 Categories of Painful Shoulder Syndromes

Impingement syndromes and other painful shoulder conditions have varying etiologic factors and therefore can be categorized several ways.

Based on Degree or Stage of Pathology of the Rotator Cuff (Neer's Classification of Rotator Cuff Disease)¹¹⁸

- *Stage I.* Edema, hemorrhage (patient usually < 25 years of age)
- *Stage II.* Tendinitis/bursitis and fibrosis (patient usually 25 to 40 years of age)
- *Stage III.* Bone spurs and tendon rupture (patient usually > 40 years of age)

Based on Impaired Tissue⁴¹

- Supraspinatus tendinitis
- Infraspinatus tendinitis
- Bicipital tendinitis
- Subdeltoid (subacromial) bursitis
- Other musculotendinous strains (specific to type of injury or trauma)
 - Anterior—from overuse with racket sports (pectoralis minor, subscapularis, coracobrachialis, short head of biceps strain)
 - Inferior—from motor vehicle trauma (long head of triceps, serratus anterior strain)

Based on Mechanical Disruption and Direction of Instability or Subluxation

- Multidirectional instability from lax capsule with or without impingement
- Unidirectional instability (anterior, posterior, or inferior) with or without impingement
 - Traumatic injury with tears of capsule and/or labrum
 - Insidious (atraumatic) onset from repetitive microtrauma
 - Inherent laxity

Based on Progressive Microtrauma (Jobe's classification)⁸⁸

- *Group 1.* Pure impingement (usually in an older recreational athlete with partial undersurface rotator cuff tear and subacromial bursitis)
- *Group 2.* Impingement associated with labral and/or capsular injury, instability, and secondary impingement
- *Group 3.* Hyperelastic soft tissues resulting in anterior or multidirectional instability and impingement (usually attenuated but intact labrum, undersurface rotator cuff tear)
- *Group 4.* Anterior instability without associated impingement (result of trauma; results in partial or complete dislocation)

Based on Degree and Frequency

- Instability → subluxation → dislocation
- Acute, recurrent, fixed

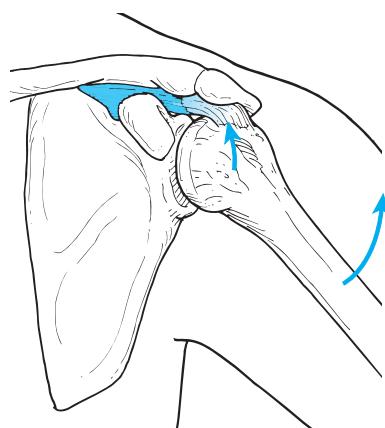

FIGURE 17.15 Decrease in the suprhumeral space during repetitive elevation activities lead to symptoms of impingement.

Primary Impingement—Rotator Cuff Disease

Primary impingement is believed to occur as a result of mechanical wear of the rotator cuff against the anteroinferior one-third of the acromion in the suprhumeral space during elevation activities of the humerus (Fig. 17.15). Encroachment may be the result of *intrinsic* or *extrinsic* factors.

Intrinsic factors. Intrinsic factors are those that are directly associated with encroachment of the subacromial space. They include vascular changes in the rotator cuff tendons, structural variations in the acromion, hypertrophic degenerative changes of the AC joint, or other trophic changes in the coracoacromial arch or humeral head. All of these factors decrease the suprhumeral space and often have to be dealt with surgically.^{58,82,149}

Neer¹²⁰ first suggested that in patients undergoing surgery for impingement syndrome the size and shape of the structures that make up the coracoacromial arch are related to rotator cuff impingement. In later studies variations in the shape and thickness of the acromion were identified and classified. One such classification, based on the shape of the anteroinferior aspect of the acromion, identified three shapes: type I (flat), type II (curved), and type III (hooked) (Fig. 17.16). Rotator cuff pathology is often associated with type II and III, but not type I, acromial shapes.^{1,115}

Extrinsic factors. Factors that result in decreased suprhumeral space and repetitive trauma to the soft tissues during elevation of the arm include posterior capsular tightness, poor neuromuscular control of the rotator cuff or scapular muscles, faulty scapulothoracic posture with muscle imbalances, or a partial or complete tear of the tissues in the suprhumeral space (incurred during a traumatic or degenerative situation).^{74,99,103,105,118,167}

Neer described three pathological stages of impingement that demonstrate the potentially progressive nature of the pathology over time (see Box 17.7).¹¹⁸ Other authors

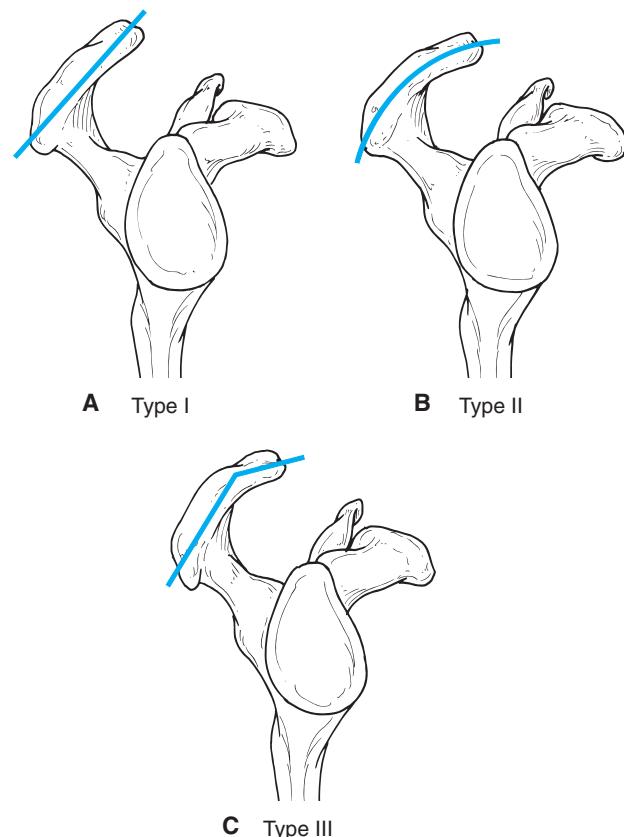

FIGURE 17.16 Classifications of the acromion by shape: (A) type I (flat); (B) type II (curved); (C) type III.

have identified chronic inflammation, possibly due to repetitive microtrauma in the joint region, as a stimulus for the development of frozen shoulder.^{66,122,125}

Tendinitis/Bursitis

Neer identified tendinitis/bursitis as a stage II impingement syndrome (see Box 17.7). The following sections describe specific pathological diagnoses and presenting signs and symptoms.

Supraspinatus tendinitis. With supraspinatus tendinitis, the lesion is usually near the musculotendinous junction, resulting in a painful arc with overhead reaching. Pain occurs with the impingement test (forced humeral elevation in the plane of the scapula while the scapula is passively stabilized so the greater tuberosity impacts against the acromion^{74,118} or with the arm in internal rotation while flexing the humerus).⁷⁴ There is pain on palpation of the tendon just inferior to the anterior aspect of the acromion when the patient's hand is placed behind the back. It is difficult to differentiate tendinitis from subdeltoid bursitis because of the anatomical proximity.

Infraspinatus tendinitis. With infraspinatus tendinitis, the lesion is usually near the musculotendinous junction,

resulting in a painful arc with overhead or forward motions. It may present as a deceleration (eccentric) injury due to overload during repetitive or forceful throwing activities. Pain occurs with palpation of the tendon just inferior to the posterior corner of the acromion when the patient horizontally adducts and laterally rotates the humerus.

Bicipital tendinitis. With bicipital tendinitis, the lesion involves the long tendon in the bicipital groove beneath or just distal to the transverse humeral ligament. Swelling in the bony groove is restrictive and compounds and perpetuates the problem. Pain occurs with resistance to the forearm in a supinated position while the shoulder is flexing (Speed's sign) and on palpation of the bicipital groove.¹⁰⁶ Rupture or dislocation of this humeral depressor may escalate impingement of tissues in the supraventricular space.^{118,126}

Bursitis (subdeltoid or subacromial). When acute, the symptoms of bursitis are the same as those seen with supraspinatus tendinitis. Once the inflammation is under control, there are no symptoms with resistance.

Other Impaired Musculotendinous Tissues

The following are examples of other musculotendinous problems in the shoulder region.

- The pectoralis minor, short head of the biceps, and coracobrachialis are subject to microtrauma, particularly in racket sports requiring a controlled backward then a rapid forward swinging of the arm, as are the scapular stabilizers as they function to control forward motion of the scapula.¹⁰⁰
- The long head of the triceps and scapular stabilizers are often injured in motor vehicle accidents as the driver holds firmly to the steering wheel on impact.
- A fall on an outstretched hand or against the shoulder may also cause trauma to the scapular stabilizers, which, if not properly healed, continue to cause symptoms whenever using the arm or when maintaining a shoulder posture.
- Injury, overuse, or repetitive trauma can occur in any muscle being subjected to stress.¹²⁹ Pain occurs when the involved muscle is placed on a stretch or when contracting against resistance. Palpating the site of the lesion causes the familiar pain.

Secondary impingement—Shoulder

Instability/Subluxation

Secondary impingement is used to describe symptoms resulting from faulty mechanics due to hypermobility or instability of the GH joint with increased translation of the humeral head. The instability may be *multidirectional* or *unidirectional*.

Multidirectional instability. Some individuals have physiologically lax connective tissue causing excessive mobility in the joints of the body. In the GH joint, the humeral head translates to a greater degree than normal in all directions.^{133,160,178} Many individuals, particularly those

involved in overhead throwing or lifting activities, have some inherent laxity or develop laxity of the capsule and instability from continually subjecting the joint to stretch forces.^{58,88} A hypermobile joint may be satisfactorily supported by strong rotator cuff muscles; but once the muscles fatigue, poor humeral head stabilization leads to faulty humeral mechanics, trauma, and inflammation of the supraventricular tissues.^{88,114} This trauma is magnified with the rapidity of control demanded in the overhead throwing action.⁵⁸ Similarly, in individuals with poor rotator cuff muscle strength and function, the ligaments become stressed with repetitive use and hypermobility, resulting in impingement. With instability, the impingement of tissue in the supraventricular space is the secondary effect.⁵⁸

Hypermobility can cause problems in addition to impingement, such as subluxation, dislocation, or rotator cuff tendinitis, which with repetitive microtrauma can lead to degenerative changes including bone spurs, tendon rupture, or capsular restrictions and frozen shoulder. Jobe developed a classification system incorporating the progression of impingement and instability in the overhead athlete based on progressive microtrauma⁸⁸ (outlined in Box 17.7).

Unidirectional instability with or without impingement.

Unidirectional instability (anterior, posterior, or inferior) may be the result of physiologically lax connective tissue but is usually the result of trauma and usually involves rotator cuff tears. The tears can be classified as acute, chronic, degenerative, or partial- or full-thickness tears. Often there is damage to the glenoid labrum and tearing of some of the supporting ligaments.

Traumatic tears or paralysis. Partial-thickness tears or full avulsion of the greater tubercle may occur in the elderly as the result of falling on an outstretched arm.¹²³ In young patients, trauma is usually associated with capsular injury, with or without labrum injury, resulting in instability. Dislocation of the humerus may occur with ensuing instability. The instability can lead to progressive degeneration and eventually tears in the supporting structures. Tears are associated with pain and most commonly weakness of shoulder abduction and external rotation.

- *Anterior instability* usually occurs with force against the arm when it is in an abducted and externally rotated position, and it frequently involves detachment of the anterior capsule and glenoid labrum (Bankart lesion). There may also be a fractured piece or flattening of the anterior lip of the glenoid.⁶⁸ Positive signs include apprehension, load and shift, and anterior drawer tests.^{106,201}
- *Posterior instability* is the result of a forceful thrust against a forward-flexed humerus or fall on an outstretched arm. There is a positive posterior drawer sign.^{106,201}
- *Inferior instability* is the result of rotator cuff weakness/paralysis and is frequently seen in patients with hemiplegia.⁶⁴ It is also prevalent in patients with multidirectional instability. This is detected with a positive sulcus sign.^{106,201}

Insidious (atraumatic) onset. Neer has identified rotator cuff tears as a stage III impingement syndrome, a condition that typically occurs in persons over age 40 after repetitive microtrauma to the rotator cuff or long head of the biceps.¹¹⁸ With aging, the distal portion of the supraspinatus tendon is particularly vulnerable to impingement or stress from overuse strain. With degenerative changes, calcification and eventual tendon rupture may occur.^{58,132} Chronic ischemia caused by tension on the tendon and decreased healing in the elderly are possible explanations, although Neer stated that, in his experience, 95% of tears are initiated by impingement wear rather than by impaired circulation or trauma.¹¹⁸

Common Impairments

Various impairments have been reported to be common in impingement syndromes, although it is not known if they are the cause or effect of the faulty mechanics.^{31,103,105,135,192} A thorough examination of the cervical spine and shoulder girdle is necessary to differentiate signs and symptoms related to primary and secondary impingements or other causes of shoulder pain.^{22,46,106}

Impaired Posture and Muscle Imbalances

Increased thoracic kyphosis, forward head, abducted and forward-tipped scapula are often identified as related to impingement syndrome. Faulty scapular alignment may be one factor in decreasing the suprhumeral space and therefore leading to irritation of the rotator cuff tendons with overhead activities.¹⁰³ Faulty upper quadrant posture leads to an imbalance in the length and strength of the scapular and GH musculature and decreases the effectiveness of the dynamic and passive stabilizing structures of the GH joint.²⁰²

Typically with increased thoracic kyphosis, the scapula is protracted and tipped forward, and the GH joint is in an internally rotated posture. With this posture, the pectoralis minor, levator scapulae, and shoulder internal rotators are tight; and the lateral rotators of the shoulder and upward rotators of the scapula test weak and have poor muscular endurance. There is no longer the stabilizing tension on the superior joint capsule and coracohumeral ligament or compressive forces from the rotator cuff muscles. Consequently, the effect of gravity tends to cause an inferior force on the humerus. When reaching overhead, there is faulty scapular and humeral mechanics, resulting in faulty alignment of the scapula and altered function in the muscles controlling the scapula and GH joint.

Focus on Evidence

In a study which examined the kinematics of 52 subjects (26 without shoulder impairment and 26 with shoulder impingement), Ludewig and Cook¹⁰³ documented delayed upward rotation of the scapula during the 31° to 60° range of humeral elevation, incomplete backward tipping of the scapula, and excessive scapular elevation in individuals with impingement compared with those without shoulder

impairments. This mechanical alteration may contribute to decreased clearance under the anterior acromion. They also documented decreased activation of the lower serratus anterior and overuse of the upper trapezius with scapular elevation, which was suggested as a possible compensation for the weak posterior tipping action of the serratus anterior.¹⁰³

Decreased Thoracic ROM

Thoracic extension is a component motion that is needed for full overhead reaching. Incomplete thoracic extension decreases the functional range of humeral elevation.

Rotator Cuff Overuse and Fatigue

If the rotator cuff musculature or long head of the biceps fatigue from overuse, they no longer provide the dynamic stabilizing, compressive, and translational forces that support the joint and control the normal joint mechanics. This is thought to be a precipitating factor in secondary impingement syndromes when there is capsular laxity and increased need for muscular stability.¹³⁷ The tissues in the subacromial space may then become impinged as a result of faulty mechanics. There is also a relationship between muscle fatigue and joint position sense in the shoulder that may play a role in impaired performance in repetitive overhead activities.³³

Muscle Weakness Secondary to Neuropathy

Muscle weakness may be related to nerve involvement. Long thoracic nerve palsy has been identified as a cause of faulty scapular mechanics resulting from serratus anterior muscle weakness, leading to impingement in the suprhumeral region.¹⁶³

Hypomobile Posterior GH Joint Capsule

Tightness in the posterior GH joint capsule compromises the normal arthrokinematics and increases forces on the head of the humerus against the anterior capsule. Harryman et al.⁶⁹ demonstrated increased anterior translation in the humeral head when there is a tight posterior capsule.

Summary of Common Impairments with Rotator Cuff Disease and Impingement Syndromes

Some, all, or none of the following may be present.

- Pain at the musculotendinous junction of the involved muscle with palpation, with resisted muscle contraction, and when stretched
- Positive impingement sign (forced internal rotation at 90° of flexion) and painful arc
- Impaired posture: thoracic kyphosis, forward head, and forward (anterior) tipped scapula with decreased thoracic mobility
- Muscle imbalances: hypomobile pectoralis major and minor, levator scapulae, and internal rotators of the GH joint; weak serratus anterior and lateral rotators
- Hypomobile posterior GH joint capsule
- Faulty kinematics with humeral elevation: decreased posterior tipping of scapula related to weak serratus anterior; scapular elevation and overuse of upper trapezius; and uncoordinated scapulohumeral rhythm

- With a complete rotator cuff tear, inability to abduct the humerus against gravity
- When acute, pain referred to the C5 and C6 reference zones

Common Functional Limitations/Disabilities

- When acute, pain may interfere with sleep, particularly when rolling onto the involved shoulder.
- Pain with overhead reaching, pushing, or pulling.
- Difficulty lifting loads.
- Inability to sustain repetitive shoulder activities (such as reaching, lifting, throwing, pushing, pulling, or swinging the arm).
- Difficulty with dressing, particularly putting a shirt on over the head.

Management: Painful Shoulder Syndromes (Without Dislocation)

NOTE: Even though symptoms may be "chronic" in terms of long standing or recurring, if there is inflammation the initial treatment priority is to get the inflammation under control.

Management: Protection Phase

Control Inflammation and Promote Healing

- Modalities and low-intensity cross-fiber massage are applied to the site of the lesion. While applying the modalities, position the extremity to maximally expose the involved region.^{42,45}
- Support the arm in a sling for rest.

Patient Education

The environment and habits that provoke the symptoms must be modified or avoided completely during this stage. The patient should be informed about the mechanics of the irritation and given guidelines for anticipated recovery with compliance.

Maintain Integrity and Mobility of the Soft Tissues

- Passive, active-assistive, or self-assisted ROM is initiated in pain-free ranges.
- Multiple-angle muscle setting and protected stabilization exercises are initiated. Of particular importance in the shoulder is to stimulate the stabilizing function of the rotator cuff, biceps brachii, and scapular muscles at an intensity tolerated by the patient.

PRECAUTION: It is important to use caution with exercises during this stage to avoid the impingement positions. Often the mid-range of abduction, scaption with internal rotation, or an end-range position when the involved muscle is on a stretch (such as putting the hand behind the back) provokes a painful response.

Control Pain and Maintain Joint Integrity

Pendulum exercises without weights can be used to cause pain-inhibiting grade II joint distraction and oscillation motions (see Fig. 17.22 in the section on exercise).

Develop Support in Related Regions

- Postural awareness and correction techniques are used. (See related information on interventions for impaired posture in Chapter 14.)
- Supportive techniques such as shoulder strapping or scapular taping, tactile cues, and mirrors can be used for reinforcement. Repetitive reminders and practice of correct posture is necessary throughout the day.

Management: Controlled Motion Phase

Once the acute symptoms are under control, the main emphasis becomes use of the involved region with progressive, nondestructive movement and proper mechanics while the tissues heal. The components of the desired functions are analyzed and initiated in a controlled exercise program.^{44,45,90,198,199} If there is a functional laxity in the joint, the intervention is directed toward learning neuromuscular control of and developing strength in the stabilizing muscles of both the scapula and gleno-humeral joint.^{29,90,93,162,181} If there is restricted mobility that prevents normal mechanics or interferes with function, mobilization of the restricted tissue is performed. Exercise techniques and progressions are described later in the chapter.

Patient Education

Patient adherence with the program and avoidance of irritating the healing tissues are necessary. The home exercise program is progressed as the patient learns safe and effective execution of each exercise.

Develop a Strong, Mobile Scar

- Manual therapy techniques such as cross-fiber or friction massage are used. The extremity is positioned so the tissue is on a stretch if it is a tendon or in the shortened position if it is in the muscle belly. The technique is applied to the tolerance of the patient.
- Following massage, the patient is instructed to perform an isometric contraction of the muscle in several positions of the range. The intensity of contraction should not cause pain.
- The patient should be taught how to self-administer the massage and isometric techniques.

Improve Postural Awareness

It is important to continue to reinforce proper postural habits. Tactile and verbal cues are used to increase patient awareness of scapular and cervical posture every time an exercise is performed, such as touching the scapular adductors and chin and reminding the patient to "pull the shoulders back" and "lift the head" while doing the shoulder exercises.

Focus on Evidence

In a random placebo-controlled, crossover study of 120 subjects (60 with impingement and 60 without symptoms), changing posture resulted in a significant increase in ROM in flexion, abduction, and scaption; and the point in the range where symptoms were felt was significantly higher.

Thoracic and scapular taping had a positive influence in modifying posture; there was less forward head posture, smaller kyphosis, less lateral scapular displacement, less elevated and forward scapula position, and increased pain-free range of scaption compared with the measurements taken after placebo taping in both the symptomatic and asymptomatic groups.⁹⁹

Modify Joint Tracking and Mobility

Mobilization with movement (MWM) may be useful for modifying joint tracking and reinforcing full movement when there is painful restriction of shoulder elevation because of a painful arc or impingement¹¹⁶ (see Chapter 5 for a description of principles).

- Posterolateral glide with active elevation (Fig. 17.17A)
- Patient position:* Sitting with the arm by the side and head in neutral retraction.

Therapist position and procedure: Stand on the side opposite the affected arm and reach across the patient's torso to stabilize the scapula with the palm of one hand. The other hand is placed over the anteromedial aspect of the head of the humerus. Apply a graded posterolateral glide of the humeral head on the glenoid. Request that the patient perform the previously painful elevation. Maintain the posterolateral glide mobilization throughout both elevation and return to neutral. Ensure that no pain is experienced during the procedure. Adjust the grade and direction of the glide as needed to achieve pain-free function. Add resistance in the form of elastic resistance or a cuff weight to load the muscle.

Self-Treatment. A mobilization belt provides the posterolateral glide while the patient actively elevates the affected limb against progressive resistance to end range (Fig. 17.17B).

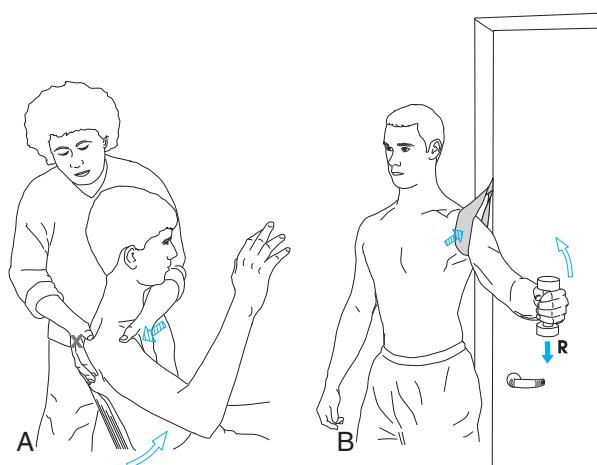

FIGURE 17.17 MWM to modify joint tracking and improve active elevation. A posterolateral glide is applied to the humeral head (A) manually or (B) with a belt for self-treatment, while the patient actively elevates the humerus. A weight is used to strengthen the muscles through the pain-free range.

Develop Balance in Length and Strength of Shoulder Girdle Muscles

It is important to design a program that specifically addresses the patient's impairments. Typical interventions in the shoulder girdle include but are not limited to:

- *Stretch shortened muscles.* Shortened muscles typically include the pectoralis major, pectoralis minor, latissimus dorsi and teres major, subscapularis, and levator scapulae.
- *Strengthen and train the scapular stabilizers.* Scapular stabilizers typically include the serratus anterior and lower trapezius for posterior tipping and upward rotation and the middle trapezius and rhomboids for scapular retraction. It is important that the patient learns to avoid scapular elevation when raising the arm. Therefore, practice scapular depression when abducting and flexing the humerus.
- *Strengthen and train the rotator cuff muscles,* especially the shoulder lateral rotators.

Develop Muscular Stabilization and Endurance

- Alternating isometric resistance is applied to the scapular muscles in *open-chain positions* (side-lying, sitting, supine), including protraction/retraction, elevation/depression, and upward/downward rotation so the patient learns to stabilize the scapula against the outside forces (see Fig. 17.36 and the exercise section).
- Scapular and glenohumeral patterns are combined using flexion, abduction, and rotation. Alternating isometric resistance is applied to the humerus while the patient holds against the changing directions of the resistance force (see Figs. 17.37, 17.38, and 17.41 in the exercise section).
- *Closed-chain stabilization* is performed with the patient's hands fixated against a wall, a table, or the floor (quadruped position) while the therapist provides a graded, alternating isometric resistance or rhythmic stabilization. Observe for abnormal scapular winging. If it occurs, the scapular stabilizers are not strong enough for the demand; so the position should be changed to reduce the amount of body weight (see Fig. 17.42 in the exercise section).
- *Muscular endurance* is progressed by increasing the amount of time the individual holds the pattern against the alternating resistance. The limit is reached when any one of the muscles in the pattern can no longer maintain the desired hold. The goal at this phase should be stabilization for approximately 3 minutes.

Progress Shoulder Function

As the patient develops strength in the weakened muscles, it becomes important to develop a balance in strength of all shoulder and scapular muscles within the range and tolerance of each muscle. To increase coordination between scapular and arm motions, dynamically load the upper extremity within tolerance of the synergy with submaximal resistance. To improve muscular endurance, have the patient increase control from 1 minute to 3 minutes.

BOX 17.8 Patient Instructions to Prevent Recurrences of Shoulder Pain

- Prior to exercise or work, massage the involved tendon or muscle; follow with isometric resistance and then with full ROM and stretching of the muscle.
- Take breaks from the activity if repetitive in nature. If possible, alternate the stressful, provoking activity with other activities or patterns of motion.
- Maintain good postural alignment; adapt seating or workstation to minimize stress. If sport-related, seek coaching in proper techniques or adapt equipment for safe mechanics.
- Prior to initiating a new activity or returning to an activity for which not conditioned, begin a strengthening and training program.

Management: Return to Function Phase

Specificity of training toward the desired functional outcome begins as soon as the patient has developed control of posture and the basic components of the desired activities without exacerbating the symptoms. While working with the patient, continue to instruct him or her on how to progress the program when discharged as well as how to prevent recurrences. Suggestions are summarized in Box 17.8.

Increase Muscular Endurance

To increase muscular endurance, repetitive loading of the defined patterns is increased from 3 minutes to 5 minutes.

Develop Quick Motor Responses to Imposed Stresses

- The stabilization exercises are applied with increased speed.
- Plyometric training in both open-chain and closed-chain patterns is initiated if power is a desired outcome.

Progress Functional Training

Specificity of training progresses to an emphasis on timing and sequencing of events.

- Eccentric training is progressed to maximum load.
- Desired functional activities are simulated—first under controlled conditions, then under progressively challenged situations using acceleration/deceleration drills.
- The patient is involved in assessing performance in terms of safety, symptom provocation, postural control, and ease of execution and then practices adaptations to correct any problems.

PAINFUL SHOULDER SYNDROMES: SURGERY AND POSTOPERATIVE MANAGEMENT

Surgical intervention is an option for painful shoulder syndromes when conservative management does not resolve

symptoms and improve a patient's function. For an individual with primary impingement as a result of structural variations in the acromion (see descriptions and Fig. 17.16 in the previous section), subacromial decompression may be performed. An individual with a partial- or full-thickness rotator cuff tear may require surgical repair. The subacromial decompression and rotator cuff repair surgeries and postoperative management are described in this section. Surgical repair and postoperative management due to instabilities and dislocations are described in a later section of this chapter.

Subacromial Decompression and Postoperative Management

When pain and loss of functional mobility associated with primary impingement do not resolve sufficiently with non-operative management, *subacromial decompression*, designed to increase the volume of the subacromial space and provide adequate gliding room for tendons, followed by postoperative rehabilitation is often warranted. Subacromial decompression, is commonly referred to as *anterior acromioplasty* or *decompression acromioplasty*. However, acromioplasty, which alters the shape of the acromion, is typically but not always one of the components of subacromial decompression.¹¹¹

Indications for Surgery

The following are generally accepted indications for surgical management of impingement syndromes.*

- Pain during overhead activities and loss of functional mobility of the shoulder as the result of primary impingement that persists (typically for 3 to 6 months or longer) despite a trial of nonoperative interventions.
- Stage II (Neer classification) (see Box 17.7) impingement with nonreversible fibrosis or bony alterations of the subacromial compartment, calcific deposits in the cuff tendons, and symptomatic subacromial crepitus.
- Intact or minor tear of the rotator cuff.

NOTE: Patients who present with secondary impingement (GH joint hypermobility or instability associated with a partial- or full-thickness tear of the rotator cuff) are not candidates for surgical subacromial decompression alone. For these patients subacromial decompression is combined with concomitant repair of the cuff tear; otherwise the procedures inherent in subacromial decompression can worsen GH instability.^{71,111,190}

Procedures

Surgical approach. Subacromial decompression is performed using an arthroscopic or open approach. Although an open approach has been used successfully for many years,^{75,117,120,149} the preferred procedure today in most cases is an arthroscopic approach.^{53,190} Unlike a traditional open approach, in which the proximal attachment of the deltoid must be detached and then repaired prior to

*See references 1, 53, 71, 75, 111, 120, 149, 155, 190.

closure,¹²⁰ with an arthroscopic approach the deltoid remains intact, enabling the patient to regain functional use of the upper extremity more rapidly after surgery.

Another option, preferred by some surgeons to either a traditional open or arthroscopic decompression, is a “mini-open” approach, which involves splitting the deltoid insertion vertically rather than detaching it.¹¹¹ For the most part, the traditional open approach for subacromial decompression is now reserved for some patients with a massive rotator cuff tear who also are undergoing an open repair.

Component procedures. There are several surgical procedures that can be performed for subacromial decompression depending on the pathology observed during examination of the shoulder prior to or during surgery.^{1,53,67,71,111,131,155,190}

- Removal of the subacromial bursa (*bursectomy*), which is typically thickened (enlarged) by chronic inflammation.
- Release of the coricoacromial ligament, which is usually hypertrophied and may also be frayed, followed by complete or partial resection or recession.
- Resection of the anterior acromial protuberance and contouring the undersurface of the remaining portion of the acromion (*acromioplasty*) to enlarge the subacromial space (Fig. 17.18).
- Removal of any osteophytes at the AC joint and in some cases resection of the distal portion of the clavicle for advanced arthritis of the AC joint.

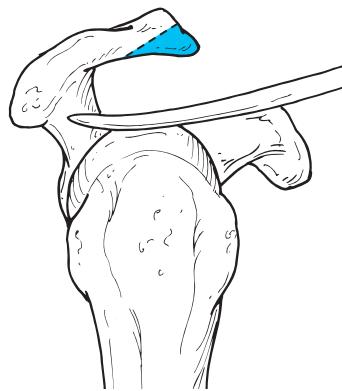

FIGURE 17.18 Arthroscopic acromioplasty showing the line of resection of the anterior acromion.

Postoperative Management

The type of surgical approach used and the status of the rotator cuff significantly affect the progression of rehabilitation after subacromial decompression (acromioplasty). More often than not an arthroscopic approach is used. If the rotator cuff is intact preoperatively, rehabilitation after arthroscopic acromioplasty progresses quite rapidly because the shoulder musculature is left intact during the procedure. In contrast, if a repair of the rotator cuff is required in addition to acromioplasty or if the surgeon elects to use a mini-open or open approach, rehabilitation progresses at a slower rate to allow the repaired shoulder musculature adequate time to heal.

NOTE: The guidelines outlined in this section are for postoperative rehabilitation after *arthroscopic* subacromial decompression for a patient with primary shoulder impingement who has an *intact rotator cuff*. If subacromial decompression is combined with repair of the rotator cuff (arthroscopic, mini-open, or open approach), the guidelines presented in a later section of this chapter on rehabilitation after rotator cuff repair are appropriate.

Immobilization

The shoulder is immobilized and supported in a sling with the arm positioned at the patient’s side or in slight abduction, the shoulder is internally rotated, and the elbow is flexed to 90°. The sling is worn for comfort for 1 to 2 weeks but is removed for exercise the day after surgery.^{111,190,200}

Exercise

Exercise interventions after subacromial decompression target the same impairments common to rotator cuff impingement as do the exercises selected for a nonoperative program. These impairments and the associated pathomechanics of the shoulder girdle were discussed and summarized previously in this chapter. This information merits review to understand why specific exercises are included in the following postoperative rehabilitation program.

The suggested criteria and timelines for a patient to progress from one phase of rehabilitation to the next, as well as the goals, exercises, and activities in this section, are drawn from several published resources.^{3,53,71,91,111,190,200} The exercises noted for each phase impose gradually increasing demands as soft tissues heal. In addition, patient education, emphasizing *prevention* of postures and movements that contribute to impingement and provoke pain, is woven throughout each phase of rehabilitation.

Because arthroscopic decompression often is performed on an outpatient basis, a patient must carry out the prescribed exercises at home with little supervision. Therefore, on the few visits the patient may have with a therapist, patient education is of the utmost importance for each phase of rehabilitation.

Exercise: Maximum Protection Phase

The first phase of rehabilitation after arthroscopic decompression begins on the day after surgery and extends for 3 to 4 weeks. Emphasis is placed on pain control and immediate but comfortable assisted movement of the shoulder to prevent adhesions of the cuff tendons in the subacromial space. Attaining full or nearly full passive ROM of the operated shoulder (compared to the noninvolved shoulder) is a reasonable goal by 4 to 6 weeks postoperatively.⁷¹

Patient education begins immediately and is directed toward helping the patient recognize and prevent postures during exercise and ADL that contribute to symptoms. Active (unassisted) shoulder ROM is permissible as soon as motions are pain-free and proper scapulothoracic and glenohumeral control can be maintained. This may be possible as early as 2 weeks after arthroscopic decompression

if the rotator cuff did not require repair and is functioning sufficiently.

Goals and interventions. The following goals and exercises are indicated for the early stage of tissue healing.^{1,3,37,71,111,200}

● **Control pain and inflammation.**

- Use of a sling when the arm is dependent.
- Use of cryotherapy and prescribed anti-inflammatory medication.
- Active ROM of the cervical spine and shoulder relaxation exercises.

● **Prevent loss of mobility of peripheral joints.**

- Active ROM of the elbow, wrist, and hand.

● **Develop postural awareness and control.**

- Active exercises of the scapula with emphasis on retraction.
- Posture training, reinforcing an erect trunk (avoiding excessive thoracic kyphosis) for prevention of postures that can contribute to impingement symptoms during exercises and ADL.

● **Restore pain-free shoulder mobility.**

- Pendulum exercises for pain control and mobility.
- Assisted shoulder ROM as tolerated by pain, initially guiding with the sound upper extremity and later a wand. Start in the supine position to provide additional stability to the scapula against the thorax and with the upper arm on a folded towel in slight abduction and flexion. Shoulder motions include elevating the arm in the plane of the scapula, forward flexion, abduction, rotation, and horizontal abduction and adduction. Progress to performing exercises in a semi-reclining position and then in a seated or standing position while maintaining thoracic extension.
- Assisted shoulder extension in a standing position with a wand held behind the back.
- Stretching the posterior shoulder structures in pain-free range using a cross-chest stretch into horizontal adduction. Postpone until next phase if painful.
- Active ROM (unassisted) of the shoulder and scapula within pain-free ranges maintaining proper scapulothoracic and glenohumeral control; begin supine and progress to sitting. Active shoulder motions may be possible by 2 weeks postoperatively.

● **Prevent reflex inhibition and atrophy of shoulder girdle musculature.**

- Pain-free, low-intensity, multiple-angle isometrics of GH musculature with the arm supported and emphasis on the rotator cuff against minimal resistance. Begin submaximal isometrics a week or so postoperatively. Lightly resist with the uninvolved upper extremity. Focus on increasing repetitions more than resistance.^{103,163}
- Submaximal alternating isometric and rhythmic stabilization exercises for scapulothoracic muscles with the involved arm supported by the therapist. Target the scapular retractors and upward rotators.

Exercise: Moderate Protection Phase

Exercises during the second phase of rehabilitation are directed toward attaining full, pain-free shoulder ROM and improving neuromuscular control and muscle performance (strength, muscular endurance) of the deltoid, rotator cuff, and scapular stabilizers. The patient may be ready to begin this phase of rehabilitation as early as 3 to 4 weeks postoperatively but more often by 4 to 6 weeks. This phase extends over a 4- to 6-week period or until the patient meets the criteria to progress to the next phase.

Criteria for progression. Criteria to advance to the second phase include^{37,71,91,111,200}:

- Minimal discomfort when the shoulder is unsupported; arm swing is comfortable during ambulation.
- Nearly complete, pain-free, *passive* ROM of the shoulder (full mobility of the scapula; at least 150° of shoulder elevation; full rotation).
- In the supine position, pain-free *active* elevation of the arm well above the level of the shoulder.
- Pain-free, *active* external rotation of the shoulder to about 45°.
- At least fair (3/5) and preferably good (4/5) muscle testing grade of shoulder musculature.

Goals and interventions. The goals, exercises, and activities during the second (intermediate) phase of rehabilitation are^{37,71,91,200}:

● **Restore and maintain full, pain-free passive mobility of the shoulder girdle and upper trunk.**

- Joint mobilization, emphasizing posterior and caudal glides of the humerus and scapulothoracic mobility.
- Low-intensity self-stretching of range-limiting muscles that could restrict sufficient upward rotation of the scapula and rotation of the humerus necessary for full elevation of the arm overhead, specifically the levator scapulae, rhomboids, middle trapezius, latissimus dorsi, and pectoralis major and minor. Remember, shortening of these muscles contributes to impingement of soft tissues during overhead movements of the arm.
- Self-stretching (cross-chest stretch) of the posterior deltoid and posterior capsule of the GH joint. These structures are usually tight in the presence of shoulder impingement. A tight posterior capsule causes excessive anterior translation and superior migration of the head of the humerus in the glenoid, which in turn causes impingement of soft tissues during overhead reach.⁶⁹
- Self-stretch of the upper trunk to increase thoracic extension by lying supine on a rolled towel placed vertically between the scapulae.
- Use the gained ROM in exercises and functional movement patterns during ADL.

● **Reinforce posture awareness and control.**

- Through patient education, continue to incorporate an erect trunk into exercises and function activities.

● **Develop dynamic stability, strength, endurance, and control of scapulothoracic and GH muscles.**

- Stabilization exercises against increasing resistance and in weight-bearing postures. If winging of the scapula occurs with weight bearing, provide manual support or decrease the imposed loads. Emphasize isolated strengthening of the serratus anterior and trapezius muscles.
- Upper extremity ergometry for muscular endurance. To avoid an impingement arc, initiate in a standing position rather than while seated.
- Dynamic strengthening exercises of isolated shoulder muscles against low loads (1- to 5-lb weight or light-grade elastic tubing), gradually increasing repetitions. Begin resisted elevation of the arm in the supine position to stabilize the scapula against the thorax; progress to sitting or standing.
- Use the involved arm for functional activities that involve light resistance.

NOTE: Target the upward rotators of the scapulothoracic joint (serratus anterior, upper and lower trapezius) and the rotator cuff muscles,¹⁶⁶ as well as the latissimus dorsi, teres major, and biceps brachii, which act as humeral head depressors and therefore oppose superior translation during active elevation of the arm. Initially perform resisted motions of the humerus below the level of the shoulder; later progress to overhead exercises if motions remain pain-free.

PRECAUTION: Be certain the patient can perform active shoulder flexion and abduction against gravity without hiking the shoulder before progressing to resisted exercises above shoulder level.

Exercise: Minimum Protection/ Return to Function Phase

The final phase of rehabilitation usually begins by 8 weeks postoperatively, at which time soft tissues are reasonably well healed and require little to no protection. Exercises continue until about 12 to 16 weeks postoperatively or until the patient has returned to full activity. Exercises are directed toward continuing to improve strength and endurance of the shoulder girdle muscles using isolated movements and those that simulate functional activities. Patients often see continued improvement in functional use of the operated upper extremity for 6 months postoperatively.³

The time necessary for full recovery and unrestricted activities depends largely on the level of demand of the anticipated activities. A patient wishing to return to competitive sports requires a more demanding progression of advanced exercises (e.g., plyometric training and sport-specific drills) than a sedentary individual.^{37,200,203}

Criteria for Progression. The criteria that should be met to progress to the final phase of rehabilitation are^{37,91,200}:

- Negative impingement test.
- Full, pain-free, active ROM of the shoulder without evidence of substitute motions.
- Seventy-five percent or more strength of the shoulder musculature compared with the sound shoulder.²⁰⁰

Goals and Interventions. The goals, exercises, and activities during the final phase of rehabilitation after subacromial decompression and for the final phase of nonoperative management of primary impingement syndrome are similar. Refer to the information presented in the previous section of this chapter as well as other resources.^{37,45,113,198,200,203}

Outcomes

There appears to be no significant difference in the *long-term* results (pain-free ROM and return to desired functional activities) after either open or arthroscopic surgery for primary impingement syndrome with or without associated rotator cuff disease.^{53,111,190} Based on the results of numerous outcome studies of open and arthroscopic procedures, 85% to 95% of patients report good to excellent results 1.0 to 2.5 years postoperatively.^{1,71,111,190} In general, patients reporting the least satisfaction with their function after surgery are those who participate in high-demand athletic activities that involve overhead throwing and those with work-related injuries who are receiving workers' compensation.¹¹¹

Follow-up studies have documented several advantages of an arthroscopic over comparable open surgical management of impingement syndrome. They include less postoperative pain; earlier restoration of full ROM and strength; earlier return to work (often as early as 1 week postoperatively); lower cost (shorter hospital stay or outpatient surgery); and a more favorable cosmetic result.^{1,71,111,190}

Although exercises are routinely prescribed after subacromial decompression, the effectiveness of exercise has been the focus of very few studies. One prospective, randomized study carried out in Denmark looked at the effectiveness of a 6-week therapist-supervised exercise program compared to a self-managed program after arthroscopic subacromial decompression.³ Patients in the therapist-supervised group received exercise instruction while in the hospital and then for a 1-hour therapy session once a week for 6 weeks after discharge from the hospital. Patients in the self-managed group received exercise instruction on one occasion prior to discharge from the hospital. Both groups received written instructions. At 6 weeks and 3, 6, and 12 months, all patients demonstrated improvement in all parameters tested. However, there were no significant differences between the two groups with the exception of one measurement. At 3 months postoperatively, the therapist-supervised group had a higher level of pain than the self-managed group. The authors concluded that initial, therapist-directed exercise instruction followed by a home-based, self-managed exercise program achieved rehabilitation goals as effectively as a therapist-supervised program.

Rotator Cuff Repair and Postoperative Management

There are two broad categories of rotator cuff tears, defined by the depth of the tendon tear: partial-thickness and full-thickness tears. Either type may require surgical

management. A *partial-thickness tear* extends inferiorly or superiorly through only a portion of the tendon from either the acromial (bursal) or humeral (articular) surface of the tendon. A *full-thickness tear* is a complete tear, which extends the entire depth of the tendon.^{71,77,111}

Indications for Surgery

The primary indications for surgical management of a rotator cuff tear confirmed by imaging are pain and impaired function as the result of the following.*

- Partial-thickness or full-thickness tears of the rotator cuff tendons resulting from repetitive microtrauma and chronic impingement, which lead to irreversible degenerative changes in soft tissues. Some patients with stage II lesions and most with stage III lesions (Neer classification¹¹⁸) who continue to be symptomatic and have functional limitations after a trial of nonoperative treatment are candidates for surgery.
- Acute, traumatic rupture (frank, full-thickness tear) of the rotator cuff tendons often combined with avulsion of the greater tuberosity, labral damage, or acute dislocation of the GH joint in individuals with no known history of cuff injury. Full-thickness, traumatic tears occur most often in young, active adults.

NOTE: Surgical repair is not indicated in patients who are asymptomatic despite the presence of a cuff tear confirmed by imaging.

Procedures

Depending on the severity and location of a tear of one or more of the rotator cuff tendons, the extent of associated lesions, the onset of the tear (repetitive microtrauma or traumatic injury), the quality and mobility of the torn tissues, bone quality, patient-related considerations (age, health, activity level) and the surgeon's preference and experience, there are several operative options for repairing a torn rotator cuff.^{71,72,111,190}

Type of Repair

The type of cuff repair is typically classified by the surgical approach and techniques used. There are three categories of repair.

- **Arthroscopic approach.** The entire procedure is performed arthroscopically and requires only a few small incisions for port sites.^{8,59,60,71,111,172,190,210}
- **Mini-open (arthroscopically assisted) approach.** There are two variations of this type of procedure, both of which involve arthroscopic subacromial decompression and a *deltoid-splitting* approach. In one variation only the subacromial decompression is performed arthroscopically, whereas in the other variation a portion of the cuff repair itself is also performed arthroscopically.²¹⁰ In both cases, an anterolateral incision is made at the acromion and is extended distally (either 1.5 or 3.5 cm but no more than 4 cm to avoid the axillary nerve) along the fibers of the deltoid insertion. The deltoid is split longi-

tudinally between its anterior and middle portions to allow visualization of the cuff tear without detaching the deltoid from its proximal insertion.^{56,111,138,180}

- **Traditional open approach.** An anterolateral incision is made that extends obliquely from the middle one-third of the inferior aspect of the clavicle, across the coracoid process, and to the anterior aspect of the proximal humerus. The proximal insertion of the deltoid must be detached and reflected for exposure of the operative field during an open subacromial decompression and cuff repair. After the cuff repair is complete, the deltoid is reattached to the acromion.[†] As arthroscopic and arthroscopically assisted repairs of the rotator cuff have advanced, the use of the traditional open approach has decreased.

Components of a Rotator Cuff Repair

Regardless of the approach, subacromial decompression is performed (particularly for cuff tears associated with chronic impingement) before repair of the cuff is undertaken. After the tear is visualized through the approach selected, the margins of the torn tendon are débrided. The tendon is then released from any adherent soft tissues and mobilized for advancement and apposition to bone that has been prepared for sutures, followed by *tendon-to-bone* fixation. Depending on whether an arthroscopic or mini-open approach is used, fixation is accomplished by sutures and suture anchors, tacks, or staples.^{56,59,71,111,179,190}

In addition to subacromial decompression, other concomitant procedures may be required.^{71,111} For example, capsular tightening or labral reconstruction may be performed if unidirectional or multidirectional instability of the GH joint is present. Because degenerative changes in the tendon of the long head of the biceps brachii are often associated with chronic rotator cuff disease, a repair of this tendon may also be necessary.

Selection of Surgical Procedures

The surgeon weighs many factors when determining which type of cuff repair is most appropriate for each patient. One such consideration is the severity of the tear, including thickness (partial or full), size, and number of tendons torn. Although there is some variability in the literature, there are four generally accepted categories that describe the longitudinal size of rotator cuff tears: *small* (1 cm or less), *medium* (1 to 3 cm), *large* (3 to 5 cm), and *massive* (more than 5 cm or a full-thickness tear of more than one tendon).^{8,56,71,191}

If a small, *partial-thickness* cuff tear is managed surgically after failed nonoperative treatment, a fully arthroscopic approach typically is performed to débride the frayed margins of the torn tendon, coupled with a subacromial decompression procedure. However, the torn portion of the tendon may or may not be repaired.^{8,71,111,172,179,190}

Two decades ago, primarily small and medium *full-thickness* cuff tears (≤ 1 to 3 cm) were managed with a fully arthroscopic approach.^{60,71,111} With the evolution of arthroscopic techniques, an increasing number of large,

*See references 8, 12, 71, 77, 111, 138, 140, 167, 178, 190, 210.

[†]See references 12, 77, 97, 111, 140, 178.

full-thickness cuff tears and occasionally massive tears as well are managed with a fully arthroscopic approach.^{190,210} However, variations of the mini-open (deltoid splitting) approach frequently are the surgeon's choice for repair of medium and large tears.^{56,111,146,180} Even some massive tears (> 5 cm) are managed with a deltoid-splitting approach.^{111,191} The traditional open approach, requiring detachment and repair of the deltoid, now primarily is reserved for repairs of multiple tendon tears associated with extensive injury to the shoulder or for use as a component of an open surgical procedure, such as total shoulder replacement arthroplasty.^{56,111}

The location of the cuff tear, amount of retraction and mobility of a full-thickness tear, and the quality of the remaining tendon and underlying bone also influence the surgeon's selection of the type of cuff repair expected to be most effective.^{71,111,179,190} Whereas small, medium, and large tears of the supraspinatus (the most frequently torn cuff tendon) or infraspinatus are routinely managed with arthroscopic or mini-open approaches, tears of the subscapularis are often managed with a traditional open approach.⁵⁶ If there is significant retraction and poor mobility of the torn tendon or poor tissue quality, many surgeons believe that a stronger repair can be achieved with an open procedure (mini-open or traditional) than with an arthroscopic repair.⁷¹

Postoperative Management

After surgical repair of a torn rotator cuff tendon, there are many factors that influence decisions about the position and duration of immobilization, the selection and application of exercises, and the rate of progression of each patient's post-operative rehabilitation program. These factors and their potential impact are summarized in Table 17.3. Furthermore, these factors can affect postoperative outcomes.

There is little consensus reported in the literature or practiced in the clinical setting as to how and to what extent each of these factors, singularly or collectively, has an impact on the decisions made by the surgeon and the therapist about a patient's postoperative rehabilitation program. Hence, predetermined guidelines and protocols for postoperative management after rotator cuff repair are diverse and sometimes contradictory.* For example, some authors have pointed out that if deltoid detachment and repair are components of the surgery, as is necessary for a traditional open repair, deltoid strengthening exercises should be postponed for approximately 6 to 8 weeks postoperatively until the repaired deltoid has healed.^{37,52,111} Yet another author suggested that rehabilitation should proceed similarly regardless of whether deltoid detachment was required so long as secure fixation of the deltoid was achieved.⁷¹

*See references 8, 24, 37, 50, 52, 56, 71, 111, 138.

TABLE 17.3 Factors that Influence Progression of Rehabilitation After Repair of the Rotator Cuff

Factors	Potential Impact on Rehabilitation
• Onset of injury	• Chronic impingement and atraumatic cuff deficiency → slower progression than after acute traumatic injury.
• Size and location of the tear	• Larger tears with more structures involved and probability of more extensive surgery → slower progression.
• Associated pathologies such as GH instability or fracture	• Associated pathologies often lengthen the period of immobilization → slower progression of exercises or the need for additional precautions.
• Preoperative strength and mobility of the shoulder	• Preexisting weakness and atrophy of the dynamic stabilizers or limited passive and active mobility of the shoulder → slower postoperative progression.
• Patient's general health	• Patient in poor health; history of smoking; history of inflammatory disease → slower progression.
• History of steroid injections or previous, failed cuff surgery	• Compromised bone and tendon tissue quality, which affects the security of the repair (fixation) → slower progression.
• Preinjury level of activity of postoperative goals	• Higher level goals require a more extended and advanced postoperative training program because of a higher risk of reinjury.
• Age of patient	• Older patient who has an insidious (chronic) onset and may have articular changes → slower progression.
• Type of approach	• Traditional open approach (with deltoid detachment and repair) → slightly slower progression than after an arthroscopic or arthroscopically assisted (mini-open/deltoid splitting) repair.
• Type of repair	• Tendon to tendon → slower progression than tendon to bone.
• Mobility (no excessive tension on the repaired tendon when arm at side) and integrity of the repair	• If mobility is inadequate → longer duration of exercise within a protected ROM during early rehabilitation.
• Patient's compliance with the program	• Lack of compliance (doing too much or too little) can affect outcome.
• Philosophy, skill, and training of the surgeon	• All have an impact that could → either slower or more accelerated progression.

Given the diverse characteristics of patients undergoing repair of the rotator cuff and the variety of surgical options available, it is not surprising that no single postoperative program can be used for all patients or has been shown to yield better outcomes than another. Therefore, to meet each patient's needs and goals, a therapist can use published protocols or those developed at individual clinical facilities as general guidelines for postoperative management and can modify the guidelines based on ongoing examination of the patient's response to interventions and close communication with the surgeon.

Despite variations among postoperative programs, they share three common elements: (1) immediate or early postoperative motion of the GH joint; (2) control of the rotator cuff for dynamic stability; and (3) gradual restoration of strength and muscular endurance. The purpose of this section is to present *general* exercise guidelines that incorporate these elements into progressive phases of rehabilitation after arthroscopic or mini-open repair of a *full-thickness* cuff tear and to identify the differences in precautions and the progression of exercises for a traditional open procedure or differences based on the size and location of the tear and the quality of the repair.

NOTE: The goals, exercise interventions, and progression of rehabilitation after débridement rather than repair of a *partial-thickness* tear are comparable to postoperative management after subacromial decompression for cuff impingement presented in the previous section of this chapter.

Immobilization

The position and duration of immobilization of the operated shoulder after rotator cuff repair are dependent on many factors, such as the severity and location of the tear and the type and quality of the repair. One of those factors, the size of the cuff tear, in part determines whether the patient's operated arm is supported in a sling (shoulder adducted, internally rotated, and elbow flexed to 90°) or in an abduction orthosis or pillow (shoulder elevated in the plane of the scapula approximately 45°, shoulder internally rotated, and elbow flexed). Some patients, using an abduction splint, initially may be required to have a family member support the operated arm in the 45° shoulder position when the splint is removed for exercise or dressing and even for bathing.

Table 17.4 summarizes the variations noted in the literature for fully arthroscopic and mini-open/deltoid-splitting approaches. Immobilization after a traditional open procedure that involves deltoid detachment and repair, is not included in Table 17.4 because of the variations in guidelines reported in the literature.^{37,71,111,191}

The rationale for initially immobilizing the operated shoulder in abduction is based on two principles. (1) In the abducted position, the repaired cuff, as well as the reattached deltoid with an open approach, are held in a relaxed position, which reduces the possibility of reflexive muscle contractions that could disrupt the repairs. (2) Supporting the arm in abduction rather than adduction reduces tension on the tendons and therefore may improve blood flow to the repaired tendon(s).

Exercise

Regardless of whether a patient undergoes a rotator cuff repair on an inpatient or outpatient basis, contact with a therapist for exercise instruction after surgery is usually limited to a few visits unless the patient does not progress satisfactorily. Therefore, the emphasis of a therapist's interaction with a patient must be placed on patient education for an effective and safe home-based exercise program. As with rehabilitation after arthroscopic subacromial decompression,³ the extent of therapist-directed exercise after rotator cuff surgery also has been investigated.

Focus on Evidence

In a randomized, controlled study by Roddey and colleagues,¹⁵⁰ two approaches to exercise instruction following arthroscopic repair of a full-thickness rotator cuff tear were compared, specifically in-person instruction by a therapist and video-based instruction. On the first postoperative day, both groups of patients (total 108) received one visit from the therapist for initial instruction in the postoperative program (sling use and passive shoulder exercises). Patients in both groups received written handouts about the home exercise program. In addition, patients in the video-instruction group received a video containing exercises for all phases of the rehabilitation program.

After discharge, patients in the video group saw the therapist four times (at 2, 6, 12, and 24 weeks) for evalua-

TABLE 17.4 Relationships of Type and Duration of Immobilization after Arthroscopic and Mini-Open Repair* to the Size of the Rotator Cuff Tear**

Size of Tear	Type and Duration of Immobilization
Small (≤ 1 cm)	Sling for 1–2 weeks; removal for exercise the day of surgery or 1 day postop
Medium to large (> 5 cm) [†]	Sling or abduction orthosis/pillow for 3–6 weeks; removal for exercise 1–2 days postop
Massive (> 5 cm) [†]	Sling or abduction orthosis/pillow for 4–8 weeks; removal for exercise 1–3 days postop

*Fully arthroscopic and mini-open (arthroscopically assisted//deltoid splitting) approaches.

**Age of the patient, onset of the injury, and quality of repaired tissue also influence the position and duration of immobilization.

[†]A fully arthroscopic approach is not often used to repair massive cuff tears.

tion and an okay to advance to the next phase of rehabilitation, but they received all exercise instruction by watching the video at home. Patients in the other group also saw the therapist four times at identical intervals after discharge for follow-up evaluations and one-to-one instructions from the therapist on how to perform the exercises during the next phase of the home program. Between visits both groups had telephone access to their therapist for questions, and at 52 weeks all patients were evaluated a final time.

Results of this study indicated that there were no significant differences between the two groups in compliance with the exercise program and functional outcomes measured with a self-report instrument. The authors concluded that video-based exercise instruction was equally effective

as therapist-directed exercise instruction. It is important to note that 30% of the patients dropped out of the study. The authors did not report whether these patients were progressing well or if any of them left the study to seek individualized or more frequent therapy.

Goals and interventions for each phase of rehabilitation after arthroscopic or mini-open cuff repair follow. General guidelines for exercise and precautions after rotator cuff repair are summarized in Box 17.9. Precautions specific to a particular type of cuff tear or surgical procedure are also noted. The suggested timelines for each phase are general and must be adjusted based on factors already noted (see Table 17.3).

BOX 17.9 General Exercise Guidelines and Precautions After Repair of a Full-Thickness Rotator Cuff Tear

Early Shoulder Motion

- Perform passive or assisted shoulder ROM within *safe and pain-free ranges* based on the surgeon's intraoperative observation of the mobility and strength of the repair and the patient's comfort level during exercise.
- Only passive and no assisted ROM for 6 to 8 weeks after repair of a massive cuff tear or after a traditional open approach to prevent avulsion of the repaired deltoid.
- Initially perform passive and assisted shoulder ROM in the supine position to maintain stability of the scapula on the thorax.
- Minimize anterior translation of the humeral head and the potential for impingement. See that the humerus is positioned slightly anterior to the frontal plane of the body and in slight abduction
 - While at rest in the supine position support the humerus on a folded towel.
 - When initiating passive or assisted shoulder rotation while lying supine, position the shoulder in slight flexion and approximately 45° of abduction.
 - When initiating assisted shoulder extension, perform the exercise in prone (arm over the edge of the bed) from 90° to just short of neutral. Later progress to exercises behind the back.
- When performing assisted or active exercises in the upright position (sitting or standing), be certain that the patient maintains an erect trunk posture to minimize the possibility of impingement.
- To ensure adequate humeral depression and avoid superior translation of the head of the humerus when beginning *active* elevation of the arm, restore strength in the rotator cuff, especially the supraspinatus and infraspinatus muscles, before dynamically strengthening the shoulder flexors and abductors.
- Do not allow *active* shoulder flexion or abduction until the patient can lift the arm without hiking the shoulder.

Strengthening Exercises

- When beginning isometric resistance to scapulothoracic musculature, be sure to support the operated arm to avoid excessive tension in repaired GH musculature.

- Use low exercise loads; resisted motions should not cause pain.
- No weight-bearing (closed chain) exercises or activities for 6 weeks.
- Delay dynamic strengthening (progressive resistive exercise, or PRE) for a *minimum* of 8 weeks postoperatively for small, strong repair and for at least 3 months for larger tears.
 - If the supraspinatus was repaired, proceed cautiously when resisting external rotation.
 - If the subscapularis was repaired, proceed cautiously with resisted internal rotation.
- After an open repair, postpone isometric resistance exercises to the repaired deltoid and cuff musculature for *at least* 6 to 8 weeks unless advised otherwise.

Stretching Exercises

- Avoid vigorous stretching, the use of contract-relax procedures or grade III joint mobilizations for at least 6 weeks and often for 12 weeks postoperatively to give time for the repaired tendon(s) to heal and become strong.
 - If the supraspinatus or infraspinatus was repaired, initially avoid end-range stretching into internal rotation.
 - If the subscapularis was repaired, initially avoid end-range stretching into external rotation.
 - If the deltoid was detached and repaired, initially avoid end-range shoulder extension, adduction, and horizontal adduction.

Activities of Daily Living

- Wait until about 6 weeks after a mini-open or arthroscopic repair and 12 weeks after a traditional open repair before using the operated arm for light functional activities.
- After repair of a large or massive cuff tear, avoid use of operated arm for functional activities that involve heavy resistance (pushing, pulling, lifting, carrying heavy loads) for 6 to 12 months postoperatively.

Exercise: Maximum Protection Phase

The priorities during the initial phase of rehabilitation are protection of the repaired tendon, which is at its weakest approximately 3 weeks after repair,¹⁷⁹ and prevention of the adverse effects of immobilization through early passive motion. In almost all instances, during the first few days after surgery the immobilization (sling or splint) is removed for brief sessions of passive or assisted ROM within limited (protected) and comfortable ranges (see Table 17.4).

The maximum protection phase extends for as little as 3 to 4 weeks after a fully arthroscopic or mini-open repair of small or medium tears or as long as 6 to 8 weeks after repair of large or massive tears. After a fully arthroscopic repair of a small or medium cuff tear, every effort is made to attain nearly full passive shoulder ROM, particularly elevation and external rotation, by 6 to 8 weeks postoperatively.^{56,111,190}

Goals and interventions. The following goals and selected interventions combined with the appropriate use of pain medication are initiated during the maximum protection phase.*

Control pain and inflammation.

- Periodic use of ice.
- Arm support for comfort.
- Cervical spine ROM and shoulder relaxation exercises.
- Grade I oscillations of the GH joint.

Prevent loss of mobility of peripheral joints.

- Assisted ROM of the elbow.
- Active ROM of the wrist and hand.

Prevent shoulder stiffness/restore shoulder mobility.

- Pendulum exercises typically the first postoperative day or when the immobilizer may be removed for exercise.
- Passive ROM of the shoulder within safe and pain-free ranges. Initially perform exercises in the supine position; begin with elevation of the arm and external rotation in the plane of the scapula.
- Self-assisted ROM using the opposite hand or a wand for control by 1 to 2 weeks for patients with repairs of small to medium tears and about 2 weeks later for patients with repairs of large tears.
- Active control of the shoulder with assistance as needed from therapist or family member. With the patient lying in the supine position, place the arm in 90° of shoulder flexion if pain-free. In this position the effect of gravity on the shoulder musculature is minimal. This position has been called the “balance point position” of the shoulder.⁵⁰ Help the patient control the shoulder while moving to and from the balance point position, making small arcs and circles with the arm.
- Active shoulder ROM by the latter part of this phase for small tears and as symptoms permit, initially supine with the elbow flexed, later in a semi-reclining position with the elbow less flexed.

*See references 8, 24, 37, 50, 52, 56, 71, 111, 190, 191.

PRECAUTION: Use only passive and no assisted ROM for 6 to 8 weeks for a repair of a massive cuff tear or after a traditional open repair with deltoid detachment.^{37,191}

Prevent or correct postural deviations.

- Posture training and exercises to prevent excessive thoracic kyphosis (see Chapters 14 and 16).

Develop control of scapulothoracic stabilizers.

- Active movements of the scapula.
- Submaximal isometrics to isolated scapular muscles.¹⁰³ See that the operated arm is supported but not bearing weight to avoid excessive tension in repaired GH musculature.
- Side-lying scapular protraction/retraction to emphasize control of the serratus anterior.

Prevent inhibition and atrophy of GH musculature.

- Low-intensity muscle-setting exercises (against minimal resistance). Setting exercises should not provoke pain in a healing cuff tendon. Begin as early as 1 to 3 weeks postoperatively depending on the size of the tear and quality of the repair.^{37,50,52}

PRECAUTION: Recommendations for the safest position of the shoulder in which to begin isometric training of the GH musculature after cuff repair are inconsistent in the literature. One suggestion is to start in a position that creates minimal tension on the repaired cuff tendons (shoulder internally rotated and flexed and abducted to about 45° and elbow flexed).⁵² Another option is to place the shoulder in 100° to 110° of flexion and 10° to 20° of horizontal abduction. In this position the deltoid creates a compression force on the head of the humerus into the glenoid fossa, thus diminishing the superior shear forces generated by the deltoid than when the arm is in less flexion. As the strength of the cuff muscles improves during the later phases of rehabilitation, isometric activities can be performed with the arm positioned in less shoulder flexion.

Exercise: Moderate Protection Phase

The focus of the second phase of rehabilitation is to begin to develop strength, endurance, and neuromuscular control of the shoulder while continuing to attain full or nearly full, pain-free shoulder motion. Emphasis is placed on developing control of the scapular stabilizers and rotator cuff muscles.

For a patient with a repair of a small or medium tear, this phase begins around 4 to 6 weeks postoperatively and extends an additional 6 weeks. For most patients, strengthening exercises typically begin around 8 weeks postoperatively. This phase may begin as late as 12 weeks for a patient with a repair of a large or massive tear.

Criteria for progression. Criteria to advance to this phase are a well healed incision, minimal pain with assisted shoulder motions, and progressive improvement in ROM. The extent of improvement at just 6 weeks or so after surgery is dependent on factors such as the type and quality of the repair, the size of the tear, and preoperative ROM.

Focus on Evidence

In a descriptive study by Ellenbecker and colleagues,⁵⁰ patients ($n = 37$) with full-thickness cuff tears (small, medium, and large) but no concomitant lesions who had undergone a mini-open repair underwent physical therapy that emphasized early mobilization of the operated shoulder a mean of 10 times by 6 weeks after surgery. Investigators measured passive shoulder ROM at 6 weeks and active ROM and dynamic strength of shoulder musculature at 12 weeks and compared these measurements to those of the noninvolved limb.

At 6 weeks, mean values for passive flexion, abduction, and external and internal rotation (in 90° of abduction) of the operated shoulder approached those of the noninvolved shoulder: 154°, 138°, 74°, and 39°, respectively, in the operated shoulder compared to 156°, 164°, 91°, and 48°, respectively, in the noninvolved shoulder. Preoperative ROM was not reported in this study, nor were subjects divided into subgroups based on the size of the tear. However, the authors suggested that knowledge of short-term, objective measures of ROM and strength can assist a therapist in the clinical decision-making process, such as when to place more or less emphasis on restoring ROM or strength during a rehabilitation program. The ROM results of this study also demonstrate the value of early postoperative mobilization and to what extent return of shoulder mobility is possible just 6 weeks after mini-open rotator cuff repair.

Goals and interventions. The following goals and interventions are appropriate during this phase of rehabilitation.^{8,24,37,50,52,56,111}

● Restore nearly complete or full, nonpainful, passive mobility of the shoulder.

- Self-assisted ROM with an end-range hold by means of wand or pulley exercises, in single plane and combined (diagonal) patterns. Add shoulder internal rotation, extension beyond neutral, and horizontal adduction.
- Mobilization of the incision site if well healed to prevent adherence of the scar.

PRECAUTION: The use of passive stretching and grade III joint mobilizations, if initiated during this phase of rehabilitation, must be done *very cautiously*. Vigorous stretching is not considered safe for about 3 to 4 months, that is, until after the repaired tendons have healed and have become reasonably strong.¹¹¹

● Increase strength and endurance and re-establish dynamic stability of the shoulder musculature.

- Active ROM of the shoulder continued or begun through gradually increasing but pain-free ranges. Continue to have the patient perform active elevation of the arm in the supine position until the motion can be initiated without first hiking the shoulder. When transitioning to an upright positions (sitting or

standing), reinforce the importance of maintaining an erect trunk during exercises.

- Isometric and dynamic strengthening to key scapulo-thoracic stabilizers. First use alternating isometrics in non-weight-bearing positions. Progress to rhythmic stabilization during light upper extremity weight-bearing activities.
- Submaximal multiple-angle isometrics of the rotator cuff and other GH musculature against gradually increasing resistance.
- Dynamic strengthening and endurance training of the GH musculature within pain-free ranges against light resistance, such as light-grade elastic tubing or a 1- to 2-lb weight. Perform exercises below the level of the shoulder if pain is provoked with active movements above the shoulder.
- Upper extremity ergometry at or just below shoulder level against light resistance to increase muscular endurance.
- Use of the involved upper extremity for *light* (no-load or low-load) functional activities.

NOTE: Because weakness and atrophy of the rotator cuff were probably present prior to injury, strengthen the cuff muscles before dynamically strengthening the shoulder abductors and flexors.

Exercise: Minimum Protection/Return to Function Phase

This final (advanced) phase usually begins no earlier than 12 to 16 weeks postoperatively for patients with strong repairs or at 16 weeks or later for a tenuous repair. This phase may continue until 6 months or more depending on the patient's expected functions during work-related or recreational activities.

If full ROM still has not been restored with assisted and active exercises, passive stretching of the GH musculature and joint mobilization (if not previously incorporated into the exercise program) is now initiated. Have the patient use the gained shoulder mobility in activities, such as gently swinging a golf club or tennis racket if the motions are pain-free. Advanced, task-specific strengthening activities dominate this phase of rehabilitation.

Patients generally are not allowed to return to high-demand activities for 6 months or possibly 1 year post-operatively depending on the patient's level of comfort, strength, and flexibility as well as the demands of the desired activities.

Criteria for progression. Criteria to transition to the final phase of rehabilitation and gradually return to unrestricted activities include full, pain-free passive ROM, progressive improvement of shoulder strength and muscular endurance, and a stable GH joint.

Goals and interventions. The goals and interventions during this final phase of rehabilitation are consistent with those previously discussed for late-stage nonoperative management of cuff disorders and for the final phase of rehabilitation after subacromial decompression. However,

the progression of activities is more gradual, and the time frame for adhering to precautions is more extended.

Outcomes

A considerable number of outcome studies of operative management of rotator cuff tears have been reported in the literature with follow-up ranging from less than 6 months to 5 years or more. Outcomes commonly measured, using a variety of instruments, are pain relief, shoulder ROM and strength, overall function, and patient satisfaction.

Comparable long-term outcomes have been reported after fully arthroscopic, mini-open (arthroscopically assisted), and traditional open repairs.⁷¹ For example, after fully arthroscopic repair of full-thickness tears (mostly small or medium but some large or massive tears), overall outcomes of several studies were reported as good to excellent in 84%^{59,60} and 92%¹⁷² of patients followed for 2 to 3 years. These results are comparable to results reported for open repairs.^{71,111} However, it has been shown that regardless of the type of operative repair performed the size of the cuff tear influences postoperative outcomes. For example, comparably favorable long-term functional outcomes and pain relief have been reported after mini-open and traditional open repairs of small to medium size, full-thickness tears (< 3 cm).^{9,71,111} Outcomes are less favorable after repairs of large or massive tears.^{111,191}

Other factors, such as the acuity or chronicity of the tear and the patient's age, also affect outcomes. Repairs of acute tears in young patients are more successful than repairs of similar-size tears associated with chronic cuff impingement and insufficiency in elderly patients (> 65 years).⁶⁷ The presence of fewer associated pathologies, such as a biceps tendon tear or cuff tear arthropathy, also are associated with better postoperative outcomes.¹¹¹

Pain relief. Although the results of individual studies vary, a systematic review of the literature indicated that an average of 85% of patients who had undergone operative repair of the rotator cuff (arthroscopic, mini-open, or open), report satisfactory relief of pain. Pain relief after arthroscopic and mini-open repairs ranges between 80% and 92%.¹⁵⁷ This is comparable to results of previous studies of traditional open repairs, in which satisfactory pain relief was reported by 85% to 95% of patients.^{70,77} The preoperative size of the tear has an impact on pain relief; specifically, patients with small and medium tears (≤ 3 cm) report a higher percentage of satisfaction with pain relief than patients with large or massive lesions.^{70,111,157}

Shoulder ROM. Restrictions in preoperative ROM have an influence on postoperative ROM. In a prospective descriptive study of patients undergoing rotator cuff repair, the preoperative factor that most closely correlated with long-term limitation of shoulder ROM after surgery was the inability to place the hand behind the back.¹⁸³ Postoperative shoulder ROM also is associated with the size of the tear. For example, the results of one study showed that patients who had repairs of small to medium

tears had more active flexion and abduction than patients with large tears.⁷⁷

As indicated in a study described earlier in this section of ROM measurements 6 and 12 weeks after mini-open repair of full-thickness cuff tears, passive ROM can approach near-normal (compared to the noninvolved shoulder) by 6 weeks postoperatively.⁵⁰

Strength. As with ROM, the rate of recovery of shoulder muscle strength also appears to be associated with the size of the tear; that is, faster recovery occurs with small and medium tears than with large or massive tears. However, unlike recovery of ROM, near-complete restoration of shoulder muscle strength occurs gradually and may take a year after repair of small and medium tears. Recovery of strength after repair of large or massive tears is inconsistent.^{111,157}

Although recovery of shoulder muscle strength occurs gradually throughout the first postoperative year, the most substantial gains are seen during the first 6 months.¹¹¹ In most cases, patients achieve 80% strength in the operated shoulder (compared to the noninvolved shoulder) by 6 months and 90% by 1 year.¹⁵²

Functional abilities. It has been suggested that long-term functional outcomes correlate with the size of the tear, type of repair, tissue quality, and the integrity of the repair.¹¹¹ For example, patients who have undergone a mini-open repair return to functional activities about a month earlier than those who have had an open repair.⁹ However, this outcome may be skewed by the fact that mini-open repairs are performed more often in younger patients with less severe tears.

Lastly, in a study of patients who presented with recurrence of a rotator cuff tear after repair, 80% of the patients had been reported to have good to excellent short-term functional outcomes, measured by objective criteria. This suggests that the evidence regarding whether there is a direct relationship between the integrity of the repair and the functional outcome is inconsistent.⁷⁰

SHOULDER DISLOCATIONS: NONOPERATIVE MANAGEMENT

With a dislocation there is complete separation of the articular surfaces of the glenohumeral joint caused by direct or indirect forces applied to the shoulder.¹³³ Instability (described in the section on painful shoulder syndromes) may be a predisposing factor to dislocation, especially with repetitive stressful overhead activities, as seen in some sports.⁷⁹

Related Pathologies and Mechanisms of Injury

Traumatic Anterior Shoulder Dislocation

Anterior dislocation most frequently occurs when there is a blow to the humerus while it is in a position of external rotation and abduction. Stability normally is provided by the subscapularis, GH ligament, and long head of the

biceps when in that position.^{96,151,184} Poor integrity of any of these structures can predispose the joint to dislocation, or a significant blow to the arm may damage them along with the attachment of the anterior capsule and glenoid labrum (Bankart lesion depicted in Fig. 17.19). When dislocated, the humeral head usually rests in the subcoracoid region, rarely in the subclavicular or intrathoracic region. Traumatic anterior dislocation is usually associated with complete rupture of the rotator cuff. There may also be a compression fracture at the posterolateral margin of the humeral head (Hill-Sachs lesion also depicted in Fig. 17.19). Neurological or vascular injuries may occur during dislocations.⁶⁸ The axillary nerve is most commonly injured, but the brachial plexus or one of the peripheral nerves could be stretched or compressed.

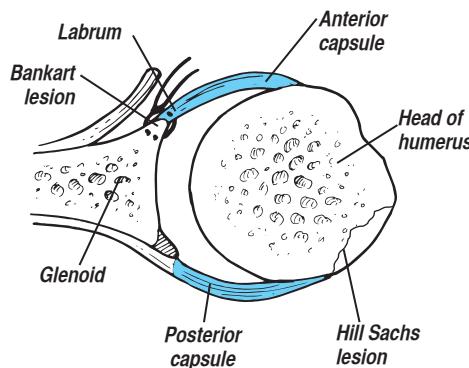

FIGURE 17.19 Lesions associated with traumatic anterior dislocation of the GH joint. A Bankart lesion is a fracture of the anterior rim of the glenoid with the attached labrum. The labrum is pulled away from the anterior glenoid along with a small piece of glenoid. A Hill-Sachs lesion is a compression fracture of the posterolateral humeral head, also may occur. (Adapted from Tovin, BJ, Greenfield, BH: Evaluation and Treatment of the Shoulder—An Integration of the Guide to Physical Therapist Practice. FA Davis, Philadelphia, 2001, p 295, with permission.)

Traumatic Posterior Shoulder Dislocation

Traumatic posterior shoulder dislocation is less common. Most posterior dislocations are subacromial, although subglenoid or subspinous posterior dislocations do occur. The mechanism of injury is usually a force applied to the humerus that combines flexion, adduction, and internal rotation, such as falling on an outstretched arm.¹⁶⁴ The person complains of symptoms when doing activities such as push-ups, a bench press, or follow-through on a golf swing.⁶⁸

Recurrent Dislocation

With significant ligamentous and capsular laxity, unidirectional or multidirectional recurrent subluxations or dislocations may occur with any movement that reproduces the abduction and external rotation forces or the flexion, adduction, and internal rotation forces, causing significant pain and functional limitation. Some individuals can voluntarily dislocate the shoulder anteriorly or posteriorly without apprehension and with minimal discomfort.^{133,164} The group in which the rate of recurrence after the first traumatic dislocation is highest is the younger population (< 30 years). Because they are more active and place

greater demands on the shoulder, longer immobilization (> 3 weeks) is advocated after dislocation than in the less than 30-year-old patient. Shorter immobilization (1 to 2 weeks) is advocated for older patients.^{110,112}

Common Impairments

- After an acute traumatic injury, symptoms resulting from tissue damage include pain and muscle guarding due to bleeding and inflammation.
- When a dislocation is associated with a complete rotator cuff tear, there is an inability to abduct the humerus against gravity, except the range provided by the scapulothoracic muscles.
- Asymmetrical joint restrictions/hypermobilities. With anterior instability, the posterior capsule may be tight; with posterior instability, the anterior capsule may be tight. After healing, there may be adhesions.
- With recurrent dislocations, the individual can dislocate the shoulder at will, or the shoulder may dislocate when doing specific activities. Instabilities, as described previously in this chapter, are present.

Common Functional Limitations/Disabilities

- With rotator cuff rupture, inability to reach or lift objects to the level of horizontal, thus interfering with all activities using humeral elevation
- Possibility of recurrence when replicating the dislocating action
- With anterior dislocation, restricted ability in sports activities, such as pitching, swimming, serving (tennis, volleyball), spiking (volleyball)
- Restricted ability, particularly when overhead or horizontal abduction movements are required while dressing, such as putting on a shirt or jacket, and with self-grooming, such as combing the back of the hair
- Discomfort or pain when sleeping on the involved side in some cases
- With posterior dislocation, restricted ability in sports activities, such as follow-through in pitching and golf; restricted ability in pushing activities, such as pushing open a heavy door or pushing one's self up out of a chair or out of a swimming pool

Closed Reduction of Anterior Dislocation

NOTE: Reduction manipulations should be undertaken only by someone specially trained in the maneuver because of the vulnerability of the brachial plexus and axillary blood vessels.

Management: Protection Phase

Protect the Healing Tissue

- Activity restriction is recommended for 6 to 8 weeks in a young patient. If a sling is used, the arm is removed from the sling only for controlled exercise. During the first week, the patient's arm may be continuously immobilized because of pain and muscle guarding.

- An older, less active patient (> 40 years of age) may require immobilization for only 2 weeks.
- The position of dislocation must be avoided when exercising, dressing, or doing other daily activities

Focus on Evidence

Traditionally, after acute anterior shoulder dislocation, immobilization (for various lengths of time) has been instituted. A clinical commentary that looked at outcomes from various studies found that the literature does not support use of a traditional sling for immobilizing the shoulder following primary anterior shoulder dislocation.⁷⁹ Still, it was noted that reports showed significantly better results (relative to redislocation) with activity restriction for 6 to 8 weeks in those < 30 years of age compared to activity restriction of less than 6 weeks.⁷⁹

The commentary also summarized two studies that looked at positioning (magnetic resonance imaging with 18 patients and a cadaveric study). The study results supported positioning the humerus in adduction and external rotation (rather than internal rotation) for better approximation between the detached glenoid labrum (Bankart lesion) and the glenoid neck.⁷⁹

Promote Tissue Health

Protected ROM, intermittent muscle setting of the rotator cuff, deltoid, and biceps brachii muscles, and grade II joint techniques (with the humerus at the side or in the resting position) are initiated as soon as the patient tolerates them.

PRECAUTIONS: In order not to disrupt healing of the capsule and other damaged tissues after anterior dislocation, ROM into external rotation is performed with the elbow at the patient's side, with the shoulder flexed in the sagittal plane, and with the shoulder in the resting position (in the plane of the scapula, abducted 55° and 30° to 45° anterior to the frontal plane) but not in the 90° abducted position. The forearm is moved from in front of the trunk (maximal internal rotation) to 0° or possibly 10° to 15° external rotation.

CONTRAINDICATION: Extension beyond 0° is contraindicated.

Management: Controlled Motion Phase

Provide Protection

The patient continues to protect the joint and avoid full return to unrestricted activity. If a sling is being used, the patient increases the time the sling is off. The sling is used when the shoulder is tired or if protection is needed.

Increase Shoulder Mobility

- Mobilization techniques are initiated using all appropriate glides except the anterior glide. The anterior glide

is *contraindicated* even though external rotation is necessary for functional elevation of the humerus. For a safe stretch to increase external rotation, the shoulder is placed in the resting position (abducted 55° and horizontally adducted 30°); it is then externally rotated to the limit of its range, after which a grade III distraction force is applied perpendicular to the treatment plane in the glenoid fossa (Fig. 17.20).

- The posterior joint structures are passively stretched with horizontal adduction self-stretching techniques.

FIGURE 17.20 Mobilizing to increase external rotation when an anterior glide is contraindicated. Place the shoulder in resting position, externally rotate it, then apply a grade III distraction force.

Increase Stability and Strength of Rotator Cuff and Scapular Muscles

Both the internal and external rotators need to be strengthened as healing occurs.²⁵ The internal rotators and adductors must be strong to support the anterior capsule. The external rotators must be strong to stabilize the humeral head against anterior translating forces and to participate in the deltoid-rotator cuff force couple when abducting and laterally rotating the humerus. Scapular stability is important for normal shoulder function and to maintain the scapula in normal alignment. The following exercises are initiated.

- *Isometric resistance* exercises with the joint positioned at the side and progressed to various pain-free positions within the available ranges.
- Partial weight-bearing and stabilization exercises.
- *Dynamic resistance*, limiting external rotation to 50° and avoiding the position of dislocation.
- At 3 weeks, supervised *isokinetic resistance* for internal rotation and adduction at speeds of 180° per second or higher.⁷
 - *Patient position and procedure:* Standing with the arm at the side or in slight flexion and elbow flexed 90°.

The patient performs internal rotation beginning at the zero position with the hand pointing anteriorly and moving across the front of the body. Progress to positioning the shoulder at 90° flexion; then perform the exercise from zero to full internal rotation. Do not position in 90° abduction.

- By 5 weeks, all shoulder motions are incorporated into exercises on isokinetic or other mechanical equipment except in the position of 90° abduction with external rotation.

Management: Return to Function Phase

Restore Functional Control

The following are emphasized.

- A balance in strength of all shoulder and scapular muscles.
- Coordination between scapular and arm motions.
- Endurance for each exercise as previously described for shoulder instabilities.

As stability improves, progress to:

- Eccentric training to maximum load
- Increasing speed and control
- Simulating desired functional patterns for activity.

Return to Maximum Function

- It is important that the patient learns to recognize signs of fatigue and impingement and stays within the tolerance of the tissues.
- The patient can return to normal activities when there is no muscle imbalance, when good coordination of skill is present, and when the apprehension test is negative. Full rehabilitation takes 2.5 to 4 months.⁷

Closed Reduction Posterior Dislocation

The management approach is the same as for anterior dislocation with the exception of avoiding the position of flexion with adduction and internal rotation during the acute and healing phases.

NOTE: During the *protection phase* a sling may be uncomfortable because of the adducted and internally rotated position, particularly if the sling elevates the humerus so the head translates in a superior and posterior direction. The patient may be more comfortable with the arm hanging freely in a dependent position while kept immobile.

When mobilization is allowed, begin joint mobilization techniques using all appropriate glides except the posterior glide. Posterior glide is *contraindicated*. If adhesions develop, preventing internal rotation, mobility can safely be regained by placing the shoulder in the resting position (abducted 55° and horizontally adducted 30°), internally rotating it to the limit of its range, and applying a grade III distraction force perpendicular to the treatment plane in the

glenoid fossa (same as in Fig. 17.20 but with the arm internally rotated).

SHOULDER INSTABILITIES: SURGERY AND POSTOPERATIVE MANAGEMENT

Surgical stabilization procedures are often necessary to repair chronic, recurrent instabilities and acute traumatic lesions in the glenohumeral, acromioclavicular, and sternoclavicular joints to restore function. Background information on GH joint instabilities and injuries that frequently occur with dislocations to this joint was described in the previous sections on nonoperative management.

Glenohumeral Joint Stabilization Procedures and Postoperative Management

If a reasonable trial of nonoperative management has not been successful in preventing recurrence of GH joint instability, surgical stabilization may be considered. Recurrent instability of traumatic origin responds more favorably to surgical management than atraumatic instabilities.^{14,110} Young, active patients who have sustained an acute, traumatic, anterior dislocation for the first time may elect to undergo surgery without a prior course of rehabilitation because there is a particularly high rate of redislocation in this group after nonoperative management.^{110,112}

Focus on Evidence

In a small, prospective, randomized study²¹ of young athletes who had sustained a first-time, acute, traumatic, anterior shoulder dislocation, one group of patients ($n = 14$) participated in a nonoperative rehabilitation program of immobilization and exercise and another group ($n = 10$) underwent arthroscopic stabilization (repair of a Bankart lesion) and postoperative rehabilitation (the same program as the nonoperative group followed). Over an average of 36 months, of the 12 nonoperatively managed patients who were available for follow-up 9 (75%) experienced recurrent instability, whereas of the 9 operatively managed patients available for follow-up only 1 (11.1%) experienced recurrent instability. Six of the nine nonoperatively treated patients who experienced recurrent instability subsequently had an open Bankart repair.

In another randomized study⁹⁴ of young patients (mean age 22 years) who sustained traumatic anterior dislocations, patients either participated in a trial of nonoperative management or underwent immediate arthroscopic stabilization. Over a 2-year period, 47% of the patients in the nonoperative group but only 15% of the surgical group experienced recurrence of the dislocation. The results of these studies demonstrate that in this population of patients, early surgical stabilization followed by postoperative rehabilitation significantly reduces the incidence of recurrent instability compared to nonoperative management.

Indications for Surgery

The following are common indications for surgical stabilization of the GH joint.^{110,112,175,190,193}

- Recurrent episodes of GH joint dislocation or subluxation that impair functional activities.
- Unidirectional or multidirectional instability during active shoulder movements that causes apprehension about placing the arm in positions of potential dislocation, leading to compromised use of the arm for functional activities.
- Instability-related impingement (secondary impingement syndrome) of the shoulder.
- Significant inherent joint laxity resulting in recurrent involuntary dislocation.
- High probability of subsequent episodes of redislocation after an acute traumatic dislocation in young patients involved in high-risk (overhead), work-related, or sport activities.
- Dislocations associated with significant cuff tears or displaced tuberosity or glenoid rim fractures.
- Irreducible (chronic, fixed) dislocation.
- Failure to resolve the instability and restore function with nonoperative management.

Procedures

Procedures designed to improve stability and prevent recurrent instability of the GH joint must balance stabilization of the joint with retention of near-normal, functional mobility. Stabilization procedures, which may involve the anterior, posterior, or inferior portions of the capsule, are performed today using either an arthroscopic or open approach depending on the type of lesion(s) present and type of procedure selected by the surgeon.^{110,112,142,175,190} Open stabilization procedures are highly successful (low recurrence of dislocation) and have been considered the standard for years. However, with advances in arthroscopic techniques and methods of tissue fixation, the use and success of arthroscopic stabilization procedures has steadily increased.¹⁹⁰

Recurrent anterior (unidirectional) dislocation is by far the most common form of GH instability managed with surgical stabilization.¹¹² In contrast, posterior or posteroinferior instabilities are less frequently managed with surgical stabilization.¹⁴² This section provides a brief description of surgical procedures for anterior and other types of GH instability. The procedures can be organized into several categories.

Bankart repair. A Bankart repair involves an open or arthroscopic repair of a Bankart lesion (detachment of the capsulolabral complex from the anterior rim of the glenoid) (see Fig. 17.19), which commonly accompanies a traumatic anterior dislocation. During the repair an anterior capsulolabral reconstruction is performed to reattach the labrum to the surface of the glenoid lip.[‡]

With an open repair, the humeral insertion of the subscapularis is detached (a takedown) or split longitudinally for access to the lesion and capsule,^{63,110,154,158} or occasionally access is achieved through the rotator cuff

interval, which allows the subscapularis to remain intact.¹¹⁰ If the subscapularis is detached, it is subsequently repaired after the labrum has been reattached. With an arthroscopic approach, multiple portal sites are used, and the subscapularis is not disturbed.^{5,190} Repair of a Bankart lesion is combined with an anterior capsular shift if capsular redundancy is present.

With an open procedure the labrum is reattached with direct transglenoid sutures or suture anchors, whereas with an arthroscopic approach transglenoid sutures, suture anchors, or tacks are used.^{79,190} Generally, more secure fixation is achieved with an open repair than with an arthroscopic repair, although in recent years advances in arthroscopic tissue fixation have improved.¹⁹⁰

Capsulorrhaphy (capsular shift). Capsulorrhaphy, which can be performed using either an open or arthroscopic approach, involves tightening the capsule to reduce capsular redundancy and overall capsule volume by incising, overlapping in a pants-and-vest manner (imbrication), and then securing the lax or overstretched portion of the capsule (plication) with direct sutures, suture anchors, tacks, or staples.* A capsular shift procedure is tailored to the direction(s) of instability: anterior, inferior, posterior, or multidirectional (anteroinferior or posteroinferior). For example, if a patient has recurrent anteroinferior (multidirectional) instability, an anterior or inferior capsular shift is performed in which the anterior or inferior portion of the capsule is incised, tightened by imbrication (plication), and resutured. Most capsular shift procedures are performed because of anterior instability.^{13,110,112,207}

Electrothermally assisted capsulorrhaphy. Electrothermally assisted capsulorrhaphy (ETAC) involves an arthroscopic approach that uses thermal energy (radiofrequency thermal delivery or nonablative laser) to shrink and tighten loose capsuloligamentous structures. The procedure—also referred to as a *thermal-assisted capsular shift* (TACS) or *thermocapsular shrinkage*—can be used alone but more often is used in conjunction with other arthroscopic procedures, such as repair of a glenoid tear, a capsular shift, débridement of a partial rotator cuff tear, or subacromial decompression.^{51,55,110,114,177,185,190,204} It has been shown in animal and human cadaveric studies that thermal energy initially makes collagen fibrils more extensible; but as the collagen tissue of the capsuloligamentous structures heals, it shortens or “shrinks” thus causing a decrease in capsular laxity.^{78,165} If one or more of the glenohumeral ligaments is detached or if rotator cuff lesions are detected that could be contributing to the instability, they are repaired arthroscopically prior to ETAC.

Soft tissue transfers. Open transfer and realignment of the subscapularis tendon (*Putti-Platt* or *Magnuson-Stack* procedures) to stabilize the anterior capsule is rarely done today. This is because they have resulted in poor func-

*See references 5, 79, 86, 93, 110, 154, 158, 190.

†See references 4, 65, 86, 110, 112, 142, 190, 207.

tional outcomes owing to significant loss of external rotation.^{110,112}

Bony procedures. Open transfer of the tip of the coracoid process to the anterior glenoid rim (with the short head of the biceps and the coracobrachialis still attached) to form a bony block (*Bristow procedure*) is of interest only from an historical perspective to understand how the management of recurrent anterior dislocation has evolved.^{110,112} As with procedures involving transfer of the subscapularis, the Bristow procedure also resulted in significant loss of external rotation.

Posterior capsulorrhaphy (posterior or posteroinferior capsular shift). Recurrent, involuntary posterior or posteroinferior instability (far less common than anterior instability), if treated surgically, can be managed with either an open or arthroscopic capsular shift to remove posterior and inferior redundancy of the capsule.[§] Additional soft tissue procedures may be necessary, such as repair of a posterior labral tear (reverse Bankart lesion) or in rare instances plication and advancement of the infraspinatus to reinforce the posterior capsule. Shoulders without an effective posterior glenoid can be surgically managed with capsulolabral augmentation¹⁹⁰ or occasionally with a glenoid osteotomy.^{110,142}

Employing arthroscopic posterior stabilization, a capsular shift and repair of the posterior labrum can be accomplished with the shoulder musculature remaining intact.¹⁴¹ For an open stabilization, a posterolateral incision is made, the deltoid is split, and the infraspinatus, teres minor, and posterior capsule are incised.^{142,176} In some instances of traumatic multidirectional instability, anterior capsulorrhaphy is used to tighten the posterior capsule indirectly.^{110,142,190}

Repair of a SLAP lesion. A tear of the superior labrum is classified as a SLAP lesion (superior labrum extending anterior to posterior).^{175,190,205} Some SLAP lesions are associated with a tear of the proximal attachment of the long head of the biceps and recurrent anterior instability of the GH joint. An arthroscopic repair involves débridement of the torn portion of the superior labrum, abrasion of the bony surface of the superior glenoid, and reattachment of the labrum and biceps tendon with tacks or suture anchors. Concomitant anterior stabilization is also performed if instability is present.

Summary. Glenohumeral stabilization procedures may be performed with an open or arthroscopic approach for correcting unidirectional or multidirectional instabilities. Associated procedures, such as a repair of the glenoid labrum or rotator cuff, may also be required.

Postoperative Management

General Considerations

As with rehabilitation after repair of rotator cuff tears, guidelines for postoperative management after surgical sta-

bilization of the GH joint are based on many factors. These factors, all of which can influence the composition and progression of a postoperative program, are summarized in Table 17.5. Additional factors, such as the philosophy and training of the surgeon and a number of patient-related variables (general health, medications, preinjury functional status and postoperative goals, education, compliance) that affect rehabilitation after GH stabilization and rotator cuff repair already have been addressed (see Table 17.3).

The content in this section identifies *general* principles of management across three broad phases of postoperative rehabilitation after a variety of surgical stabilization and reconstruction procedures for recurrent unidirectional or multidirectional instabilities of the GH joint. These general guidelines cannot begin to address the many variations of rehabilitation programs recommended for specific stabilization procedures. However, many detailed protocols or case-based descriptions of rehabilitation programs for use after specific procedures and for specific types of shoulder instabilities and associated labral or rotator cuff lesions in various patient populations are available in the literature.*

Regardless of the type of instability or associated pathology or the type of surgical stabilization procedure, a postoperative rehabilitation program must be based on the findings of a comprehensive examination and is individualized to meet the unique needs of each patient. The focus of postoperative rehabilitation always is to restore pain-free shoulder mobility and a level of strength and endurance of the shoulder musculature, particularly the dynamic stabilizers, to meet the patient's functional needs *while preventing recurrence of shoulder instability*.

Immobilization

Position. The position in which the patient's shoulder is immobilized after surgery is determined by the *direction(s)* of instability prior to surgery. After surgical reconstruction for recurrent *anterior* or *anteroinferior* instability, the shoulder is immobilized in a sling or splint in adduction (arm at the side) or varying degrees of abduction and in internal rotation (forearm across the abdomen) with the arm slightly anterior to the frontal plane of the body.^{86,110} After surgery for *posterior* or *posteroinferior* instability, the upper extremity is supported in an orthosis, and the shoulder is immobilized in the "handshake" position (neutral rotation to 10° to 20° of external rotation, 20° to 30° of abduction, elbow flexed, and arm at the side or sometimes with the shoulder in slight extension).^{54,110,142}

Duration. The duration of immobilization—that is, the period of time before use of the immobilizer is *completely* discontinued—is determined by many factors, including the type of instability and procedure(s) performed and the surgeon's intraoperative assessment. This period ranges from 1 to 3 weeks to as long as 6 to 8 weeks. However, the period of *continuous* immobilization of the operated

[§]See references 14, 76, 80, 110, 141, 142, 175, 176, 190.

TABLE 17.5 Factors that Influence the Rehabilitation Program After Surgery for Recurrent Instability of the GH Joint

Factors	Potential Impact on Rehabilitation
• Onset of instability	• Capsular redundancy and greater risk of recurrent dislocation more often associated with atraumatic instability, which requires more conservative postoperative rehabilitation than stabilization of recurrent instability of traumatic origin. ¹¹⁰
• Severity of associated lesions	• The more severe the underlying pathology, the slower the progression of rehabilitation.
• Previous failure of a surgical procedure	• Slower progression after previous failed stabilization procedure surgery.
• Direction of instability	• Stabilization of anterior instability: more rapid advancement than after stabilization of posterior or multidirectional instabilities. ¹⁴²
• Type of surgical approach	• Less postoperative pain with arthroscopic procedure but rate of progression essentially the same after open and arthroscopic stabilization or procedures because rate of healing of repaired tissues is the same in both procedures.
• Type of procedure	• Electrothermally assisted capsulorrhaphy: slower progression than arthroscopic or open capsular tightening without thermal application. ^{51,185,144} Bony reconstruction: slower progression than after soft tissue reconstruction.
• Patient variables	• The progression of postoperative rehabilitation is conservative for the inactive patient with multidirectional atraumatic instability who has generalized joint laxity and poor preoperative strength of the dynamic (muscular) stabilizers.
• Tissue integrity	
• Preoperative status of dynamic stabilizers	
• Generalized joint laxity	

shoulder (before pendulum exercises or shoulder ROM can be initiated) is kept as short as possible but varies with the type of procedure. For example, after an anterior stabilization procedure, the immobilizer may need to be worn continuously for only a day to a few days but in some cases up to 1 to 2 weeks.¹¹² In contrast, repairs of posterior or multidirectional instabilities, which are associated with a higher recurrence of dislocation, usually require a longer period of immobilization than do repairs employing an anterior stabilization procedure.^{110,142,176} After a posterior stabilization procedure, the shoulder may be continuously immobilized and ROM delayed for up to 6 weeks postoperatively.^{91,142}

Time frames for immobilization vary based on other factors that influence all aspects of postoperative rehabilitation (see Table 17.5). For example, the duration of immobilization is usually shorter for an elderly patient than for a young patient because the elderly patient is more likely to develop postoperative shoulder stiffness than the younger patient. In contrast, a patient with generalized hyperelasticity or a younger patient involved in high-demand activities, who is likely to place excessive stresses on healing tissues, requires a longer period of immobilization to reduce the risk of redislocation.¹¹⁰

Exercise

As with the position and duration of immobilization, the decisions of when the arm may be temporarily removed from the immobilizer (sling or splint) to begin shoulder exercises and to what extent specific shoulder motions

are either permissible or must be limited are also based on many of the factors previously summarized (see Table 17.5).

NOTE: During the early weeks of rehabilitation after a surgical stabilization procedure, determination of what ranges fall within "safe" limits of motion is based on the extent of intraoperative ROM that was possible without placing excessive tension on the repaired, tightened, or reconstructed tissues. This information may be available in the operative report or should be communicated by the surgeon to the therapist prior to initiating postoperative exercises.

The overall goal of postoperative exercise is to develop strength and stability as well as mobility of the shoulder consistent with functional needs while preventing recurrence of instability. A sufficient rotator cuff is a fundamental necessity for functional shoulder stability and mobility. Patient education and, when possible, supervised exercise instruction are the means by which the goals of each phase of rehabilitation are achieved.

Rehabilitation after anterior stabilization (anterior capsular shift or Bankart repair) is similar after open and arthroscopic procedures. In both instances, there are precautions that must be heeded, particularly during the first 6 weeks after surgery while soft tissues are healing. During this time period after an open procedure, the anterior capsule and the detached and repaired subscapularis must be protected from excessive stresses. With an arthroscopic anterior stabilization, although the subscapularis remains

intact, it is also necessary to protect the anterior capsule during the initial phase of rehabilitation because soft tissue fixation may not be as secure as the fixation used in an open procedure.

Focus on Evidence

In a 4-year follow-up study by Sachs and colleagues¹⁵⁸ of 30 patients who had sustained a traumatic anterior dislocation and had undergone an open Bankart repair (that included takedown and repair of the subscapularis tendon), only one factor measured postoperatively significantly correlated with the patients' perception of a successful outcome after surgery. That factor was the function of the subscapularis muscle postoperatively. Although only two patients (6.7%) reported recurrence of instability over the 4-year period, postoperative testing indicated that seven patients (23%) had incompetence of the subscapularis muscle. Specifically, the mean strength of the subscapularis in these patients was only 27%, whereas in the remaining patients, said to have a competently functioning subscapularis, the mean strength was 80% (both compared with the noninvolved shoulder). There was no significant loss of strength in other shoulder muscles in either group of patients.

Of the patients with a reasonably strong subscapularis at the 4-year follow-up, 91% reported good to excellent results determined by several measurement tools, and 100% indicated that in retrospect they would have the surgery again. However, among the patients with a substantially weak subscapularis, 57% reported good to excellent results but only 57% would undergo the surgery again. The investigators indicated that the results of their study suggested that the handling of the subscapularis tendon during the repair and protection of the subscapularis during the first few weeks after surgery were critical to shoulder function and then patients' perception of the success of an open Bankart repair. Although not noted by the investigators, emphasis on strengthening the internal rotators during the late phase of rehabilitation could also contribute to the success outcomes.

Precautions after arthroscopic or open anterior stabilization or reconstruction procedures are summarized in Box 17.10.^{37,63,79,91,110,112,128,190} Precautions for thermally assisted capsular tightening,^{51,55,144,185,204} posterior stabilization procedures,^{54,91,141,142} and repair of a SLAP lesion^{37,205} are noted in Box 17.11.

Exercise: Maximum Protection Phase

The initial phase of rehabilitation extends for about 6 weeks after surgery, during which time protection of the tightened capsule or repaired or reconstructed structures, such as the labrum or the subscapularis, is necessary while minimizing the negative consequences of immobilization. How soon after surgery the immobilizer may be temporarily removed for exercises varies significantly and depends on a number of factors already discussed. Exercises may be initiated as soon as the day after surgery for selected

BOX 17.10 Precautions After Anterior Glenohumeral Stabilization and/or Bankart Repair*

- Limit *ER, horizontal abduction, and extension* (shoulder positions that place stress on the anterior capsule) during first 6 weeks postoperatively.
- After an arthroscopic stabilization, although the subscapularis is intact, to avoid pull-out of fixation, limit ER to 5° to 10° with the arm in slight abduction or at the side for the first 2 weeks.³⁷ Then gradually progress to 45° over the next 2 to 4 weeks with the shoulder in greater abduction. With a tenuous stabilization, may need to limit ER to only neutral for the first 4 to 6 postoperative weeks.¹⁹⁰
- After an open procedure involving subscapularis take-down and repair, limit ER to 0° (no ER past neutral), to no more than 30° to 45° or to the "safe" limits identified during the intraoperative assessment for 4 to 6 weeks.³⁷
- Postpone ER combined with full shoulder abduction for at least 6 weeks.⁷⁹
- After an arthroscopic stabilization, progress forward flexion of the shoulder more cautiously than after an open stabilization.
- After bony procedures, delay passive or assisted ROM for 6 to 8 weeks to allow time for bone healing.^{110,112}
- No vigorous passive stretching to increase end-range ER for 8 to 12 weeks after either arthroscopic or open procedure except for patients with hypoelastic tissue quality.¹⁹⁰
- When stretching is permissible, avoid positioning the shoulder in abduction and external rotation during grade III joint mobilization procedures.
- After procedures with subscapularis detachment and repair, no *active or resisted IR* for 4 to 6 weeks; avoid lifting objects, especially if pushing the hands together is required.^{37,63,79,128}
- Avoid activities involving positions that place stress on the anterior aspect of the capsule for about 4 to 6 weeks.
 - Avoid functional activities that require ER, especially if combined with horizontal abduction during early rehabilitation as when reaching to put on a coat or shirt.
 - Avoid upper extremity weight bearing particularly if the shoulder is extended, as when pushing up from the armrests of a chair.
 - When dynamically strengthening the rotator cuff, maintain the shoulder in about 45° rather than 90° of abduction.

*Precautions apply primarily to early rehabilitation during the first 6 weeks after surgery except as noted. The allowable ROM during the initial phase of rehabilitation depends on the type of pathology, surgical procedure, the patient's tissue quality (degree of hyper- or hypoelasticity), and the intraoperative evaluation of shoulder stability.

patients who have had an anterior stabilization procedure,³⁷ but more often are begun 1 to 2 weeks postoperatively.^{91,128} ROM is delayed for a longer period of time after a thermally assisted stabilization,^{51,55,144,185,204} a posterior stabi-

BOX 17.11 Precautions After Additional Glenohumeral Stabilization Procedures
Thermally Assisted Capsular Tightening

- Be extremely cautious with ROM exercises for the first 4 to 6 weeks postoperatively because collagen in the thermally treated capsuloligamentous structures is initially more extensible (more vulnerable to stretch) until it heals. Some patients may begin ROM within protected ranges the day after surgery, whereas others may be required to postpone ROM exercises entirely for 2 weeks or more.
- While sleeping, complete immobilization (sling and swathe) for 2 weeks or more.
- Precautions for ROM depend on the direction of instability, patient's tissue quality (hyper- or hypoelastic), and the extent of concomitant surgical procedures necessary. For example, progress patients with congenital hyperelasticity more cautiously than those with hypoelasticity.

Posterior Stabilization Procedure and/or Reverse Bankart Repair

- Postpone all shoulder exercises or limit elevation of the arm to 90° and IR to neutral or no more than 15° to 20° and horizontal adduction to neutral (up to 6 weeks postoperatively).
- Restrict upper extremity weight bearing, particularly when the shoulder is flexed, to avoid stress to the posterior aspect of the capsule, for example during closed-chain scapulothoracic and GH stabilization exercises and functional activities, for at least 6 weeks postoperatively.
- Avoid resistance exercises that direct loads and place stress on the posterior capsule, such as bench press exercises and prone push-ups until late in the rehabilitation program, if at all.

Repair of a SLAP Lesion

- For SLAP lesions where the biceps tendon is detached, progress rehabilitation more cautiously than when the biceps remains intact.
- Limit passive or assisted elevation of arm to 60° for the first 2 weeks and to 90° at 3 to 4 weeks postoperatively.
- Perform only passive assisted humeral rotation with the shoulder in the plane of the scapula for the first 2 weeks (ER to only neutral or up to 15° and IR to 45°); during weeks 3 to 4, progress ER to 30° and IR to 60°.
- Avoid positions that create tension in the biceps, such as elbow extension with shoulder extension (as when reaching behind the back) during the first 4 to 6 weeks postoperatively.
- Postpone active contractions of the biceps (elbow flexion with supination of the forearm) for 6 weeks and resisted biceps exercises or lifting and carrying weighted objects until 8 to 12 weeks postoperatively depending on the extent and type of biceps repair; then progress cautiously.
- If the mechanism of injury was a fall onto the outstretched hand and arm causing joint compression, progress weight-bearing exercises gradually.
- If anterior instability is also present, follow precautions in Box 17.10.
- Avoid positions of abduction combined with maximum external rotation as this places torsion forces on the base of the biceps attachment on the glenoid.
- Perform latissimus dorsi strengthening (pull-down exercises) in front of the body rather than behind the head.

lization procedure,^{54,91,141,142} or repair of a SLAP lesion and torn biceps tendon^{37,205} (see Box 17.11).

Goals and interventions. The goals and exercises for the maximum protection phase are summarized in this section.^{37,51,54,79,128,203,211}

Control pain and inflammation.

- Use of a sling for comfort when the arm is dependent or for protection when in public areas. While seated, remove the sling (if permissible) and rest the forearm on a table or wide armrest with the shoulder positioned in abduction and neutral rotation. (This position provides support but prevents prolonged internal rotation and potential contracture of the subscapularis and other internal rotators of the shoulder.)
- Use of cryotherapy and prescribed anti-inflammatory medication.
- Active ROM of the cervical spine and shoulder relaxation exercises.

Prevent or correct posture impairments.

- Emphasis on spinal extension and scapular retraction; avoid excessive thoracic kyphosis.

Maintain mobility and control of structures proximal and distal to the shoulder.

- Active ROM of the elbow, forearm, wrist, and fingers the day after surgery.
- Active scapulothoracic movements.

PRECAUTION: Initially, strengthen the scapular stabilizing muscles in open-chain positions to avoid the need for weight bearing on the operated upper extremity. When weight-bearing activities are initiated, be cautious about the position of the operated shoulder to avoid undue stress to the vulnerable portion of the capsule for about 6 weeks postoperatively.

Restore shoulder mobility while protecting tightened or repaired tissues.

- Pendulum exercises (nonweighted), usually for the first 2 weeks postoperatively.
- Self-assisted ROM, wand exercises for the GH joint, initially *within protected ranges* as early as 2 weeks or as late as 6 weeks postoperatively. Begin shoulder elevation in the supine position to stabilize the scapula; begin humeral rotation with the arm supported and the shoulder in a slightly abducted and flexed position.

- With an anterior stabilization, gradually progress to near-complete ROM (compared to the unininvolved shoulder) by 6 to 8 weeks except for external rotation and extension and horizontal abduction past neutral. With a posterior stabilization, progress forward flexion, horizontal adduction, and internal rotation cautiously.
- Progression to active shoulder ROM when motion can be performed without pain, apprehension, or use of substitute motions, such as hiking the shoulder to initiate abduction.
- Use of the operated arm for *unresisted, non-weight-bearing, waist-level* functional activities by 2 to 4 weeks postoperatively.

● Prevent reflex inhibition and atrophy of GH musculature.

- Multiple-angle, low-intensity isometric (muscle-setting) exercises (very gentle isometrics) of GH musculature as early as the first week or by 3 to 4 weeks postoperatively after some procedures.
- Possible initiation of dynamic exercises against light resistance (light-grade elastic) below shoulder level at 4 to 6 weeks. Emphasize the GH stabilizers.
- Be particularly cautious when applying resistance to musculature that has been torn or surgically detached, incised, or advanced and then repaired.

NOTE: In some cases, dynamic exercises against light resistance are delayed until the intermediate phase of rehabilitation (about 6 to 8 weeks postoperatively), when only moderate protection is necessary.

Exercise: Moderate Protection Phase

The moderate protection phase of rehabilitation begins around 6 weeks postoperatively and continues until approximately 12 to 16 weeks. The focus is on always maintaining joint stability while achieving nearly full active (unassisted) ROM of the shoulder; continued development of neuromuscular control, strength, and endurance of scapulothoracic and GH musculature; and progressive use of the upper extremity through greater ROMs for functional activities.

Criteria for progression. Criteria to advance to the second phases of rehabilitation are a well healed incision, reasonable progress in ROM, minimal pain, and no sense of apprehension about instability with active motions.^{37,51,79,91}

Goals and interventions. The goals and interventions for the intermediate phase of rehabilitation are as follows.^{37,51,79,91,203,211}

● Regain nearly full, pain-free, active ROM of the shoulder.

- Continuation of active ROM with the goal of achieving nearly full ROM by 12 weeks.
- Gains in ROM used in functional activities.
- As stability permits, stretching and grade III mobilization in positions that do not provoke instability. After

an anterior stabilization procedure for chronic (atraumatic) anterior instability, pay particular attention to increasing horizontal adduction, as the posterior structures are often tight preoperatively and continue to be tight postoperatively.

● Continue to increase strength and endurance of shoulder musculature.

- Alternating isometrics against increasing resistance with emphasis on the scapula and rotator cuff musculature.
- Dynamic (concentric and eccentric) resistance exercises initiated or progressed using weights and elastic resistance with emphasis on scapulothoracic and gleno-humeral stabilizers. Begin in mid-range positions, progressing to end-range positions.
- After anterior stabilization, do not initiate dynamic strengthening of the internal rotators from full external rotation, particularly in the 90° abducted position. When strengthening the shoulder extensors, *do not extend the arm posterior to the frontal plane*. Accordingly, strengthen the shoulder extensors in the prone position with the arm over the side of the table or while standing and leaning forward with the hips flexed to approximately 90°. Use the same precaution when strengthening the horizontal abductors and adductors. In addition, maintain the shoulder in neutral rotation during horizontal abduction and adduction.
- After a posterior stabilization do not initially begin dynamic strengthening of the external rotators from full internal rotation.
- Dynamic strengthening in diagonal and simulated functional movement patterns.
- Upper extremity ergometry with a portable reciprocal exerciser on a table for muscular endurance. Include forward and backward motions.
- Progressive upper extremity weight bearing during strengthening and stabilization exercises.

Exercise: Minimum Protection/

Return To Function Phase

Criteria to progress to the final phase of rehabilitation and the focus of exercises are similar to the criteria already discussed for rehabilitation after rotator cuff repair. This phase usually begins around 12 weeks postoperatively or as late as 16 weeks, depending on individual characteristics of the patient and the surgical stabilization procedure. Stretching should continue until ROM consistent with functional needs has been attained. Gains in ROM are possible for up to 12 months as collagen tissue continues to remodel. Resistance exercises to improve strength and endurance are progressed to replicate movements involved in functional activities, including positions of provocation of instability. Plyometric training is introduced and gradually progressed, particularly in patients intending to return to high-demand sports or work-related activities. Participation in desired work-related and sports activities often takes up to 6 months postoperatively.

PRECAUTIONS: Some patients may have permanent restrictions placed on functional activities that involve high-risk movements and that could potentially cause recurrence of the instability. After some anterior stabilization procedures, full external rotation (ER) in 90° of abduction may not be advisable or possible.⁹¹

Outcomes

A successful postoperative outcome involves regaining the ability to participate in desired functional activities without a recurrence of instability of the GH joint. Follow-up studies measure subjective and objective outcomes, such as restoration of ROM and strength, recurrence of pain, apprehension of instability, ability to participate in desired activities, and general patient satisfaction. There is a wealth of follow-up studies describing various outcomes after stabilization procedures. However, most of the studies comparing the success of one surgical intervention with that of another are not randomized—understandably so because the surgeon's examination is the basis for determining which procedure is most appropriate and will most likely lead to successful results for each patient.

Although postoperative exercise (supervised or unsupervised) is consistently described as essential for optimal outcomes after stabilization surgery, no current, randomized studies were identified that compared the effectiveness of postoperative exercise programs after stabilization of the GH joint (method of instruction, content, rate of progression) for this review. As with surgical decisions, most postoperative rehabilitation programs are customized to meet each patient's needs, making comparison of outcomes difficult.

Results of surgery and postoperative rehabilitation are typically reported for specific pathologies, patient populations, and surgical stabilization procedures and are determined by means of a variety of outcome measures. Despite this, some generalizations can be made.

Recurrence of instability. As noted at the beginning of this section on stabilization procedures, recurrent instability of traumatic origin responds more favorably to surgical management than atraumatic instabilities.^{14,110} In addition, the rate of recurrence of instability is substantially higher in young patients (≤ 30 or ≤ 40 years of age) or patients who return to high-demand, work-related activities or competitive overhead sports than less active, older patients (> 30 or > 40 years of age).^{110,190}

The rates of redislocation after open and arthroscopic procedures have also been compared. Historically, recurrence rates after arthroscopic stabilization have been higher than after open stabilization.^{38,110} For example, in a review of studies on anterior stabilization procedures, the mean redislocation rate after open stabilization (Bankart lesion repair) was 11% (range 4% to 23%), but after arthroscopic stabilization recurrence rates were 18% (range 2% to 32%) with transglenoid suture fixation and 17% (range 0% to 30%) with tack fixation.⁷⁹ In another review of recent studies, the rates of recurrence of anterior instability after an arthroscopic Bankart repair ranged from 8% to 17%.¹⁹⁰ The decreasing redislocation rates

after arthroscopic procedures have been attributed to improvements in arthroscopic techniques. Today, arthroscopic stabilization has been shown, in many instances, to be equal to open stabilization for patients with unidirectional, anterior instability of the GH joint.^{38,190,194} However, for multidirectional instabilities, results of follow-up studies after arthroscopic stabilization, although promising, are not yet equal to outcomes after open stabilization.¹⁹⁰

Outcomes after stabilization procedures for anterior and posterior instabilities have also been compared. Surgical stabilization of a recurrent, unidirectional *anterior* instability has yielded more predictable results and lower rates of instability recurrence than stabilization of *posterior* or *multidirectional* instabilities.^{14,110,142,190,207} The average rate of posterior instability recurrence (after arthroscopic stabilization) has been reported to be particularly high. One source reported a 30% to 40% rate of redislocation,¹⁷⁶ and another reported rates as high as 50%.¹⁹⁰ In contrast, after anterior stabilization procedures mean recurrence rates have been reported at 11% and 17% to 18%, respectively, for open and arthroscopic procedures.⁷⁹

As the preoperative diagnosis has improved and the selection of appropriate candidates for surgery has gotten better, the recurrence of instability after posterior stabilization has decreased. In a study¹⁴¹ with a mean follow-up of 39.1 months, the rate of recurrence of instability after posterior stabilization (arthroscopic approach) was only 12.1% (4 of 33 patients with a mean age of 25 years and a history of involuntary or voluntary dislocation of the GH joint associated with acute traumatic and chronic repetitive microtrauma).

Shoulder ROM. Range of shoulder motion is another outcome often measured. Although it is possible to achieve full ROM postoperatively, after anterior stabilization procedures, full ER or horizontal abduction is sometimes not advisable or possible.⁹¹ Likewise, some posterior stabilization procedures permanently limit full internal rotation (IR) and, to some extent, overhead elevation of the arm.¹¹⁰

After open anterior stabilization and Bankart repair, which usually requires detachment and repair of the subscapularis, a mean loss of 12° of ER has been reported.⁶¹ It has been suggested that there is less loss of shoulder ER after arthroscopic procedures than after open procedures.⁷⁹ However, in a nonrandomized study that compared open and arthroscopic anterior stabilization procedures, both groups had some loss of ER (mean loss of 9° and 11°, respectively, in the arthroscopic and open groups), but these differences between groups were not significant.³⁸

After an open GH stabilization for instability due to repetitive microtrauma, postoperative loss of shoulder ER is the most common reason athletes involved in overhead sports are unable to successfully return to competition. Loss of shoulder rotation is reported to be less after arthroscopic stabilization procedures, thus enabling a greater percentage of these athletes to return to competi-

tion.¹⁴⁴ Early follow-up of patients who have undergone thermally assisted capsular stabilization is encouraging,⁵⁵ but long-term outcomes are just becoming available. To date, the largest study of overhead athletes who underwent thermally assisted stabilization followed 130 patients for a mean of 29.3 months. Of these athletes, 113 (87%) returned to competition in a mean of 8.4 months. Although postoperative ROM was not reported, the implication was that the return of ROM after thermally assisted arthroscopic stabilization was sufficient for a high percentage of athletes being able to return to competition.

Acromioclavicular and Sternoclavicular Joint Stabilization Procedures and Postoperative Management

Acromioclavicular Joint Stabilization

Grade III instability (separation), in which the acromioclavicular (AC) and coracoclavicular ligaments are completely ruptured and the clavicle is acutely or chronically dislocated in a superior direction on the acromion, may be surgically reduced and stabilized with a variety of techniques.¹²⁴ Techniques for management of acute dislocations include primary stabilization of the AC joint with Kirschner wires, Steinman pins, screws, or most recently bioabsorbable tacks, sutures, or fiber wires. A muscle-tendon transfer that includes the tip of the coracoid process and the attached tendons of the coracobrachialis and short head of the biceps to the undersurface of the clavicle,¹³¹ or use of the Weaver-Dunn procedure, which involves resecting the distal clavicle with coracoacromial (CA) ligament reconstruction (transferring the CA ligament from the acromion to the shaft of the distal clavicle) also can be performed.¹²⁴ Based on a small body of evidence in the literature, it appears the best results are achieved with primary AC and coracoclavicular stabilization procedures. Chronic AC dislocations, which are usually associated with degenerative changes of the AC joint, are most often managed with distal clavicle resection coupled with coracoclavicular stabilization.^{131,148}

Sternoclavicular Joint Stabilization

Although most sternoclavicular (SC) dislocations are managed nonoperatively, an acute posterior dislocation of the SC joint that cannot be successfully reduced with a closed maneuver or an SC joint that dislocates recurrently are managed surgically. Surgical reduction of a traumatic anterior dislocation is not recommended.¹⁴⁷ Surgical options for posterior SC dislocations include open reduction with repair of the stabilizing ligaments or resection of a portion of the medial clavicle and fixation of the remaining clavicle to the first rib or sternum with a soft tissue graft.^{147,208}

Postoperative Management

After surgical stabilization of either the AC or SC joint, the shoulder is immobilized in a sling or swathe for up to 6 weeks.⁴⁰ Exercise interventions are directed at functional recovery as the signs of healing allow. No specific muscles cross the AC and SC joints, so scapular and glenohumeral strength is developed to provide indirect control.

During the first few weeks of immobilization, the patient is encouraged to perform active ROM of the wrist and hand. If the elbow is supported on a table, the patient is permitted to perform active ROM of the elbow and forearm. The operated extremity, if supported, may be used for light functional activities, such as holding a utensil or typing, but weight bearing and shoulder ROM are completely prohibited during the first 6 weeks.⁴⁰

When the immobilization can be removed, restoration of shoulder and elbow mobility and neuromuscular control of the shoulder girdle are the focus of the exercise program to decrease the adverse effects of prolonged immobilization. Shoulder ROM (passive, progressing to assisted ROM to tolerance in the supine position to stabilize the scapula and minimize stress to the AC joint), active scapular motions, and light isometrics of the shoulder musculature are initiated. Stabilization exercises, dynamic strengthening of the shoulder and scapula musculature, and stretching to restore full ROM are gradually introduced and progressed, as graduated functional activities are integrated into the rehabilitation program.

EXERCISE INTERVENTIONS FOR THE SHOULDER GIRDLE

EXERCISE TECHNIQUES DURING ACUTE AND EARLY SUBACUTE STAGES OF TISSUE HEALING

During the *protection* and *early controlled motion* phases of management, when inflammation is present or just beginning to resolve and the healing tissues should not be stressed, early motion may be utilized to inhibit pain and muscle guarding and help prevent deleterious effects of complete immobilization. This section describes and summarizes techniques that may be used for these purposes. During the acute and early subacute stages, when motion in the shoulder itself is limited to allow tissues to begin to heal, it is also valuable to treat associated areas such as the cervical and thoracic spine, the scapulae, and the remainder of the upper extremity (elbow, wrist, and hand) to begin correcting faulty posture, relieve stresses to the shoulder girdle, and prevent fluid stasis in the extremity.

General guidelines for management during the acute stage are described in Chapter 10, and specific precautions for various pathologies and surgical interventions in the shoulder are identified throughout the second major section of this chapter. Early motion is usually passive ROM (PROM) and applied within pain-free ranges. When tolerated, active-assistive range of motion (A-AROM) is initiated.

Early Motion of the Glenohumeral Joint

Manual PROM and A-AROM techniques are described in detail in Chapter 3. This section expands on self-assisted exercises.

Wand Exercises

Patient position and procedure: Initiate A-AROM using a cane, wand, or T-bar in the supine position to provide stabilization and control of the scapula during the protection and early controlled motion phases. Motions usually included are flexion, abduction, flexion in the plane of the scapula (scaption), and rotation (Fig. 17.21A).

- If it is necessary to relieve stress on the anterior capsule, such as following surgical repair of the capsule or labrum, place a folded towel under the humerus to position the humerus anterior to the midline of the body when the patient performs internal or external rotation (Fig. 17.21B).
- When treating a shoulder impingement (primary or secondary), have the patient grasp the wand with the forearm supinated when flexing and abducting to emphasize external rotation.

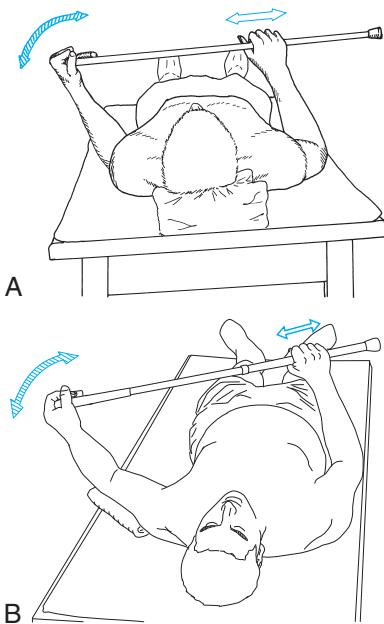

FIGURE 17.21 Self-assisted shoulder rotation using a cane (A) with the arm at the side and (B) in scaption. To relieve stress on the anterior capsule, elevate the distal humerus with a folded towel.

Ball Rolling or Table Top Dusting

Patient position and procedure: Sitting with the arm resting on a table and hand placed on a 6- to 8-inch ball or towel and the shoulder in the plane of the scapula. Have the patient initiate gentle circular motions of the shoulder by moving the trunk forward, backward, and to the side, allowing the hand to roll the ball or “dust the table.” As pain subsides, have the patient use the shoulder muscles to actively move the ball or cloth through greater ROMs.

Wall (Window) Washing

Patient position and procedure: Standing with hand placed against a wall supporting a towel or a ball. Instruct the

patient to perform clockwise and counterclockwise circular motions with the hand moving the towel or rolling the ball. Progress this activity by having the patient reach upward and outward as far as tolerated without causing symptoms.

Pendulum (Codman's) Exercises

Patient position and procedure: Standing, with the trunk flexed at the hips about 90°. The arm hangs loosely downward in a position between 60° and 90° flexion or scaption (Fig. 17.22).

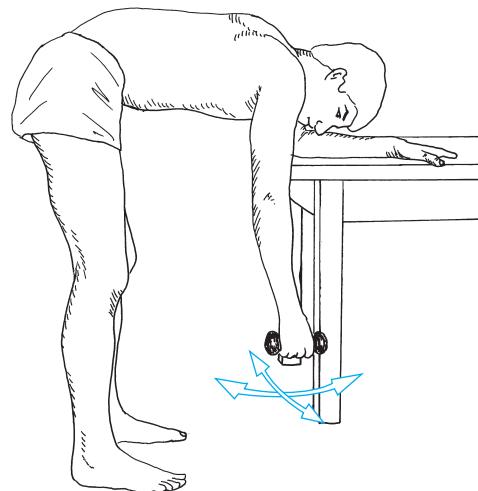

FIGURE 17.22 Pendulum exercises. For gentle distraction, no weight is used. Use of a weight causes a grade III (stretching) distraction force.

- A pendulum or swinging motion of the arm is initiated by having the patient move the trunk slightly back and forth. Motions of flexion, extension, and horizontal abduction, adduction, and circumduction can be done.³⁴ Increase the arc of motion as tolerated. This technique should not cause pain.
- If the patient cannot maintain balance while leaning over, have the patient hold on to a solid structure or lie prone on a table.
- If the patient experiences back pain from bending over, use the prone position.
- Adding a weight to the hand or using wrist cuffs causes a greater distraction force on the GH joint. Weights should be used only when joint stretching maneuvers are indicated late in the subacute and chronic stages—and then only if the scapula is stabilized by the therapist or a belt is placed around the thorax and scapula so the stretch force is directed to the joint, not the soft tissue of the scapulothoracic region.

PRECAUTIONS: If a patient gets dizzy when standing upright after being bent over, have the patient sit and rest. With increased pain or decreased ROM, the technique may be an inappropriate choice. Pendulum exercises are also inappropriate for a patient with peripheral edema.

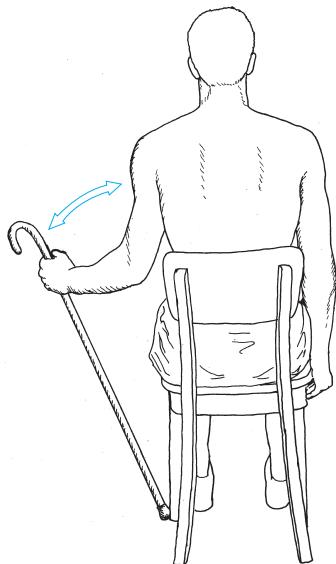

FIGURE 17.23 Gear shift exercise. Self-assisted shoulder rotation using a cane. Flexion/extension and diagonal patterns can also be done.

"Gear Shift" Exercises

Patient position and procedure: Sitting with the involved arm at the side, holding a cane or wand with the tip resting on the floor to support the weight of the arm. Instruct the patient to move the pole forward and back, diagonally, or laterally and medially in a motion similar to shifting gears in a car with a floor shift (Fig. 17.23).

Early Motion of the Scapula

PROM and A-AROM of the scapula are described in Chapter 3. During the acute phase, the side-lying position is usually more comfortable than prone-lying. If the patient can perform active scapular elevation/depression and protraction/retraction, use the sitting position.

Early Neuromuscular Control

Frequently, the muscles of the rotator cuff are inhibited after trauma or surgery.¹⁹⁸ Initiate the following to stimulate activation and develop control in key muscles as soon as the patient tolerates it.

Multiple-Angle Muscle Setting

Begin gentle multiple-angle muscle-setting exercises of the internal and external rotators in pain-free positions of humeral flexion or scaption. Activate the scapular and remaining GH muscles with gentle muscle-setting techniques in positions that do not exacerbate symptoms.

Closed-Chain or Protected Weight Bearing

Have the patient lean onto his or her hands or elbows and gently move from side to side. This helps to seat the humeral head in the glenoid fossa and stimulate muscle action.

EXERCISE TECHNIQUES TO INCREASE FLEXIBILITY AND RANGE OF MOTION

To regain neuromuscular control and function in the shoulder girdle, it may be necessary to increase flexibility in restricted muscles and fascia so proper shoulder girdle alignment and functional ranges are possible. The principles of muscle inhibition and passive stretching are presented in Chapter 4. Techniques to stretch tight joints in the shoulder girdle were discussed earlier in this chapter with reference to Chapter 5 (joint mobilization procedures). Specific manual and self-stretching techniques are described in this section.

Focus on Evidence

In a recent randomized study of 20 subjects with impaired GH joint mobility, the experimental group underwent an intervention of soft tissue mobilization of the subscapularis, followed by contract-relax against manual resistance to the internal rotators, and then actively moved their extremity through the D₂ PNF pattern (flexion, abduction, and external rotation). The control group received no treatment; they rested for 10 minutes. Those who underwent the interventions had an immediate post-treatment increase in external rotation of $16.4^\circ \pm 5.5^\circ$ compared with $0.9^\circ \pm 1.5^\circ$ in the control group ($p < 0.0005$) and an increase in overhead reach of 9.6 ± 6.2 cm compared with 2.4 ± 4.5 cm in the control group ($p = 0.009$).⁶²

It is worth noting the immediate positive results in this study; but because long-term results were not determined, it is important to reinforce the need for follow-up self-stretching and ROM exercises in the patient's home exercise program.

Self-Stretching Techniques

Teach the patient a low-intensity, prolonged stretch. Emphasize the importance of not bouncing at the end of the range.

To Increase Horizontal Flexion/Adduction—Cross-Chest Stretch

Patient position and procedure: Sitting or standing. Teach the patient to adduct the tight shoulder horizontally by placing the arm across the chest and then apply sustained overpressure to the adducted arm by pulling the arm toward the chest, being careful not to rotate the trunk (Fig. 17.24).

NOTE: This stretch is used when treating impingement syndromes to increase mobility in the structures of the posterior GH joint.

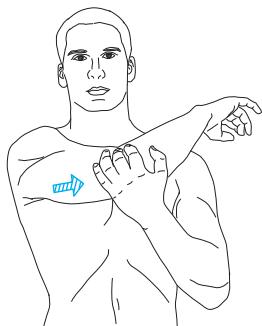

FIGURE 17.24 Self-stretching to increase horizontal adduction.

To Increase Flexion and Elevation of the Arm

Patient position and procedure: Sitting with the involved side next to the table, forearm resting along the table edge, and elbow slightly flexed (Fig. 17.25A). Have the patient slide the forearm forward along the table while bending from the waist. Eventually the head should be level with the shoulder (Fig. 17.25B).

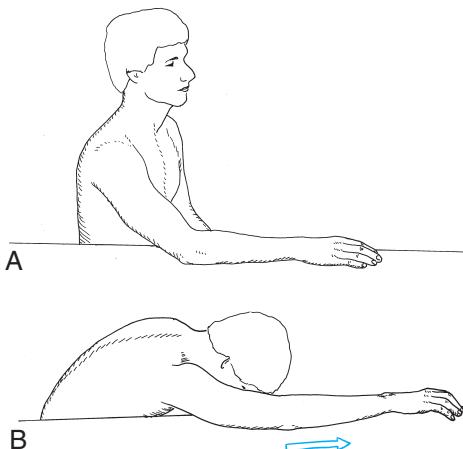

FIGURE 17.25 (A) Beginning and (B) end positions for self-stretching to increase shoulder flexion with elevation.

To Increase External (Lateral) Rotation

- *Patient position and procedure:* Standing and facing a doorframe with the palm of the hand against the edge of the frame and elbow flexed 90°. While keeping the arm against the side or in slight abduction (held in abduction with a folded towel or small pillow under the axilla), have the patient turn his or her trunk toward the fixed hand (Fig. 17.26A).
- *Patient position and procedure:* Sitting at the side of a table with the forearm resting on the table and elbow flexed to 90°. Have the patient bend from the waist, bringing the head and shoulder level with the table (Fig. 17.26B).

PRECAUTION: Avoid the stretch position (illustrated in Figure 17.26B) if there is anterior GH instability.

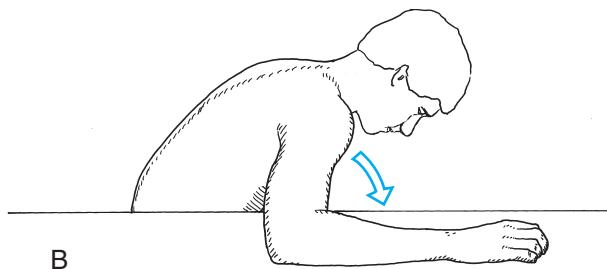

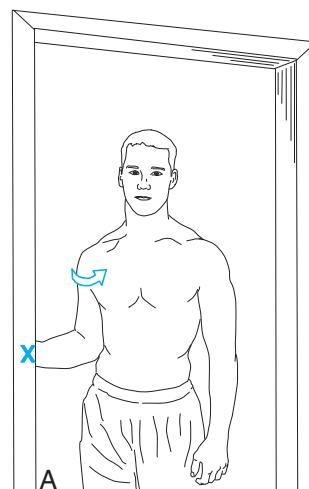

FIGURE 17.26 Self-stretching to increase lateral rotation of the shoulder (A) with the arm at the side using a doorframe and (B) with the arm in scaption using a table to stabilize the forearm.

To Increase Internal Rotation

- *Patient position and procedure:* Standing facing a doorframe with the elbow flexed to 90° and the back of the hand against the frame. Have the patient turn his or her trunk toward the fixed hand.
- *Patient position and procedure:* Side-lying on the affected side, with the shoulder and elbow each flexed to 90° and arm internally rotated to end position. Have the patient then push the forearm toward the table with the opposite hand (Fig. 17.27).

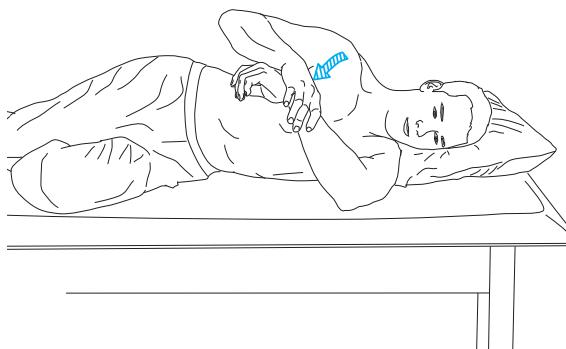

FIGURE 17.27 Self-stretching to increase internal rotation of the shoulder using a table to stabilize the humerus.

To Increase Abduction and Elevation of the Arm

- Patient position and procedure:** Sitting with the side next to a table, the forearm resting with palm up (supinated) on the table and pointing toward the opposite side of the table (Fig. 17.28A). Have the patient slide his or her arm across the table as the head is brought down toward the arm and the thorax moves away from the table (Fig. 17.28B).
- Patient position and procedure:** Same as above with a folded towel or belt placed across the proximal humerus and held in the opposite hand. Have the patient pull downward on the towel to cause a caudal slide of the humeral head when in the end-range stretch position of abduction.

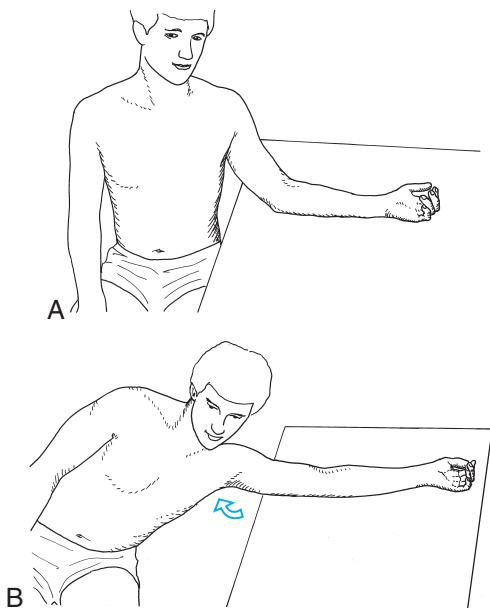

FIGURE 17.28 (A) Beginning and (B) end positions for self-stretching to increase shoulder abduction with elevation.

To Increase Extension of the Arm

Patient position and procedure: Standing with the back to the table, both hands grasping the edge with the fingers facing forward (Fig. 17.29A). Have the patient begin to squat while letting the elbows flex (Fig. 17.29B).

PRECAUTION: If a patient is prone to anterior subluxation or dislocation, this stretching technique should not be done.

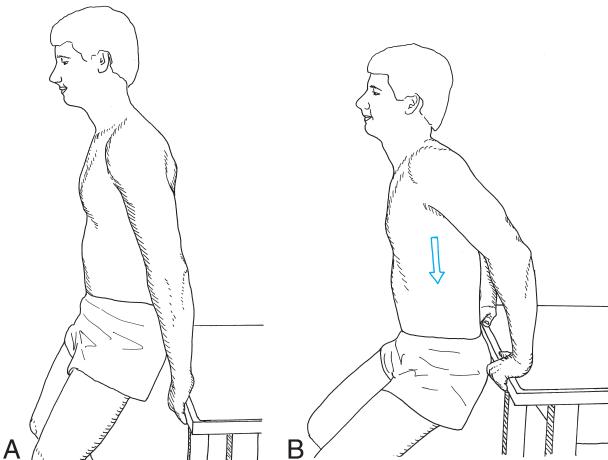

FIGURE 17.29 (A) Beginning and (B) end positions for self-stretching to increase shoulder extension.

To Increase Internal Rotation, Extension, and Scapular Tipping (Towel or Wand Stretch)

Patient position and procedure: Sitting or standing. Instruct the patient to hold each end of a towel (or wand) with one arm overhead and the arm to be stretched behind the lower back, and then pull up on the towel with the overhead hand (see Fig. 17.13). This stretch is used to increase the ability to reach behind the back. It is a generalized stretch that does not isolate specific tight tissues. Before using it, each component of the motion should be stretched so no one component becomes the “weak link” in the chain.

PRECAUTION: If a patient has anterior or multidirectional GH joint instability or has had recent anterior stabilization surgery to correct a dislocated shoulder, this exercise should not be done until late in the rehabilitation program, when the capsule is well healed, because it forces the head of the humerus against the anterior capsule.

Manual and Self-Stretching Exercises for Specific Muscles

Manual stretching of specific multijoint muscles that affect alignment of the shoulder girdle are presented in this section along with self-stretching techniques for these muscles.

To Stretch the Latissimus Dorsi Muscle

Manual Stretch

Patient position and procedure: Supine, with hips and knees flexed so the pelvis is stabilized in a posterior pelvic tilt. Provide additional stabilization to the pelvis with one hand,

if necessary. With the other hand grasp the distal humerus and flex, laterally rotate, and partially abduct the shoulder to the end of the available range. Instruct the patient to contract into extension, adduction, and medial rotation while providing resistance for a hold-relax maneuver. During the relaxation phase, elongate the muscle (see Fig. 4.16B).

Self-Stretch

- **Patient position and procedure:** Hook-lying with the pelvis stabilized in a posterior pelvic tilt and the arms flexed, laterally rotated, and slightly abducted overhead as far as possible (thumbs pointing toward floor). Allow gravity to provide the stretch force. Instruct the patient to not allow the back to arch.
- **Patient position and procedure:** Standing with back to a wall and feet forward enough to allow the hips and knees to partially flex and flatten the low back against the wall, with the arms in a “hold-up” position (abducted 90° and laterally rotated 90° if possible). Tell the patient to slide the back of the hands up the wall as far as possible without allowing the back to arch.

NOTE: This exercise is also used to strengthen the lower trapezius and serratus anterior as they upwardly rotate and depress the scapulae during humeral abduction.

To Stretch the Pectoralis Major Muscles

Manual Stretch

Patient position and procedure: Sitting on a treatment table or mat, with the hands behind the head. Kneel behind the patient and grasp the patient's elbows (Fig. 17.30). Have the patient breathe in as he or she brings the elbows out to the side (horizontal abduction and scapular adduction). Hold the elbows at this end-point as the patient breathes out. No forceful stretch is needed against the elbows, because the rib cage is elongating the proximal attachment

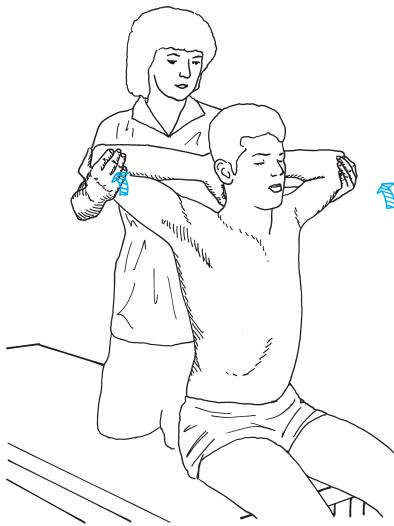

FIGURE 17.30 Active stretching of the pectoralis major muscle. The therapist gently pulls the elbows posteriorly while the patient breathes in and then holds the elbows at the end-point as the patient breathes out.

of the pectoralis major muscles bilaterally. As the patient repeats the inhalation, again move the elbows up and out to the end of the available range and hold as the patient breathes out. Repeat only three times in succession to avoid hyperventilation.

NOTE: Hyperventilation should not occur because the breathing is slow and comfortable. If the patient does become dizzy, allow time to rest; then reinstruct for proper technique. Be sure the patient maintains the head and neck in the neutral position, not forward.

Self-Stretch

- **Patient position and procedure:** Standing, facing a corner or open door, with the arms in a reverse T or a V against the wall (Fig. 17.31). Have the patient lean the entire body forward from the ankles (knees slightly flexed).

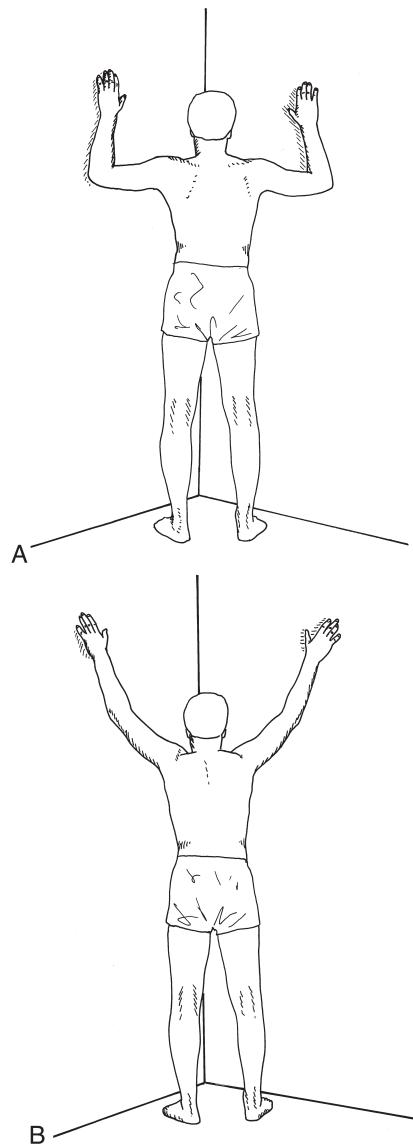

FIGURE 17.31 Self-stretching the pectoralis major muscle with the arms in a reverse T to stretch (A) the clavicular portion and in a V to stretch (B) the sternal portion.

The degree of stretch can be adjusted by the amount of forward movement.

- **Patient position and procedure:** Sitting or standing and grasping the wand with the forearms pronated and elbows flexed 90°. Have the patient then elevate the shoulders and bring the wand behind the head and shoulders (Fig. 17.32). The scapulae are adducted, and the elbows are brought out to the side. Combine with breathing by having the patient inhale as he or she brings the wand into position behind the shoulders; then exhale while holding this stretched position.

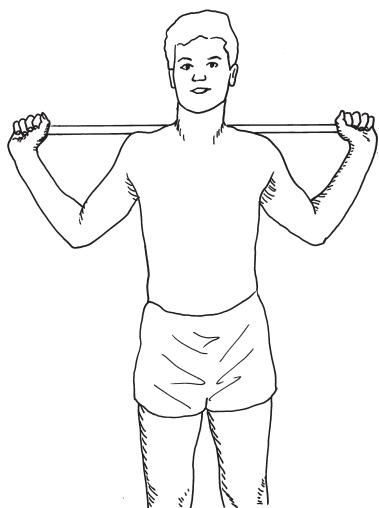

FIGURE 17.32 Wand exercises to stretch the pectoralis major muscle.

To Stretch the Pectoralis Minor Muscle

Patient position and procedure: Sitting, place one hand posterior on the scapula and the other hand anterior on the shoulder just above the coracoid process (Fig. 17.33).

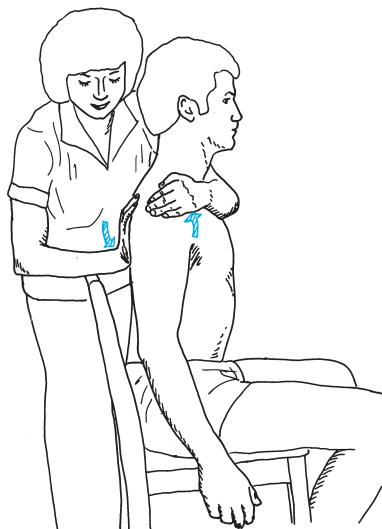

FIGURE 17.33 Active stretching of the pectoralis minor muscle. The therapist holds the scapular and coracoid process at the end-point as the patient breathes out.

As the patient breathes in, tip the scapula posteriorly by pressing up and back against the coracoid process while pressing downward against the inferior angle of the scapula; then hold it at the end-position while the patient breathes out. Repeat, readjusting the end-position with each inhalation and stabilizing as the patient exhales.

To Stretch the Levator Scapulae Muscle

NOTE: The levator scapulae muscle attaches to the superior angle of the scapula and causes it to rotate downward and elevate; it also attaches to the transverse processes of the upper cervical vertebrae and causes them to backward bend and rotate to the ipsilateral side. To minimize stress to the cervical spine, it is recommended that the cervical spine and head be placed at end range and stabilized and that the stretch force be applied against the scapula.

Manual Stretch

Patient position and procedure: Sitting with the head rotated opposite to side of tightness (looking away from the tight side) and forward bent until a slight pull is felt in the posterolateral aspect of the neck (in the levator muscle). The arm on the side of tightness is abducted, and the hand is placed behind the head to help stabilize it in the rotated position. Stand behind the patient and stabilize with one arm; place the other hand (same side as the tight muscle) over the superior angle of the scapula (Fig. 17.34). With the muscle now in its stretched position, have the patient breathe in, then out. Hold the shoulder and scapula down to maintain the stretch as the patient breathes in again (he or she contracts the muscle against the resistance of the fixating hand). To increase the stretch, press down against the superior angle of the scapula. This is not a forceful stretch but a gentle hold-relax maneuver. Do not stretch the muscle by forcing rotation on the head and neck.

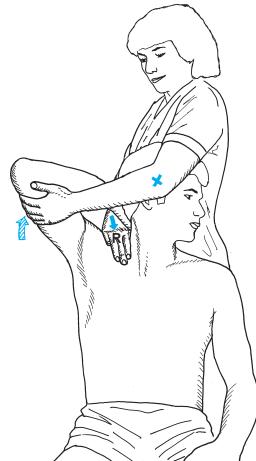

FIGURE 17.34 Stretching of the levator scapulae muscle. The therapist stabilizes the head and scapula as the patient breathes in, contracting the muscle against the resistance. As the patient relaxes, the rib cage and scapula depress, which stretches the muscle.

Self-Stretch

- Patient position and procedure:** Standing with the head side bent and rotated away from the tight side and bent elbow against a wall. The other hand can be placed across the forehead to stabilize the rotated head. Instruct the patient to slide the elbow up the wall as he or she takes in a breath, then hold the position while exhaling (Fig. 17.35A).
- Patient position and procedure:** Sitting with head side bent and rotated away from the tight side. To stabilize the scapula, have the patient reach down and back with the hand on the side of the tightness and hold onto the seat of the chair. The other hand is placed on the head to gently pull it forward and to the side in an oblique direction opposite the line of pull of the tight muscle (Fig. 17.35B).

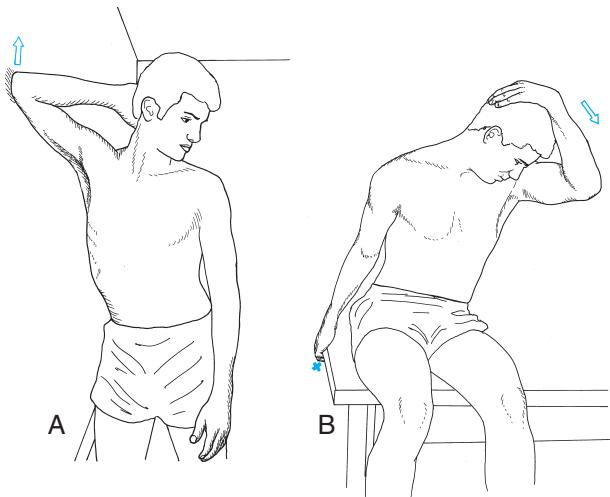

FIGURE 17.35 Self-stretching the levator scapulae muscle (A) using upward rotation of the scapula and (B) using depression of the scapula.

EXERCISES TO DEVELOP AND IMPROVE MUSCLE PERFORMANCE AND FUNCTIONAL CONTROL

Developing control of the scapula and GH joint musculature is fundamental to correcting pathomechanics of the shoulder girdle and for improving strength, muscle endurance, power, and performance of functional activities. During observation of scapular alignment and movement, if excessive tipping, winging, or poorly coordinated scapu-

lohumeral rhythm during humeral elevation is identified, it is important to correct these faulty mechanics with properly chosen exercises. Insufficient stabilization and control of GH rotation and translation during humeral elevation likewise necessitate the selection of exercises that emphasize training the rotator cuff musculature. When designing an exercise program, the intensity and type of exercises must not exceed the capability of the healing tissues whether the cause of the impaired control is nerve injury, disuse, traumatic insult, overuse, instability, or surgery.

The exercises described in the following sections begin at the most simple or least stressful level and progress to more difficult levels for each type of exercise. They also progress from uniplanar or isolated muscle activity to more complex and functional patterns. Initially, choose exercises that help the patient focus on using correct muscles to counteract the identified impairments; then increase the challenge by emphasizing patterns of exercises that prepare the musculature to respond to functional demands.

No matter what the level of exercise, it is important to challenge patients at intensities they can meet so they can safely progress to more intense levels. Before teaching the resistance exercises and functional training activities presented in this section, it is important that the reader understands and knows how to apply the principles of resistance exercise and open- and closed-chain training described in Chapter 6. It is also important to know the principles of tissue healing described in Chapter 10 and the precautions for various shoulder pathologies and surgical interventions presented in this chapter. Because posture has a direct effect on the function of the shoulder girdle, refer to Chapters 14 and 16 for principles and exercises to correct postural impairments that might underlie faulty shoulder girdle mechanics. Box 17.12 summarizes a method of progressing an individual toward functional recovery.

Isometric Exercises

Isometric exercises are applied along a continuum of very gentle to maximum contraction, and they are applied at varying muscle lengths and joint angles. Choice of the intensity, muscle length, or joint angle and the number of repetitions is based on strength, stage of recovery after injury or surgery, and/or the pathomechanics of the region.

Scapular Muscles

Patient position and procedure: Side-lying, prone-lying, or sitting, with the arm supported if necessary. Resist elevation, depression, protraction, or retraction with pressure

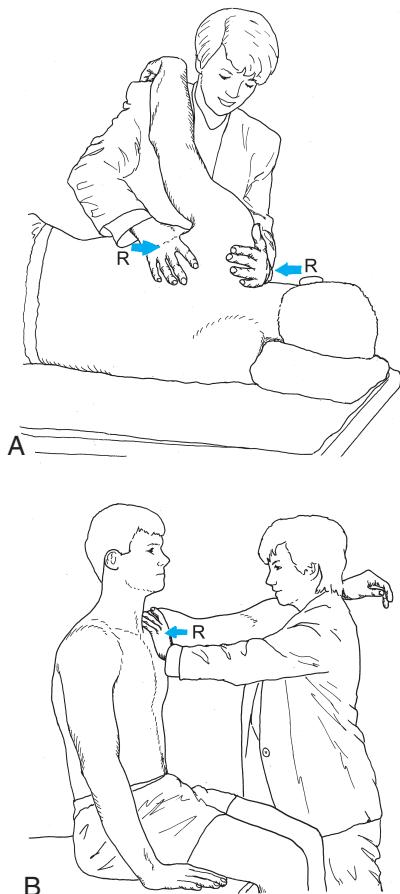

FIGURE 17.36 Isometric or dynamic manual resistance to scapular muscles. (A) Resistance to elevation/depression. (B) Resistance to protraction/retraction. Direct the patient to reach across the therapist's shoulder to protract the scapula while the therapist resists against the coracoid and acromion process. The other hand is placed behind the scapula to resist retraction.

directly on the scapula in the direction opposite the motion (Fig. 17.36).

Depression (lower trapezius). Activation of the lower trapezius is emphasized when there is forward tipping and delayed upward rotation of the scapula often seen with impingement syndromes. Apply resistance against the inferior angle of the scapula (Fig. 17.36A).

Protraction (serratus anterior). Activation of the serratus anterior is emphasized when there is scapular winging or when there is delayed or incomplete upward rotation of the scapula with GH elevation. Apply resistance against the axillary border of the scapula or coracoid process or indirectly against the humerus positioned in the plane of the scapula (Fig. 17.36B).

BOX 17.12 Summary of Exercise Progressions for Shoulder Function

- Develop awareness and control of weak or disused muscles.
- For weak or surgically repaired musculature, begin with setting exercises and multiple-angle isometrics against minimal resistance and active-assistive ROM in open- and closed-chain positions within pain-free or protected ranges.
- Provide just enough resistance and repetitions to challenge the muscles without provoking symptoms.
- Develop control in postural muscles for stability of scapular and glenohumeral joints with stabilization exercises in both open- and closed-chain positions.
- As stabilizing control develops in the scapula and GH muscles, progress to dynamic resistance exercises, emphasizing scapular and rotator cuff muscle control during open- and closed-chain motions.
- First isolate and strengthen weak motions and weak muscles so substitute actions do not dominate.
- Develop muscle endurance simultaneously while developing muscle strength.
- Progress to combined patterns of motion that simulate functional activities and train muscle groups to function in a coordinated sequence of control and motion.
- Integrate simple functional tasks into the exercise program and progress to more complex and challenging activities.
- As necessary, based on functional goals, progress training at increasing speeds of movement, such as coordination and agility drills and plyometric training.

Retraction (rhomboids and trapezius). Activation of the rhomboids and trapezius muscle groups is emphasized when the scapular posture is protracted (abducted), as typically seen with a forward head and increased kyphotic posture. Apply resistance against the medial border of the scapula.

Multiple-Angle Isometrics to the GH Muscles

Patient position and procedure: Supine, sitting, or standing. If pain from joint compression occurs, apply a slight distractive force to the GH joint as resistance is applied.

Internal and external rotation. Position the humerus at the patient's side in slight flexion, slight abduction, or scaption (plane of the scapula) and with the elbow flexed 90°. Apply resistance against the forearm as if turning a crank (Fig. 17.37).

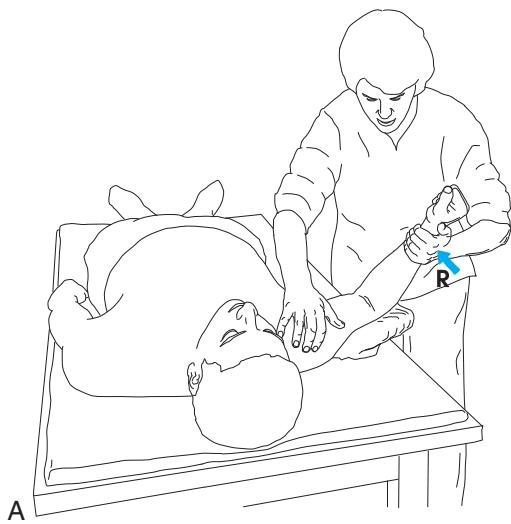

FIGURE 17.37 Isometric or dynamic resistance to shoulder rotation. (A) External rotation with the shoulder in the plane of the scapula. (B) Internal rotation with the shoulder at 90° abduction.

Abduction. Maintain the humerus neutral to rotation and resist abduction at 0°, 30°, 45°, and 60°. If there are no contraindications to motion above 90°, preposition the humerus in external rotation before elevating the humerus and resisting above 90° abduction.

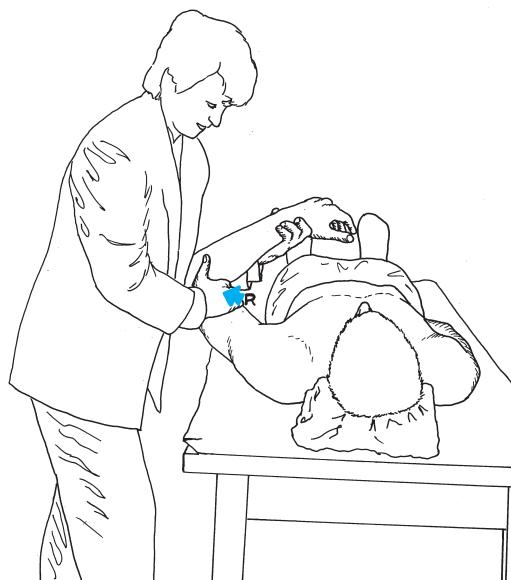

FIGURE 17.38 Isometric resistance in scaption. The shoulder is positioned between 30° and 60° degrees of scaption, and controlled manual resistance is applied against the humerus.

Scaption. Position midway between flexion and abduction and resist at various positions in the range, such as 30° and 60° in the plane of the scapula (Fig. 17.38).

Extension. Position the humerus at the side or in various positions of flexion and apply resistance against the humerus.

Adduction. Position the humerus between 15° and 30° abduction and apply resistance.

Elbow flexion with the forearm supination. Position the humerus at the side and neutral to rotation. Apply resistance to forearm flexion, causing tension in the long head of the biceps. Change the position of the shoulder into more flexion or extension and repeat the isometric resistance to elbow flexion.

Self-Applied Multiple-Angle Isometrics

Teach the patient how to independently apply isometric resistance using positions and intensities consistent with therapeutic goals. The patient can use the opposite hand (Fig. 17.39) or a stationary object such as a wall or door frame (Fig. 17.40).

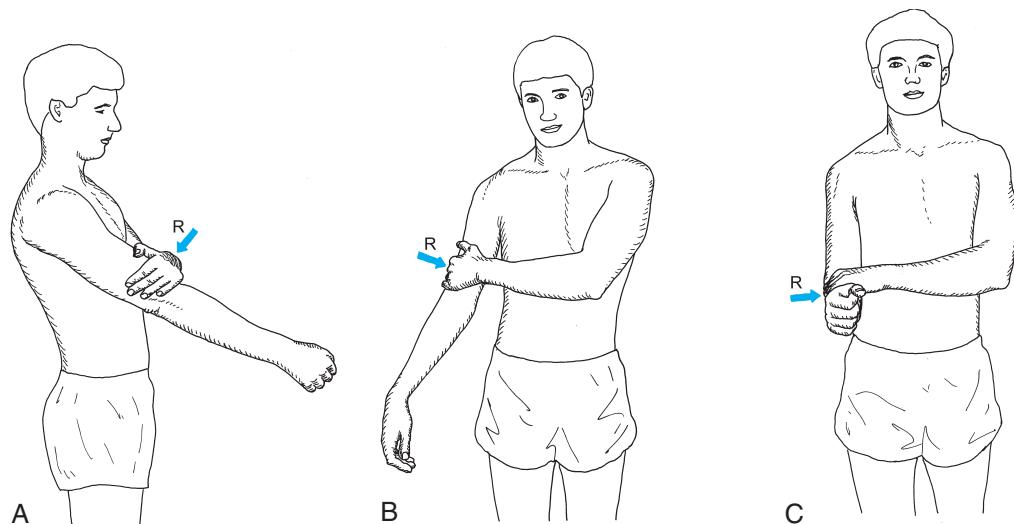

FIGURE 17.39 Self-resistance for isometric (A) shoulder flexion, (B) abduction, and (C) rotation.

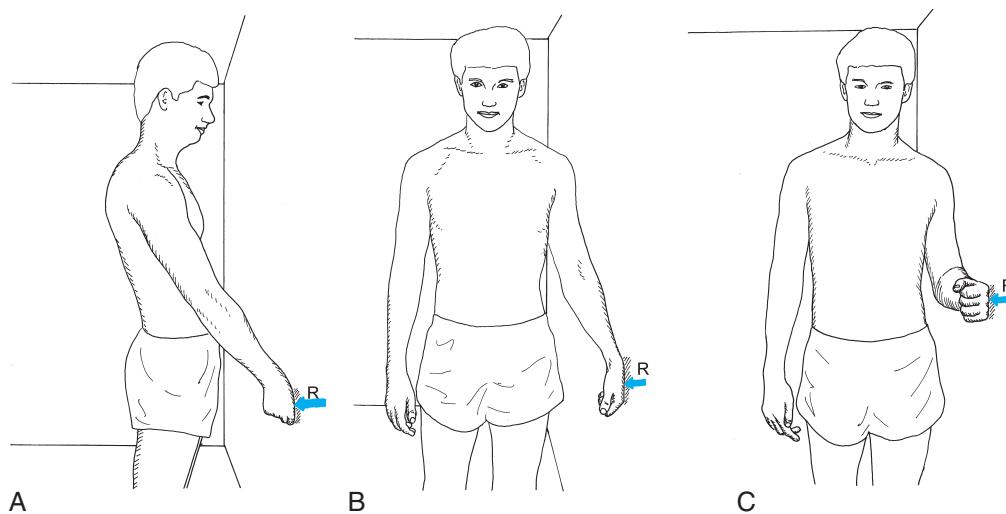

FIGURE 17.40 Using a wall to provide resistance for isometric (A) shoulder flexion, (B) abduction, or (C) rotation.

Stabilization Exercises

The application of alternating isometrics and rhythmic stabilization techniques (described in Chapter 6) is designed to develop strength and stability of proximal muscle groups in response to shifting loads. The shoulder girdle functions in both open- and closed-chain activities, and therefore the muscles should be trained to respond to both situations.

Begin training the scapular muscles so when the muscles of the GH joint need to contract they have a stable base (scapular stability). Initially, apply the alternating resistance slowly and command the patient to “hold” against the resistance. At the beginning of training it may also be necessary to tell the patient which way you are going to push to help the patient focus on the contracting muscles and alternating forces. As the patient learns to respond by contracting the proper muscles and stabilizing

the joints, increase the rapidity of the shifting resistance and decrease the verbal warning so the muscles learn to respond accordingly.

Open-Chain Stabilization Exercises for the Scapular Muscles

Begin with the patient side-lying, with the affected extremity up. Drape the forearm of the involved extremity over your shoulder. The degree of shoulder flexion, scaption, or abduction can be controlled by your stance and the relative position of the patient. Progress to sitting with the patient’s arm draped over your shoulder; apply resistance to all scapular motions in the same manner as described previously.

Scapular elevation/depression. Place your top hand superiorly and the other hand inferiorly around the scapula to provide manual resistance (see Fig. 17.36A).

Scapular protraction/depression. Place your top hand along the medial border and the other around the coracoid process to provide resistance (see Fig. 17.36B).

Scapular upward and downward rotation. Place one hand around the inferior angle and the other hand around the acromion and coracoid process to provide resistance.

Open-Chain Stabilization Exercises for the Shoulder Girdle

Patient position and procedure: Supine holding a rod or ball with elbows extended and shoulders flexed to 90°. Stand at the patient's head and grasp the rod; instruct the patient to hold against or match the resistance you provide. Push, pull, and rotate the rod in various directions (Fig. 17.41). Resistance can also be applied directly against the arm or forearm.

- If too much assistance is being given by the normal extremity, apply the stabilization technique to just the involved extremity.
- As the patient gains control, progress to sitting and then standing and have the patient hold the arm in various positions as the alternating resistance is applied. Observe the scapula to be sure there is good stabilization. If not, return to the exercises described above or decrease the intensity of resistance. Progress these exercises to functional patterns as strength and control improves.

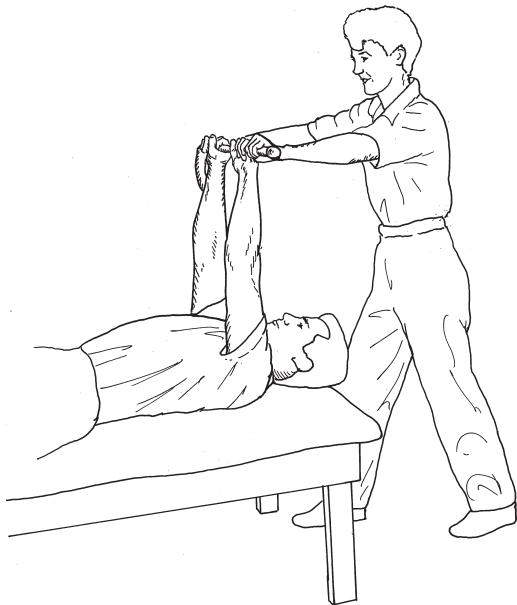

FIGURE 17.41 Stabilization exercises. The patient stabilizes with the shoulder girdle musculature (isometrically) against the resistance imposed by the therapist. Resistance to flexion/extension, abduction/adduction, and rotation is applied in a rhythmic sequence.

Static Closed-Chain (Weight-Bearing) Stabilization Exercises

Weight bearing activates contraction of stabilizing muscles in proximal joints and may be a stimulus for improving fluid dynamics of the articular cartilage as described in Chapter 5. Early during the controlled motion phase of treatment (subacute stage), if the healing tissues tolerate it, it may be beneficial to initiate protected weight-bearing stabilization exercises. The amount and intensity of weight bearing and resistance is progressed as tissues heal.

NOTE: If scapular winging is observed when the patient is weight bearing, do not progress these exercises until there is enough strength to stabilize the scapula against the rib cage.

Focus on Evidence

Seeking an answer as to when upper extremity weight-bearing exercises could be included in an exercise program, Uhl and colleagues¹⁸⁶ analyzed the pectoralis major, anterior and posterior deltoid, supraspinatus, and infraspinatus with surface electromyography (EMG) in a progression of static exercises in 18 healthy subjects. Positions for isometric exercises included the prayer position (to simulate weight bearing against a wall), quadruped, tripod, pointer, push-up position (shoulders flexed to 90°), push-up position with feet elevated 18 inches (45 cm), and one-arm push-up position. There was a significant correlation between the increasing weight-bearing postures and increased muscular activity ($r = 0.97, p < 0.01$) in all the muscles. Also, the infraspinatus was the most active of the muscles tested in all positions except the prayer position (in which the pectoralis major was most active).

The authors suggested that the prayer and quadruped positions were appropriate for early rehabilitation owing to the low-activity level in all the muscles; that the tripod and pointer positions placed an intermediate demand on the infraspinatus and deltoid musculature; and that the push-up positions placed a high demand on the infraspinatus. They also concluded that the two-handed positions required less demand on the posterior deltoid but more load on the anterior deltoid and pectoralis muscles and that the one-arm push-up placed a high demand on all muscles except the supraspinatus.

Scapular stabilization.

Patient position and procedure: Side-lying on unininvolved side. Both the elbow and shoulder of the involved arm are flexed to 90°, with the hand placed on the table and bearing some weight. Resist the scapular motions of elevation/depression and retraction directly against the scapula; resist protraction by pushing against the elbow.

● **Protected weight bearing.**

Patient position and procedure: Sitting with forearms resting on thighs or a table; or standing with arms resting on a table. Apply a gentle resistance force against the shoulders and ask the patient to match the resistance and “hold.” Alternate resisting in various directions.

● **Progression of closed-chain stabilization exercises.**

Patient position and procedure: Standing with shoulder at 90° and one or both hands leaning against a wall or on a ball (Fig. 17.42).

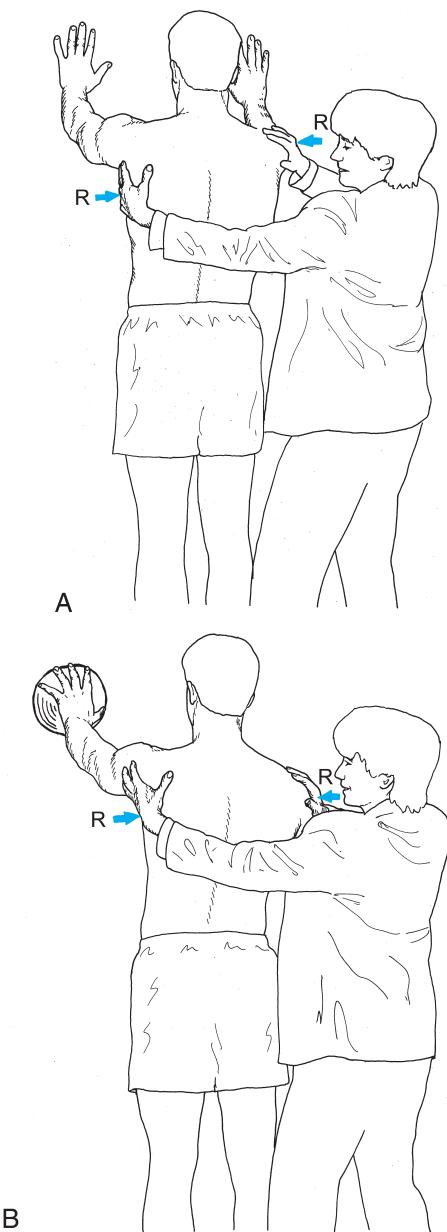

FIGURE 17.42 Closed-chain scapular and glenohumeral stabilization exercises. (A) Bilateral support in a minimal weight-bearing position with both hands against a wall. (B) Unilateral support on a less stable surface (ball).

The therapist applies alternating resistance while the patient stabilizes against the resistance, or the therapist applies resistance as the patient moves from side to side.

Additional, more advanced progressions include having the patient in the “all-fours,” or quadruped, position with hands on the floor, on a rocker or wobble board, or on a ball. The ball provides an unstable surface and requires greater neuromuscular control and balance reactions. Each of the positions can also be done with weight on only the involved upper extremity. Apply alternating resistance against the shoulders or trunk and ask the patient to “hold” against the force. Pressing forward against the trunk increases the effect of the body weight and requires the serratus anterior to stabilize more strongly against the additional force. As already noted, if the scapula wings, the resistance is either too strong and should be reduced, or the degree of weight bearing is excessive.

Dynamic Closed-Chain Stabilization Exercises

Dynamic stabilization in weight-bearing positions requires the stabilizing muscles to maintain control of the scapula and GH joint while *moving the body weight* over the fixed extremity or extremities.

- **Patient position and procedure:** Standing with shoulders flexed 90° and hands supported against a wall, leaning hands on a table, or assuming a quadruped (all-fours) position. Have the patient shift his or her body weight from one extremity to the other (rock back and forth). Apply resistance against the shoulders (see Fig. 17.42).
- Progress by having the patient alternately lift one extremity and then the other, so one extremity bears the body weight and stabilizes against the shifting load. Apply manual resistance to the shoulders or strap a weight around each wrist.
- When the muscles are able to control and stabilize, progress to using unstable surfaces [such as a rocker board, biomechanical ankle platform system (BAPS) board, or ball]. Suggestions for more vigorous closed-chain activities are described in the following section.

Dynamic Strengthening Exercises—Scapular Muscles

It is imperative that the proximal stabilizing muscles of the thorax, neck, and scapula function properly before initiating dynamic strengthening of the muscles that move the GH joint through the ROM to avoid faulty mechanics. Strengthening exercises can be done in both open- and closed-chain positions. Progress exercises with repetitions and resistance within the mechanical limits of the involved tissues.

Initially apply light resistance with multiple repetitions to develop dynamic control and muscular endurance. As control develops, progress to combined patterns of motion and training for muscle groups to function in a coordinated sequence. Begin with simple functional activities and progress to more complex and challenging activities. Both muscular endurance and strength are necessary for postural and dynamic control of activities.

Focus on Evidence

Two EMG studies analyzed exercises often used to strengthen the scapular muscles using either free weights or elastic tubing against maximum resistance.^{49,81} The findings of these studies indicate the degree of activation of the trapezius and serratus anterior muscles during the following exercises.

- *Shoulder shrug, standing:* strongly activates the upper trapezius.
- *Full elevation of the arm above the head in the prone-lying position:* activates all three portions of the trapezius and serratus anterior when the shoulder is in line with the fibers of the lower trapezius.
- *External rotation in the prone-lying position with the shoulder positioned at 90° abduction and the elbow flexed 90°:* strongly activates the lower trapezius. This position is the “best exercise” to cause maximum depression of the scapula and isolation of the lower trapezius from the middle and upper portions.⁴⁹
- *Horizontal abduction in the prone-lying position with the shoulder in external rotation:* activates the middle and lower trapezius.
- *Rowing action, seated or prone-lying:* emphasizes the middle trapezius over the upper and lower trapezius.
- *Diagonal exercises (flexion, abduction, external rotation), and shoulder abduction in the plane of the scapula above 120°, standing resulting in upward rotation of the scapula:* higher activity in the serratus anterior than in the trapezius.
- *Isolated protraction exercises:* do not activate the serratus anterior to as great a degree as upward rotation exercises.⁴⁹

Scapular Retraction (Rhombooids and Middle Trapezius)

The following exercises are designed to isolate scapular retraction. Once the patient is able to retract the scapula against resistance, combine patterns with the GH joint to progress strength and functional patterns as described in the next sections.

- *Patient position and procedure:* Prone, sitting, and standing. Instruct the patient to clasp the hands together behind the low back. This activity should cause scapular adduction. Draw attention to the adducted scapulae and have the patient hold the adducted position of the scapulae while the arms are lowered to the sides. Have the patient repeat the activity without arm motion.
- *Patient position and procedure:* Prone with the arm over the edge of the table in a dependent position and a weight in the hand. Instruct the patient to pinch the scapulae together (Fig. 17.43). Progress this exercise to prone rowing and horizontal abduction against gravity (described below).

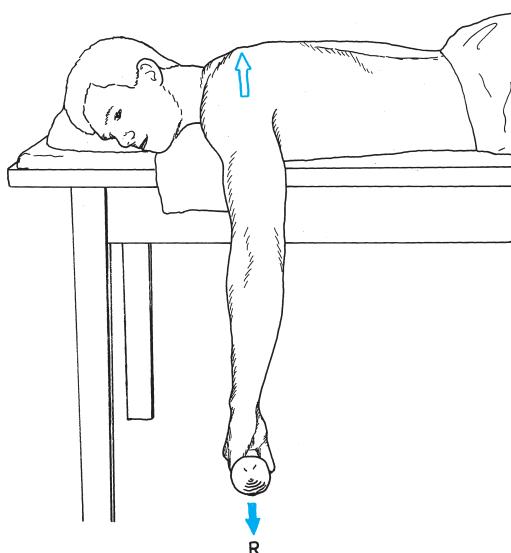

FIGURE 17.43 Scapular retraction against handheld resistance in the prone position.

- *Patient position and procedure:* Sitting or standing with the shoulder flexed to 90° and elbows extended. Have the patient grasp each end of an elastic band or tubing that has been secured at shoulder level or a two-handled pulley that is at shoulder level, and pinch the scapulae together by pulling against the resistance.

Scapular Retraction Combined with Shoulder Horizontal Abduction/Extension (Rhombooids, Middle Trapezius, Posterior Deltoid)

- *Patient position and procedure:* Prone with shoulders abducted 90°, elbows flexed, and forearms pointed vertically toward the floor. Instruct the patient to perform horizontal abduction with scapular retraction. This exercise can also be done with the elbows extended for greater resistance (Fig. 17.44). Progress this exercise by adding weights and then by having the patient perform the rowing motion standing or sitting in front of a length of elastic resistance that has been secured at shoulder level.

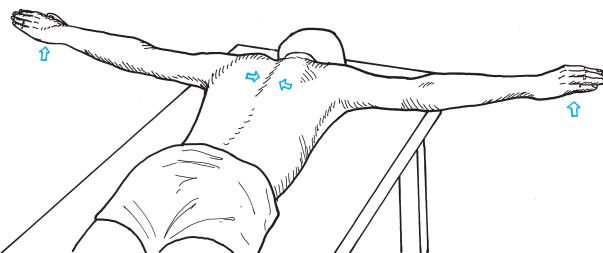

FIGURE 17.44 Horizontal abduction and scapular adduction exercises, with the arms positioned for maximal resistance from gravity. External rotation of the shoulders (thumbs pointing upward) emphasizes the middle and lower trapezius. To progress the exercise further, weights can be placed in the patient's hands.

● **Corner press-out.**

Patient position and procedure: Standing with the back toward a corner, shoulders abducted 90°, and elbows flexed. Instruct the patient to press the elbows into the walls and push the body weight away from the corner (Fig. 17.45).

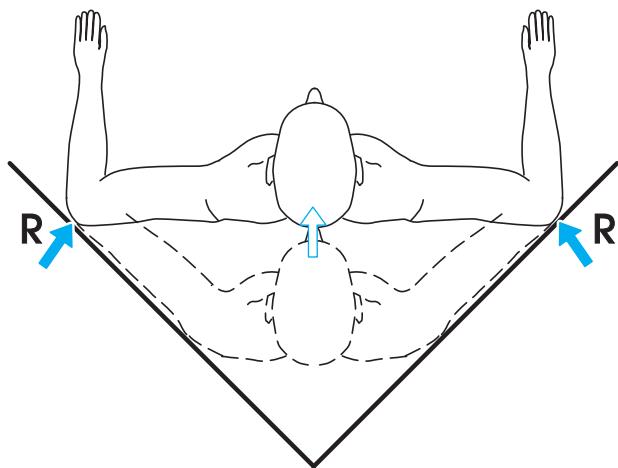

FIGURE 17.45 Corner press-outs to strengthen scapular retraction and shoulder horizontal abduction (view looking from above).

Scapular Retraction and Shoulder Horizontal Abduction Combined with External Rotation (Rhomboids, Trapezius, Posterior Deltoid, Infraspinatus, Teres Minor)

- *Patient position and procedure:* Prone with shoulders abducted 90° and externally rotated 90° (90–90 position). The elbows can be flexed 90° (easier position) or extended (more difficult position). Instruct the patient to lift the arm a few degrees off the table. To do this correctly the scapulae must adduct simultaneously. Greater ROM can be used if these exercises are done on a narrow bench so the arm can begin in a horizontally adducted position.
- *Patient position and procedure:* Sitting or standing with shoulders in the 90–90 position. Secure the middle of a piece of elastic resistance in front of the patient slightly above the shoulders and have the patient grasp each end of the resistance. Then have the patient pull the hands and elbows back while simultaneously adducting the scapulae (Fig. 17.46).

FIGURE 17.46 Combined scapular adduction with shoulder horizontal abduction and lateral rotation against resistance.

Scapular Protraction (Serratus Anterior)

- *Patient position and procedure:* Sitting or standing with shoulder flexed around 90° and elbow extended. Secure a piece of elastic resistance behind the patient at shoulder level or use a pulley system. Instruct the patient to “push” outward against the resistance without rotating the body (Fig. 17.47).

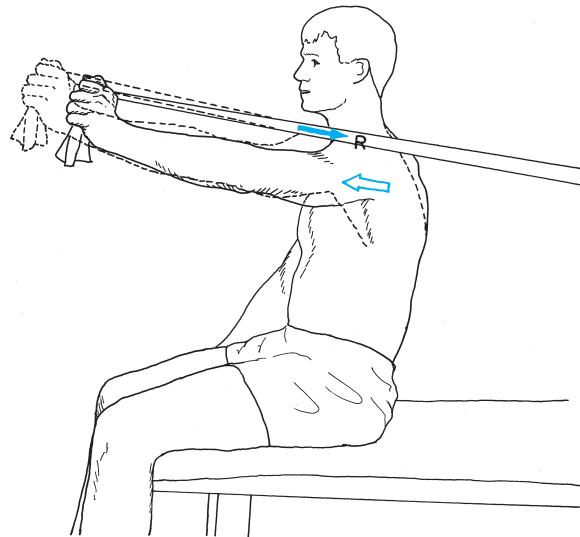

FIGURE 17.47 Scapular protraction; pushing against elastic resistance.

NOTE: According to a study by Ekstrom and colleagues,⁴⁹ isolated protraction exercises do not activate the serratus anterior as effectively as exercises that involve upward rotation of the scapula.

- **Patient position and procedure:** Supine with the arm flexed 90° and slightly abducted and the elbow extended. Place a light weight in the hand if resistance is tolerated and have the patient “push” the weight upward without rotating the body.

● **Push-ups with a “plus.”**

Patient position and procedure: Standing with arms against a wall, leaning on a table or lying prone. Have the patient place his or her hands directly in front or slightly to the side of the shoulders and push the trunk up (or away from the wall). Once full GH range is reached, instruct the patient to “give an extra push” to protract the scapulae. Progress the wall push-ups to table push-ups, then prone push-ups with knees as a fulcrum, and finally prone-lying push-ups, lifting the full body weight (Fig. 17.48). Add weight around the trunk if the patient is able to tolerate greater resistance.

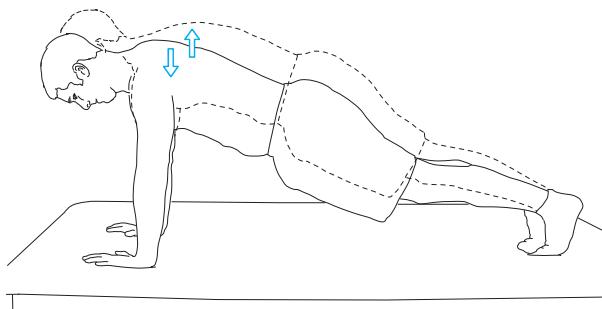

FIGURE 17.48 Push-ups with a “plus” to strengthen scapular protraction.

Scapular Depression (Lower Trapezius, Lower Serratus Anterior)

● **Shoulder rolls.**

Patient position and procedure: Sitting or standing. Ask the patient to roll the shoulders forward, up, and then around to the back so the scapulae are resting in the retracted and depressed position. Have the patient do this frequently throughout the day as part of a posture correction activity (see Chapter 14).

- **Patient position and procedure:** Sitting with elbow flexed. Provide manual resistance in an upward direction under the elbow, and ask the patient to push down into your hands. Caudal gliding of the humeral head may also occur (Fig. 17.49A).

● **Scapular “push-ups.”**

Patient position and procedure: Sitting or standing with both hands on blocks, on the armrests of a chair, or on parallel bars. Have the patient push down on the hands and lift the body (Fig. 17.49B).

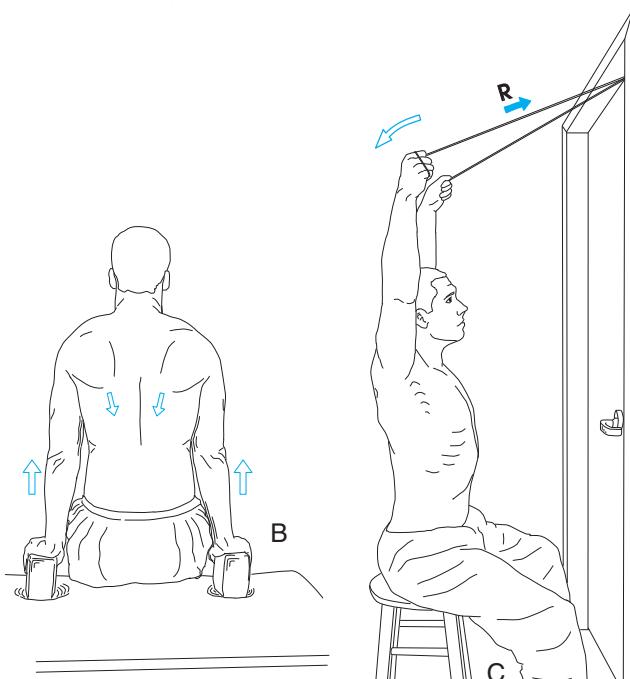

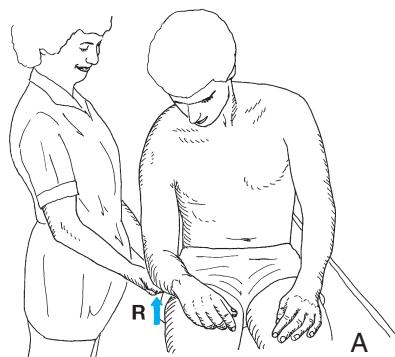

FIGURE 17.49 Exercises that emphasize the lower trapezius. (A) Shoulder girdle depression against manual resistance. (B) Closed-chain shoulder girdle depression using body weight for resistance. (C) Scapular depression with upward rotation of the scapula against elastic resistance (this also brings in the upper and middle trapezius and serratus anterior).

Scapular Upward Rotation with Depression (Lower Trapezius, Serratus Anterior)

Scapular upward rotation with depression cannot be isolated from the humerus. The upward rotation action of the trapezius and serratus anterior require coordination with humeral elevation. As noted elsewhere in this chapter, a patient may substitute with scapular elevation, primarily using the upper trapezius, so this exercise draws attention to maintaining the scapula in depression while upwardly rotating.

● **“Superman” motion.**

Patient position and procedure: Prone, with humerus elevated overhead. Ask the patient to barely lift the arm off the table. This end-range motion may not be possible for patients with restricted glenohumeral mobility or who have impingement syndrome.

Patient position and procedure: Sitting or standing if the patient has a tight shoulder and cannot do the “superman motion” lying prone. Secure elastic resistance overhead and instruct the patient to move the shoulder into greater flexion with scapular depression. The scapular depression is most important; it may be necessary to use tactile cues on the lower trapezius to help the patient focus on scapular depression, not scapular elevation (Fig. 17.49C).

Patient position and procedure: Standing with the back to the wall, heels away from the wall enough to comfortably do a posterior pelvic tilt and maintain the back flat against the wall. Begin with arms slightly abducted and externally rotated and the elbows flexed 90° (backs of the hands should be against the wall). Have the patient slide the hands and arms up the wall (abduction) as far as possible while maintaining the back flat against the wall.

Dynamic Strengthening Exercises—Glenohumeral Muscles

Several EMG studies have investigated exercises commonly used to activate and strengthen shoulder muscles using either free weights or elastic resistance.^{10,16,81,143} The findings of these studies indicate the extent of activation of the rotator cuff, deltoid, pectoralis major, and latissimus dorsi muscles under maximum load conditions during the following exercises.

- **Shoulder shrug:** causes highest activation in the subscapularis, trapezius, and latissimus dorsi; also activates the supraspinatus, infraspinatus, and serratus anterior.⁸¹
- **Middle-grip and narrow-grip seated rowing:** activates subscapularis.⁸¹
- **Wide grip seated rowing:** activates the infraspinatus and trapezius and to a lesser extent the supraspinatus.⁸¹
- **External rotation:** *in prone and side-lying positions and in the plane of the scapula:* activates the infraspinatus and teres minor.^{10,16,143}
- **Internal rotation:** *movement across the body with arm at side and elbow flexed 90°* activates the subscapularis and pectoralis major.⁸¹
- **Forward punch:** causes highest activation in the supraspinatus and anterior deltoid; resistance also activates the pectoralis major and infraspinatus.⁸¹
- **Horizontal abduction at 100° with full external rotation:** activates the supraspinatus, middle and posterior deltoid.¹⁴³

Shoulder External Rotation (Infraspinatus, Teres Minor)
Position the arm at the patient’s side or in various positions of abduction, scaption, or flexion. Flex the elbow to 90° and apply the resistive force at right angles to the forearm.

Be sure the patient rotates the humerus and does not extend the elbow. When the arm is positioned at the patient’s side, a folded towel placed between the elbow and side of the rib cage reminds the patient to keep the elbow at the side and ensures proper technique. However, it does not significantly alter recruitment of the external rotators.¹⁴³ As indicated in the supporting evidence just presented, external rotation applied in the side-lying position (arm at side), prone-lying in the 90/90 position, and standing with the humerus in scaption (45° abduction, 30° horizontal adduction) produces the strongest contractions of these muscles compared with other external rotation exercises.¹⁴³

- **Patient position and procedure:** Sitting or standing, using elastic resistance or a wall pulley in front of the body at elbow level. Have the patient grasp the elastic material or the pulley handle and rotate his or her arm outward (Fig. 17.50).
- **Patient position and procedure:** Side-lying on the normal side with the involved shoulder up and the arm resting on the side of the thorax with a rolled towel under the elbow. Have the patient use a handheld weight, cuff weight, or elastic resistance and rotate the arm through the desired ROM.
- **Patient position and procedure:** Prone on a treatment table, upper arm resting on the table with the shoulder at 90° if possible, elbow flexed with forearm over the edge of the table. Lift the weight as far as possible by rotating the shoulder, not extending the elbow (Fig. 17.50B).
- **Patient position and procedure:** Sitting with elbow flexed 90° and supported on a table so the shoulder is in the resting position (scaption). The patient lifts the weight from the table by rotating the shoulder (Fig. 17.50C).

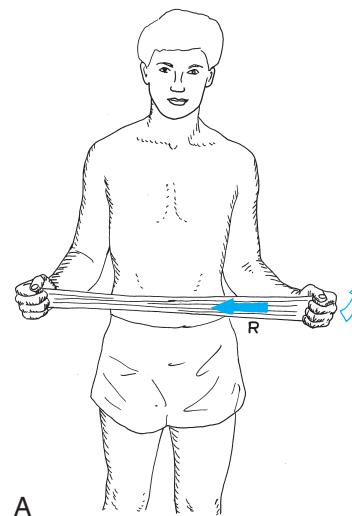

FIGURE 17.50 Strengthening external rotation with (A) the arm at the side using elastic resistance

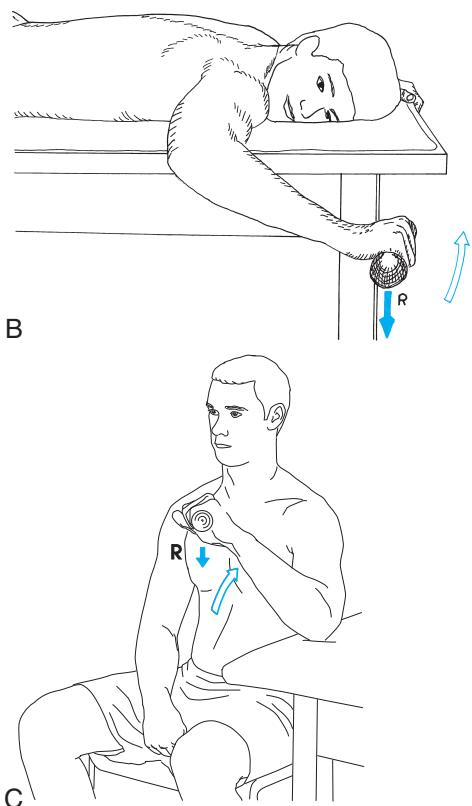

FIGURE 17.50 (continued) (B) prone with the arm at 90° using a free weight, and (C) sitting with the shoulder in scaption using a free weight.

Shoulder Internal Rotation (Subscapularis)

Position the arm at the patient's side or in various positions of flexion, scaption, or abduction. The elbow is flexed to 90°, and the resistive force is held in the hand.

- **Patient position and procedure:** Side-lying on the involved side with the arm forward in partial flexion. Have the patient lift the weight upward off the table into internal rotation (Fig. 17.51).
- **Patient position and procedure:** Sitting or standing using elastic resistance or a pulley system with the line of force out to the side and at the level of the elbow. Have the patient pull across the front of the trunk into internal rotation.

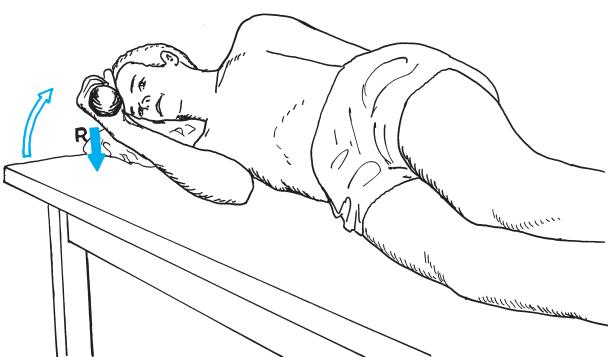

FIGURE 17.51 Resisted internal rotation of the shoulder using a handheld weight. To resist external rotation, place the weight in the patient's upper hand.

Shoulder Abduction and Scaption (Deltoid and Supraspinatus)

Abduction exercises are classically done with the humerus moving in the frontal plane. It is commonly accepted that most functional activities occur with the humerus 30° to 45° forward to the frontal plane where the arc of motion is more in line with the glenoid fossa of the scapula. Many abduction exercises can be adapted to be performed in scaption.

PRECAUTION: Teach the patient that whenever the shoulder elevates beyond 90° it must externally rotate to avoid impingement of the greater tubercle against the acromion. If the patient has impingement syndrome, limit the range to avoid the painful arc.

● **Military press.**

Patient position and procedure: Sitting, arm at the side in external rotation with elbow flexed and forearm supinated (thumb pointing posteriorly). Have the patient lift the weight straight up overhead (Fig. 17.52).

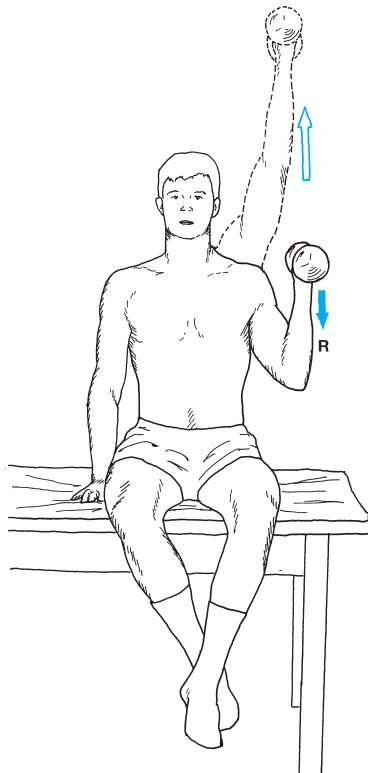

FIGURE 17.52 Military press-up. Beginning with the arm at the side in external rotation with elbow flexed and forearm supinated (thumb pointing posteriorward), the weight is lifted overhead.

Patient position and procedure: Sitting or standing with a weight in hand. Have the patient abduct the arm to 90° and then laterally rotate and elevate the arm through the rest of the range. This same motion can be performed with elastic resistance secured under the patient's foot, but be cautious in that the greater the elastic stretch, the greater the resistance. The patient

may not be able to complete the ROM because of the increased resistance at the end of the range.

Patient position and procedure: Side-lying with involved arm uppermost. Have the patient lift a weight up to 90°. The greatest effect of the resistance is at the beginning of the range. At 90° all of the force is through the long axis of the bone.

- **“Full can” and “empty can.”**

Patient position and procedure: Standing with the humerus either externally rotated (full can) or internally rotated (empty can). Have the patient raise the arm away from the side in the plane of the scapula, halfway between abduction and flexion (Fig. 17.53). Performing scaption with the humerus in various positions of rotation has the value of emphasizing each of the rotatory muscles of the cuff in their synergy with the supraspinatus and deltoid muscles.¹⁰⁶ Resistance is applied with a handheld weight or from elastic resistance secured under the patient’s foot.

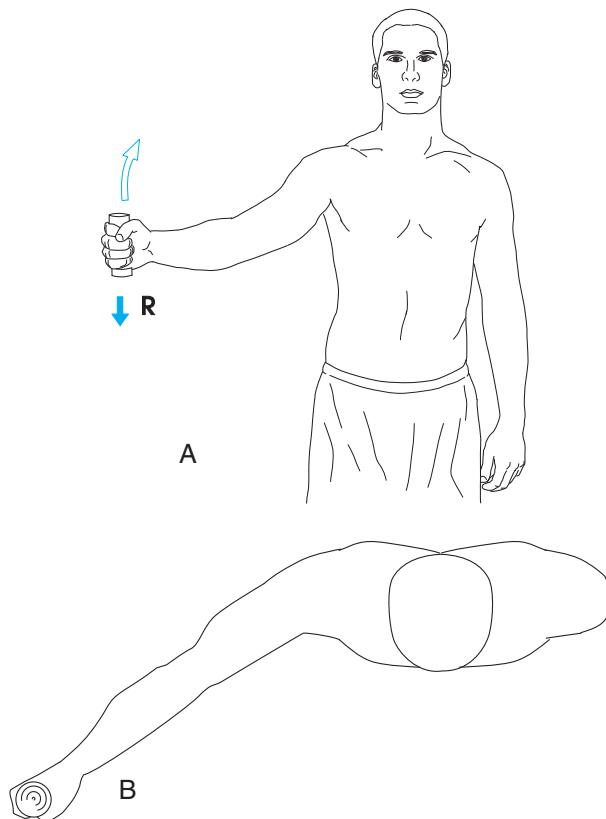

FIGURE 17.53 Abduction in the plane of the scapula (scaption). This is called the “full can” exercise because the shoulder is held in external rotation as if lifting a full can. (A) Front view. (B) Top view. If the shoulder is held in internal rotation, it is called an “empty can” exercise.

Focus on Evidence

EMG studies have confirmed that no one exercise isolates the action of the supraspinatus muscle from the other rotator cuff or deltoid muscles.^{107,181} The supraspinatus muscle is effectively activated in both the “empty can”^{87,198} and

“full can”^{85,107,181} exercises. It also contracts strongly with the military press¹⁸¹ and horizontal abduction with external rotation exercises.^{16,107,209} These findings give the therapist several choices of exercises for strengthening the supraspinatus. Several authors,^{45,83,85} as well as the authors of this text, have suggested that the “empty can” exercise (scaption with internal rotation of the humerus) should not be used for shoulder rehabilitation because it can cause impingement of the suprhumeral tissues, especially as the arm approaches and elevates above 90°. The “full can” position (scaption with external rotation) does not cause impingement.^{45,85}

Shoulder Flexion (Anterior Deltoid, Rotator Cuff, Serratus Anterior)

Patient position and procedure: Sitting, standing, or supine. If a free weight is used when supine, the greatest resistive force is at the beginning of the range; during standing, the greatest resistive force is when the shoulder is flexed 90°. Elastic resistance also can be used if secured under the patient’s foot or a solid object.

Shoulder Adduction (Pectoralis Major, Teres Major, Latissimus Dorsi)

Patient position and procedure: Sitting or standing with the arm abducted. Have the patient pull down against a pulley force or elastic resistance tied overhead. The greatest resistance is when the line of the resistive force is at right angles to the patient’s arm.

Shoulder Horizontal Adduction (Anterior Deltoid, Coracobrachialis, Pectoralis Major)

Patient position and procedure: Supine. Begin with one or both arms out to the side in horizontal abduction. Have the patient bring the arms forward into horizontal adduction until the arm or arms are vertical.

Shoulder Extension (Posterior Deltoid, Latissimus Dorsi, Rhomboids)

● *Patient position and procedure:* Prone with the arm over the side of the table in 90° flexion. Have the patient lift the weight and extend the shoulder. Simultaneous elbow flexion while extending the shoulder is easiest (shortest lever arm); maintaining elbow extension while extending the shoulder is more difficult (longer lever arm).

● *Patient position and procedure:* Sitting or standing with the arm flexed. A pulley or elastic resistance is secured overhead. Have the patient pull down against the resistance into extension.

Elbow Flexion (Biceps Brachii)

● **Biceps Curls.**

Patient position and procedure: Sitting or standing. Have the patient flex the elbow while holding a handheld weight and keeping the forearm supinated and the arm at the side or with the shoulder moving into slight extension (see Fig. 18.11).

NOTE: Because the biceps brachii is a two-joint muscle, the muscle not only serves to flex the elbow as its primary

function, the long head assists the rotator cuff muscles by acting as an additional dynamic stabilizer of the GH joint by approximating the humeral head against the glenoid fossa and by depressing the head of the humerus as the arm elevates and the scapula upwardly rotates.⁹⁸ As such, the biceps brachii must be strengthened in a shoulder rehabilitation program.

PNF (Diagonal) Patterns

Proprioceptive neuromuscular facilitation (PNF) patterns, as described in Chapter 6, utilize the entire upper extremity or address specific regions, such as the scapula. Apply resistance manually to emphasize specific muscles in the pattern by adjusting hand placement and resistance. Teach the patient exercises that utilize PNF patterns with weights or elastic resistance.

● D₁ flexion pattern.

Patient position and procedure: Standing. The arm begins in extension, internal rotation, and slight abduction. Have the patient bring the arm into flexion, adduction, and external rotation while holding a weight or pulling against elastic resistance that is secured under the foot.

● D₂ flexion pattern.

Patient position and procedure: Standing. The arm begins in extension, internal rotation, and slight adduction. Have the patient bring the arm into flexion, abduction, and external rotation while holding a weight or pulling against elastic resistance (Fig. 17.54).

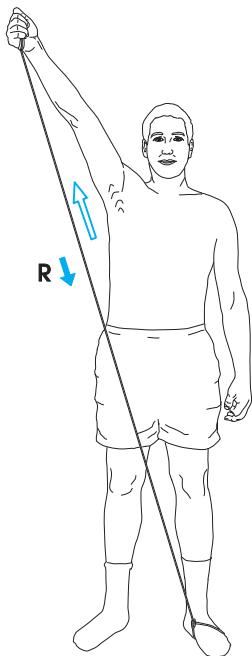

FIGURE 17.54 Elastic resistance to the D₂ flexion pattern, emphasizing shoulder flexion, abduction, and external rotation using elastic resistance.

● D₁ extension pattern.

Patient position and procedure: Supine, standing, or sitting. The arm begins in flexion, adduction, and external rotation. Have the patient pull against elastic resistance that is secured above the head or against an overhead cable attached to a weighted pulley system with a combined extension, abduction, and internal rotation motion.

● D₂ extension pattern.

Patient position and procedure: Supine, standing, or sitting. The arm begins in flexion, abduction, and external rotation. Have the patient pull against elastic resistance that is secured above the head with combined extension, adduction, and internal rotation.

Isokinetic Training

The principles of isokinetic training are discussed in Chapter 6. Early in an isokinetic exercise program have the patient use *submaximal* effort at slow speeds. During the advanced phase of rehabilitation, when tissues are reasonably well healed, have the patient perform maximum-effort concentric and eccentric exercises at medium to high speeds. Simulate functional patterns of movement if the equipment setup allows.

Resisted Exercises Using Functional Movement Patterns

A variety of exercise devices can be used or modified for shoulder girdle strengthening that require coordination between the stabilizing and dynamic functions of the scapula and humerus. Some are considered closed-chain exercises in that the proximal segments move over the stabilized extremity, or there is pressure through the extremity causing approximation of the GH joint surfaces. The exercises may be used to accomplish several goals, such as improving strength, power, endurance (muscular and/or cardiovascular/pulmonary), balance, coordination, and skill.

● Handwalking on a treadmill.

Patient position and procedure: Kneeling at the end of a treadmill. The surface can be moving forward or backward. Have the patient “walk” with his or her hands while bearing weight through the shoulders.

● ProFitterTM.

Patient position and procedure: Kneeling with one or both hands on the movable platform. The hands slide the platform from side to side. Change the position of the unit to obtain different angles of motion (Fig. 17.55).

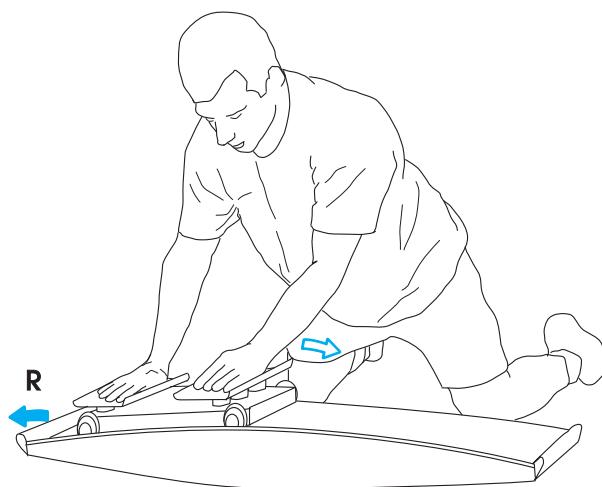

FIGURE 17.55 Advanced closed-chain exercise to resist the upper extremity using a ProFitter™ to provide an unstable, moving surface.

● **Stepping machine.**

Patient position and procedure: Kneeling with each hand on a step of the unit. The upper extremities do the climbing. Encourage the patient to use scapular protraction/retraction rather than elbow flexion/extension.

● **Rowing machine.**

Patient position and procedure: Long-sitting. Follow the instructions provided by the manufacturer if a commercial unit is used. Elastic resistance or a cable system on a pulley can be used to simulate a commercial rowing machine. Have the patient secure the elastic resistance under the feet or around a solid object, grasp the ends of the resistance, and pull backward in a rowing action with the arms. Also have the patient long-sit facing a cable system with the pulley at ground level. If there is just one cable, secure a bar to the cable and have the patient pull the bar toward his or her trunk in a rowing action.

● **“Lawnmower pull.”**

Patient position and procedure: Standing with hips partially flexed and holding onto a table or chair for balance with the hand of the sound upper extremity. Have the patient reach diagonally across the midline and grasp a piece of elastic resistance that is secured under the foot of the sound side or attached to the floor. Then have the patient pull upward on the resistance as if starting a lawnmower. This may also be simulated with a free weight (see Fig. 18.18).

● **Upper body ergometry.**

Patient position and procedure: Sitting or standing in front of an ergometer with hands on the handles. Determine the arc of motion and the direction (forward or backward), speed, and time. This machine may be used for general warm-up, ROM, strengthening, or endurance training. Because tight or overused anterior

structures and weak or underused posterior structures tend to be the pattern with shoulder impairments, place emphasis on backward (retro) motions of the ergometer.

Advanced Closed-Chain Stabilization and Balance Activities

Patient position and procedure: Quadruped on the floor with hands on an unstable surface such as a BAPS board, rocker board, wobble board, foam roll, or an 8- to 10-inch ball. Alternatively, have the patient assume a quadruped position with knees on a mat and hands on a large gym ball on the floor next to the mat. A variety of activities can then be done. For example, have the patient perform the following activities.

- Maintain a balanced posture as resistance is applied to the shoulders or trunk to disturb balance.
- Shift body weight from one hand to the other using an alternating protraction/retraction motion of the scapulae.
- Alternately flex each upper extremity so only one hand is balanced on the unstable surface.
- Perform push-ups and push-ups with a plus on the unstable surface.
- Increase speed of the above activities.

Functional Activities

As soon as the patient develops control of scapular and humeral motions and the basic components of the desired activities without exacerbating the symptoms, initiate specificity of training toward the desired functional outcome by progressing the strengthening exercises to maximum resistance concentrically and eccentrically. Use the actual patterns and type of contraction required in the desired outcome and progress to the desired speed first in a controlled manner, then with less control.

An individual who has a sedentary lifestyle may require postural adaptations and ergonomic analysis of his or her home environment or workstation to change repetitive stress, whereas an athlete or industrial worker may require high-intensity exercises that develop endurance, power, and skill. Functional exercises may begin simply by having the patient unload a dishwasher and place the dishes on a low shelf using correct shoulder mechanics or washing windows using small circular motions. Body mechanics are incorporated into lifting, pushing, or pulling activities (Fig. 17.56). If catching and throwing or swinging a bat or golf club are necessary, total body patterns are practiced with the upper extremity exercises. Creativity in adapting exercises to meet progressive upper extremity challenges is a must. Basic principles to progress the patient during the return to function phase of therapy follow.

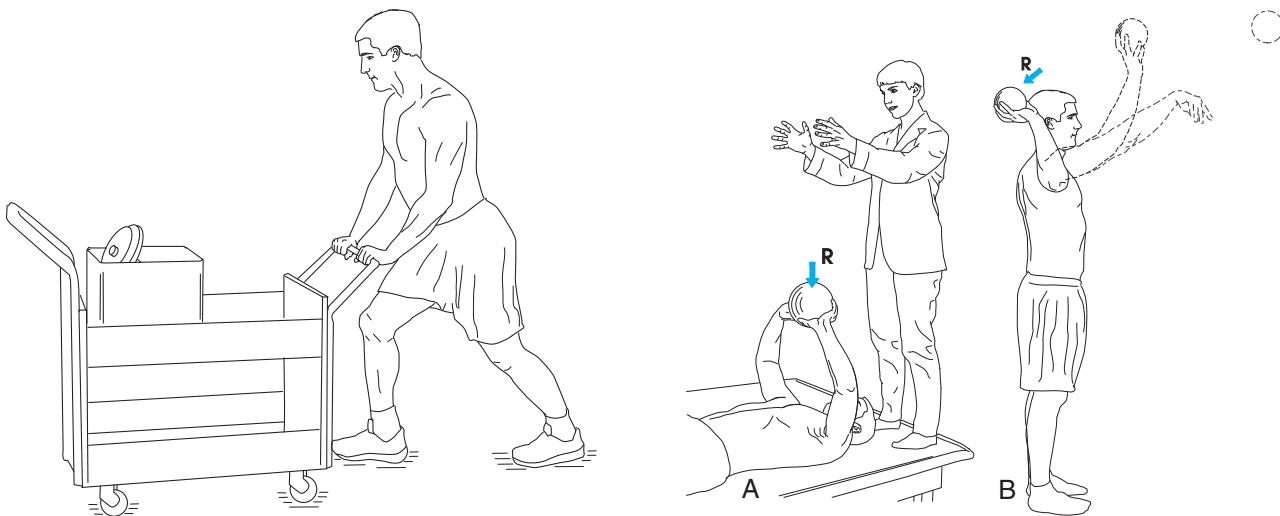

FIGURE 17.56 Functional exercise incorporating body mechanics.

Endurance Training

Muscle and cardiopulmonary endurance are important for general health as well as for functioning throughout a workday. Utilize repetitive loading of each exercise for 3 to 5 minutes using patterns of motion that simulate work or functional activities. Principles of conditioning are discussed in Chapter 7. Have the patient maintain his or her target heart rate for 20 minutes with repetitive exercises.

Eccentric Training

Eccentric exercises are high-intensity exercises and may be used for specific training. Because eccentric contractions tolerate greater resistance than concentric contractions, when loading resistance for eccentric training the patient is taught to assist the arm to the end of the shortened range of the muscles to be stressed; then the muscles control the return motion. This can be performed with elastic resistance, pulleys, or free weights first in single-plane motions and then progressed to simulated functional patterns.

Plyometric Training

Initiate *stretch-shortening drills* in safe, controlled patterns with light resistance; then progress speed and resistance as tolerated. For example, toss a weighted ball such as a Plyoball® for the patient to reach for and catch and then immediately toss it back using the reciprocal pattern (Fig. 17.57). Progress to total body patterns, which include step

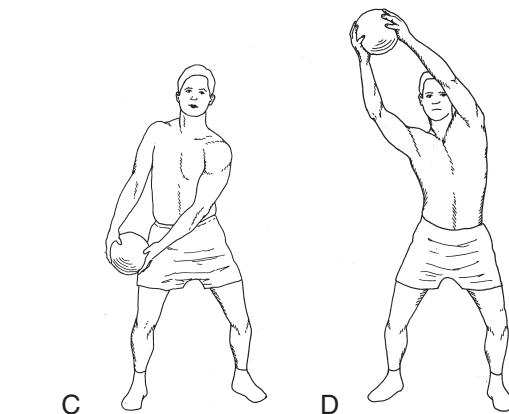

FIGURE 17.57 Plyometric activities catching and throwing a weighted ball (A) in a stable supine position, (B) in a standing position, (C) in a diagonal extension pattern, and (D) in a diagonal flexion pattern.

and throw and overhead pass activities. Spring-loaded rebounders and elastic tubing are commercially available so the patient can do the activity independently once the drills are learned.^{197–199}

Total Body Training

Increase *speed* with superimposed stresses to tolerance while simulating the desired activity. Assess the total body function while the desired activity is being carried out. Develop timing and sequencing of events that are consistent with the functional activity.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Describe the functions and interrelationships of the scapulothoracic and GH musculature as dynamic stabilizers of the shoulder.
2. Which structures can restrict normal upward rotation of the scapula, and how does inadequate passive or active

upward rotation of the scapula adversely affect elevation of the arm?

3. How does sitting or standing in a slumped posture (excessive thoracic kyphosis and forward head) with scapular abduction versus an erect posture with scapular adduction alter ROM of the shoulder?

4. Which mechanisms and structures could be sources of pain in primary impingement syndrome?
5. How are impingement and instability related to each other in secondary impingement syndrome?
6. A patient experienced a traumatic shoulder injury when falling down five cement steps 2 weeks ago. She now has a capsular pattern, decreased joint play, and muscle guarding with passive GH motions. She does not actively use the extremity because of pain. You observe edema in the hand. What potential complications could develop if left untreated? Design an exercise program for this patient at her present level of involvement. What would you teach the patient about her symptoms, impairments, and parameters for recovery?
7. An individual with a history of diabetes has developed a frozen shoulder. She has had shoulder discomfort for several months, but she did not seek treatment until 1 week ago when she was unable to wash or fix her hair with her left hand. Identify your intervention plan and instructions for this patient.
8. A new patient describes experiencing episodes of numbness and tingling in the hand with occasional periods of “puffiness.” She reports that it is particularly annoying because it happens whenever she carries her briefcase or heavy purse with a shoulder strap. She also experiences pain at night and wakes up with her hand “having fallen asleep.” What shoulder girdle problems could cause these symptoms? What is the probable cause of the symptoms? Create a scenario of objective findings, identify the impairment and functional goals, and outline a plan of intervention. What precautions are related to nerve pathologies?
9. During the early and middle stages of a rehabilitation program, what types of functional activities (ADL, work-related, or sport-related) should initially be avoided or modified for patients with a history of recurrent anterior dislocation of the GH joint? With recurrent posterior dislocation of the GH joint?
10. What criteria should patients with each of the following shoulder diagnoses meet before progressing to *overhead* exercises and functional activities: primary impingement syndrome; anterior GH instability; frozen shoulder; S/P rotator cuff repair?

Laboratory Practice

1. With your partner, review and practice key tests and measurements that you might need to do to determine what is causing shoulder pain and/or diminished upper extremity function. What does each of those tests indicate?
2. Mobilize the scapula with manual techniques.
3. Mobilize the GH joint capsule with manual techniques; practice the mobilization with movement techniques for the shoulder.
4. Teach your partner a series of self-mobilization techniques for the GH joint capsule.
5. Using appropriate stabilization, manually stretch all major muscle groups of the shoulder.

6. Teach your partner effective self-stretching techniques for each of these muscle groups.
7. Practice a sequence of exercises to strengthen the muscles of the scapula using manual resistance (applied by the therapist). Use open-chain and closed-chain positions.
8. Teach your partner a progressive sequence of strengthening exercises that he or she could do in a home exercise program to develop stability and dynamic control of the scapula.
9. Teach your partner a progressive sequence of strengthening exercises that he or she could do in a home exercise program to develop strength, stability, and endurance of the GH muscles. Have your patient perform each exercise for a specified number of repetitions and at a specified level of resistance. Correct any faulty postures or motions as your partner executes each exercise. Watch for and teach your partner signs of fatigue and poor exercise technique.
10. Develop a series of functional activities to complement the self-stretching and self-strengthening exercise you have taught your partner.

Case Studies

1. A patient referral states: Evaluate and treat shoulder pain S/P MVI. The patient describes shoulder pain whenever reaching overhead. She is a nurse and finds symptoms worsen whenever placing solutions on an IV pole, a frequent activity for her. She was the driver of the car in a head-on collision. Examination reveals painful resisted scapular protraction, elbow extension, and shoulder extension with pain on palpation of the long head of the triceps near its insertion on the inferior glenoid as well as pain in the serratus anterior in the axilla. Other impairments include weak rhomboids and lower trapezius muscles (4/5).
 - Explain why these muscles would be injured in this type of accident.
 - Explain why this patient’s job would perpetuate these symptoms.
 - Outline a treatment plan to manage the acute symptoms and initiate a therapeutic exercise program.
 - Identify a measurable functional outcome goal and interventions you would use to reach the goal.
 - As the patient’s symptoms subside, how would you progress her exercise program?
2. Your patient describes pain whenever reaching overhead. He likes to play volleyball in a weekend league but otherwise has a sedentary lifestyle. On examination, you observe moderate atrophy in the infraspinous fossa, a protracted scapula, and thoracic kyphosis with forward head. You have him assume the quadruped position in anticipation of instruction in closed-chain rhythmic stabilization and scapular protraction exercises and note significant winging of the scapula.
 - Describe what muscles probably test weak with these observations.

- How would you change the quadruped exercise to develop control and strength in the involved muscles at a safe resistance level?
 - Based on your assumptions of muscle involvement, develop an intervention plan for this patient that includes a home exercise program. Indicate parameters (frequency, repetitions), positions, safety, and progressions.
3. You have received a referral to “evaluate and treat” a 62-year-old patient who had undergone total shoulder arthroplasty for osteoarthritis 2 weeks ago. The patient has been wearing a sling to support and protect the operated shoulder but has been allowed to remove the sling for daily pendulum exercises and active ROM of the elbow, wrist, and hand.
- Prior to initiating your examination and developing an exercise program, what additional information would you like to find out from the surgeon?
- What information do you want to gather from the patient?
 - What examination procedures would you wish to perform during the patient’s initial visit?
 - The patient’s insurance, most likely, initially approves six visits. Develop, implement, teach, and then progress a series of exercises over a period of six visits with the patient.
4. Six months ago your patient underwent surgery for repair of a Bankart lesion and stabilization of the anterior capsule (capsular shift) after a traumatic anterior dislocation of the GH joint. The patient now has full ROM and 90% strength in the shoulder after a program of rehabilitation. Your patient wants to return to recreational sports, such as tennis, softball, and volleyball, but is apprehensive that the shoulder might dislocate during these activities. Design an advanced rehabilitation program to gradually return the patient to the desired recreational activities.

A freely mobile but strong and stable elbow complex is required for normal upper extremity function. The design of the elbow and forearm adds to the mobility of the hand in space by shortening and lengthening the upper extremity and by rotating the forearm. The muscles provide control and stability to the region as the hand is used for various activities, from eating, dressing, and grooming; to pushing, pulling, turning, lifting, throwing, catching, and reaching for objects; to coordinated use of equipment, tools, and

machines.^{33,43,55,59,67} Most activities of daily living require a 100° arc of flexion and extension at the elbow, specifically between 30° and 130°, as well as 100° of forearm rotation, equally divided between pronation and supination.^{55,56} Tasks such as drinking and eating primarily require elbow flexion, whereas a task such as reaching to tie shoelaces requires substantial elbow extension.

Injury or disease of bony, articular, or soft tissue structures of the elbow and forearm can cause pain and compro-

mised mobility, strength, stability, and functional use of the upper extremity. Loss of active or passive elbow flexion interferes with grooming and eating, whereas loss of elbow extension restricts a person's ability to push up from a chair or reach out for objects. In general, loss of terminal flexion of the elbow contributes to greater limitation of function than loss of terminal extension.⁵⁵

The anatomical and kinesiologic relationships of the elbow and forearm are outlined in the first section of this chapter. Chapter 10 presents information on principles of soft tissue healing and management; the reader should be familiar with that material before proceeding with establishing a therapeutic exercise program to improve function of the elbow and forearm.

STRUCTURE AND FUNCTION OF THE ELBOW AND FOREARM

The distal end of the humerus has two articular surfaces: the trochlea, which articulates with the ulna, and the capitulum, which articulates with the head of the radius (Fig. 18.1). Flexion and extension occur between these two joint surfaces. The radius also articulates with the radial notch on the ulna and is called the proximal radioulnar joint. This joint participates in pronation and supination along with the distal radioulnar joint. The capsule of the elbow encloses the humeroulnar, humeroradial, and proximal radioulnar articulations. The distal radioulnar joint is structurally separate from the elbow complex even though its function is directly related to the proximal radioulnar joint.

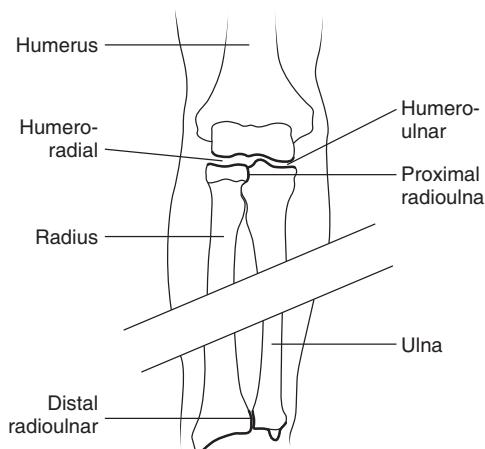

FIGURE 18.1 Bones and joints of the elbow and forearm.

JOINTS OF THE ELBOW AND FOREARM

There are four joints involved in elbow and forearm function: the humeroulnar, humeroradial, proximal radioulnar, and distal radial ulnar joints.

Elbow Joint Characteristics and Arthrokinematics

The elbow is a compound joint with a lax joint capsule, supported by two major ligaments—the medial (ulnar) and lateral (radial) collateral—which provide medial and lateral stability, respectively.^{13,37,59,67}

Humeroulnar Articulation

Characteristics. The humeroulnar (HU) articulation is a modified hinge joint. The medially placed hourglass-shaped trochlea at the distal end of the humerus is convex. It faces anteriorly and downward 45° from the shaft of the humerus. The concave trochlear fossa, on the proximal ulna, faces upward and anteriorly 45° from the ulna (see Fig. 5.27). The primary motion at this articulation is flexion and extension

Arthrokinematics. During flexion/extension the concave fossa slides in the same direction in which the ulna moves, so with elbow flexion the fossa slides around the trochlea in an anterior and distal direction. With elbow extension, the fossa slides in a posterior and proximal direction.

There is also slight medial and lateral sliding of the ulna, allowing for full elbow range of motion (ROM); it results in a valgus angulation of the joint with elbow extension and a varus angulation with elbow flexion. When the bone moves in a medial/lateral direction, the trochlear ridge provides a convex surface, and the trochlear groove provides a concave surface—so with varus the ulna slides in a lateral direction and with valgus the ulna slides in a medial direction.

The arthrokinematics are summarized in Box 18.1.

Humeroradial Articulation

Characteristics. The humeroradial (HR) articulation is a hinge-pivot joint. The laterally placed, spherical capitulum at the distal end of the humerus is convex. The concave bony partner, the head of the radius, is at the proximal end of the radius. Flexion/extension and pronation/supination occur at this articulation.

BOX 18.1 Summary of Joint Arthrokinematics of the Elbow and Forearm Joints

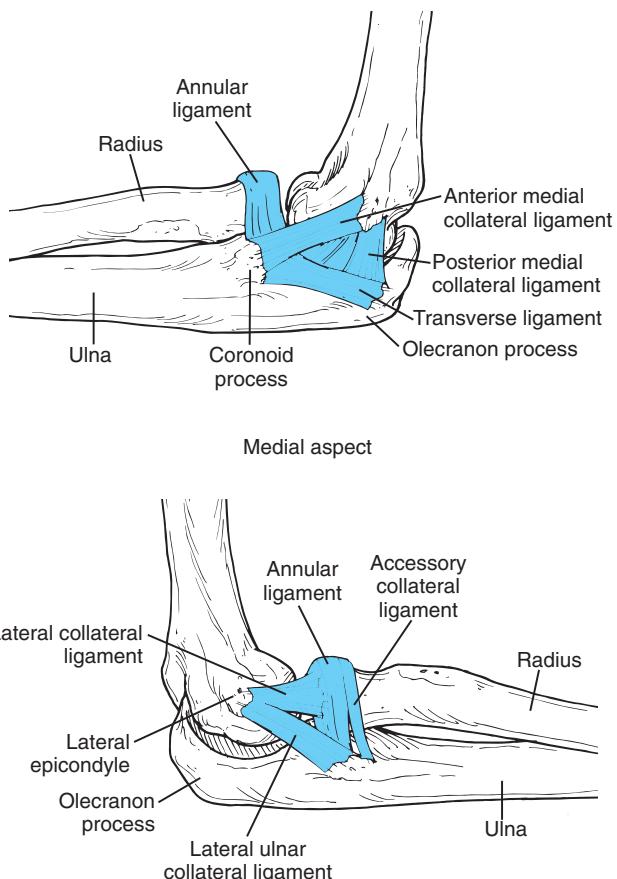

Physiological Motion	Roll	Slide
<i>Humeroulnar articulation</i>	<i>Motion of ulnar joint surface</i>	
Flexion	Anterior	Distal/anterior
Extension	Posterior	Proximal/posterior
<i>Humeroradial articulation</i>	<i>Motion of radial joint surface</i>	
Flexion	Anterior	Anterior
Extension	Posterior	Posterior
<i>Forearm varus</i>	<i>Motion of proximal forearm</i>	
	Medial	Lateral
<i>Forearm valgus</i>	<i>Motion of proximal forearm</i>	
	Lateral	Medial
<i>Proximal radioulnar joint</i>	<i>Motion of rim of radial head</i>	
Pronation	Anterior	Posterior (dorsal)
Supination	Posterior	Anterior (volar)
<i>Distal radioulnar joint</i>	<i>Motion of distal radial joint surface</i>	
Pronation	Anterior	Anterior
Supination	Posterior	Posterior

Arthrokinematics. As the elbow flexes and extends, the concave radial head slides in the same direction as the bone motion so with elbow flexion the concave head slides anteriorly and with elbow extension it slides posteriorly. With pronation and supination of the forearm, the radial head spins on the capitulum (see Box 18.1).

Ligaments of the Elbow

Medial (ulnar) collateral ligament. The medial collateral ligament complex consists of bundles of fibers that may be differentiated into anterior, posterior, and transverse portions (Fig. 18.2A). Various portions of the ligament are taut in different ROMs, providing medial support to the elbow against valgus stresses and limiting end-range elbow extension. The ligament also keeps the joint surfaces in approximation.^{59,67} Activities such as throwing and golfing impose significant stresses to the medial collateral ligament complex.

Lateral (radial) collateral ligament. The lateral collateral ligament complex, a fan-shaped ligament on the lateral surface of the elbow, is composed of the lateral collateral ligament, the lateral ulnar collateral ligament, and the annular ligament.⁵⁹ This complex provides stability to the lateral aspect of the elbow against varus forces and prevents posterior translation of the radial head (Fig. 18.2B).

B Lateral aspect

FIGURE 18.2 (A) The three parts of the medial (ulnar) collateral ligament are shown on the medial aspect of the right elbow. The musculature and joint capsule have been removed to show the ligament's attachments. (B) The lateral collateral ligament complex includes the lateral (radial) collateral ligament, lateral ulnar collateral ligament, and annular ligament. The musculature and joint capsule have been removed to show the ligaments' attachments. (From Norkin, with permission.)

Forearm Joint Characteristics and Arthrokinematics

Both the proximal and distal radioulnar joints are uniaxial pivot joints that function together to produce pronation and supination (rotation) of the forearm.^{13,37,59,67}

Proximal (Superior) Radioulnar Articulation

The proximal radioulnar (RU) articulation is within the capsule of the elbow joint but is a distinct articulation.

Characteristics. The convex rim of the radial head articulates with the concave radial notch on the ulna and the annular ligament. This ligament encircles the rim of the radial head and stabilizes it against the ulna. The primary motion is pronation/supination.

Arthrokinematics. As the forearm rotates into pronation and supination, the convex rim of the radial head slides opposite the bone motion, so with pronation the head slides posteriorly (dorsally) on the radial notch and with supination it slides anteriorly (volarly). It also slides in the annular ligament (see Fig. 18.2), and the proximal surface spins on the capitulum (see Box 18.1).

Distal (Inferior) Radioulnar Articulation

Characteristics. The distal RU joint is an anatomically separate joint at the distal end of the radius and ulna. The concave ulnar notch on the distal radius articulates with the convex notch on the head of the ulna. It, along with the proximal RU joint, participates primarily in pronation/supination.

Arthrokinematics. As the forearm rotates, the concave radius slides in the same direction as the physiological motion. It slides anterior (volar) with pronation and posterior (dorsal) with supination (see Box 18.1).

MUSCLE FUNCTION AT THE ELBOW AND FOREARM

Primary Actions at the Elbow and Forearm

Elbow Flexion

Brachialis. The brachialis is a one-joint muscle that inserts close to the axis of motion on the ulna, so it is unaffected by the position of the forearm or the shoulder; it participates in all flexion activities of the elbow.^{13,59,67}

Biceps brachii. The biceps is a two-joint muscle that crosses both the shoulder and elbow and inserts close to the axis of motion on the radius, so it also acts as a supinator of the forearm. It functions most effectively as a flexor of the elbow between 80° and 100° of flexion. For the optimal length–tension relationship, the shoulder extends to lengthen the muscle when it contracts forcefully for elbow and forearm function.^{13,59,67}

Brachioradialis. With its insertion a great distance from the elbow on the distal radius, the brachioradialis mainly functions to provide stability to the joint. However, it also participates as the speed of flexion motion increases and a load is applied with the forearm from mid-supination to full pronation.^{13,59,67}

Elbow Extension

Triceps brachii. The long head of the triceps brachii crosses both the shoulder and elbow; the other two heads are uniaxial. The long head functions most effectively as an elbow extensor if the shoulder simultaneously flexes. This maintains an optimal length–tension relationship in the muscle.^{59,67}

Anconeus. The anconeus muscle stabilizes the elbow during supination and pronation and assists in elbow extension.^{59,67}

Forearm Supination

Supinator. The proximal attachment of the supinator at the annular and lateral collateral ligaments may function to stabilize the lateral aspect of the elbow. Its effectiveness as a supinator is not affected by the elbow position as is the biceps brachii.⁶⁹

Biceps brachii. The biceps muscle acts as a supinator if the elbow simultaneously flexes or if resistance is given to supination when the elbow is in extension.¹⁰

Brachioradialis. The brachioradialis contributes to pronation and supination only as an accessory muscle when resistance is provided to the motion.¹⁰ It cannot function alone as a rotator or stabilizer of the forearm joints when other forearm muscles are paralyzed.⁶⁷

Forearm Pronation

Pronator teres. The pronator muscle pronates as well as stabilizes the proximal radioulnar joint and helps approximate the humeroradial articulation.⁵⁹

Pronator quadratus. The pronator quadratus is a one-joint muscle and is active during all pronation activities.

Relationship of Wrist and Hand Muscles to the Elbow

Many muscles that act on the wrist and hand are attached on the distal portion (epicondyles) of the humerus. This allows for movement of the fingers and wrist, whether the forearm is in pronation or supination. The muscles provide stability to the elbow but contribute little to motion at the elbow. The position of the elbow affects the length–tension relationship of the muscles during their actions on the wrist and hand.⁵⁹

Wrist Flexor Muscles. Originating on the *medial epicondyle* are the flexor carpi radialis, flexor carpi ulnaris, palmaris longus, and flexor digitorum superficialis and profundus.

Wrist Extensor Muscles. Originating on the *lateral epicondyle* are the extensor carpi radialis longus and brevis, extensor carpi ulnaris, and extensor digitorum.

REFERRED PAIN AND NERVE INJURY IN THE ELBOW REGION

For a detailed description of referred pain patterns and injuries to the peripheral nerves coursing through the elbow and forearm region, see Chapter 13. Table 13.1 in Chapter 13 summarizes the muscle involvement and functional loss that occurs with each of the nerve injuries.

Common Sources of Referred Pain into the Elbow Region

Symptoms referred from the C5, C6, T1, and T2 nerve roots cross the elbow region but are not usually isolated in the elbow.

Nerve Disorders in the Elbow Region

Ulnar nerve. The ulnar nerve courses posteromedial to the olecranon process in the cubital tunnel, which is the most common site for compression of this nerve in the elbow region.

Radial nerve. The radial nerve pierces the lateral muscular septum anterior to the lateral epicondyle and passes under the origin of the extensor carpi radialis brevis and then divides into a superficial and deep branch. Entrapment of the deep branch may occur under the edge of the extensor carpi radialis brevis, or injury may occur with a radial head fracture. The superficial branch may receive direct trauma as it courses along the lateral aspect of the radius.

Median nerve. The median nerve courses the elbow region deep in the cubital fossa, medial to the tendon of the biceps

and brachial artery, where it is well protected. The nerve then progresses between the ulnar and humeral heads of the pronator teres muscle and dips under the flexor digitorum profundus muscle. Entrapment may occur between the heads of the pronator muscle, mimicking carpal tunnel syndrome.

MANAGEMENT OF ELBOW AND FOREARM DISORDERS AND SURGERIES

In order to make sound clinical decisions when treating patients with elbow and forearm disorders with conservative interventions or after surgery, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting impairments, functional limitations, and possible disabilities. In this section pathologies and surgical procedures are presented and related to the corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*³ (Table 18.1). Conservative and postoperative guidelines for managing these conditions are described in this section.

TABLE 18.1 Elbow and Forearm Pathologies/Surgical Procedures, and Preferred Practice Patterns

PATHOLOGY/SURGICAL PROCEDURE	PREFERRED PRACTICE PATTERN AND ASSOCIATED IMPAIRMENTS ³
<ul style="list-style-type: none"> • Arthritis (rheumatoid arthritis, traumatic arthritis, osteoarthritis) • Postimmobilization arthritis (stiff joint) • Joint instability (subluxation, dislocation) • Overuse syndromes (lateral epicondylitis, medial epicondylitis) • Myositis ossificans (heterotopic bone formation) 	<ul style="list-style-type: none"> • Pattern 4D—impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
<ul style="list-style-type: none"> • Acute arthritis • Acute “pulled elbow,” distal subluxation of radius 	<ul style="list-style-type: none"> • Pattern 4E—impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
<ul style="list-style-type: none"> • Fracture (nondisplaced distal humerus, proximal radius, proximal ulna fractures—closed reduction) 	<ul style="list-style-type: none"> • Pattern 4G—impaired joint mobility, muscle performance, and ROM associated with fracture
<ul style="list-style-type: none"> • Total elbow arthroplasty—linked and unlinked • Excision of the radial head with prosthetic implant • Interposition arthroplasty 	<ul style="list-style-type: none"> • Pattern 4H—impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
<ul style="list-style-type: none"> • Open reduction and internal fixation of displaced/communited elbow fracture-dislocations • Resection of the radial head without implant • Synovectomy • Ligament repair/reconstruction • Capsulotomy • Arthrodesis 	<ul style="list-style-type: none"> • Pattern 4I—impaired joint mobility, motor function, muscle performance, and ROM associated with bony or soft tissue surgery
<ul style="list-style-type: none"> • Median, ulnar, or radial nerve entrapment or injury in the elbow/forearm region 	<ul style="list-style-type: none"> • Pattern 5F—impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

JOINT HYPOMOBILITY: NONOPERATIVE MANAGEMENT

Related Pathologies and Etiology of Symptoms

Pathologies such as rheumatoid arthritis (RA), juvenile rheumatoid arthritis (JRA), and degenerative joint disease (DJD) as well as acute joint reactions after trauma, dislocations, or fractures affect this joint complex. Postimmobilization contractures and adhesions develop in the joint capsule and surrounding tissues any time the joint is immobilized in a cast or splint. This typically occurs after dislocations and fractures of the humerus, radius, or ulna. The reader is referred to Chapter 11 for background information on arthritis and fractures.

Common Impairments

Acute stage. When symptoms are acute, joint effusion, muscle guarding, and pain restrict elbow flexion and extension, and there is usually pain at rest. If pronation and/or supination are restricted after an acute injury, other conditions such as fracture, subluxation, or dislocation may be present.²⁰ These conditions require medical intervention.

Subacute and chronic stages. A capsular pattern usually exists in the subacute or chronic stages. Elbow flexion is more restricted than extension. There is a firm end-feel and decreased joint play. In long-standing arthritis at the elbow, pronation and supination also become restricted with a firm end-feel and decreased joint play in the proximal RU joint.²⁰ Arthritis in the distal RU joint results in pain on overpressure.

Common Functional Limitations/Disabilities

- Difficulty turning a doorknob or key in the ignition
- Difficulty or pain with pushing and pulling activities, such as opening and closing doors
- Restricted hand-to-mouth activities for eating and drinking and hand-to-head activities for personal grooming and using a telephone
- Difficulty or pain with pushing self up from a chair
- Inability to carry objects with a straight arm
- Limited reach

Joint Hypomobility: Management— Protection Phase

See guidelines for management related to the stages of tissue healing in Chapter 10, Box 10.1.

Educate the Patient

- Inform the patient regarding the anticipated length of acute symptoms and teach methods of joint protection

and how to modify activities of daily living (ADL). For example, the patient should avoid activities that involve lifting or pushing off with the involved upper extremity.

- Instruct the patient to avoid excessive fatigue by performing exercises frequently during the day but limiting the number of repetitions during each bout (set) of exercises.

Reduce Effects of Inflammation or Synovial Effusion and Protect the Area

- Immobilization in a sling provides rest to the part, but complete immobilization can lead to joint hypomobility, contractures, and limited motion; therefore, frequent periods of controlled movement within a pain-free range should be performed.

NOTE: Often the elbow is immobilized in 90° flexion. The position of relative extension (20° to 30° flexion) is used to prevent or treat ulnar neuropathy by preventing positions that could aggravate the ulnar nerve already at risk in the cubital tunnel because of joint swelling. The somewhat extended position and use of a posterior splint bubbled out around the cubital tunnel deepen the cubital tunnel, thereby reducing pressure on the ulnar nerve.¹¹

- Gentle grade I or II distraction and oscillation techniques in the resting position may inhibit pain and move synovial fluid for nutrition in the involved joints (see Chapter 5 for principles of application and techniques).

Maintain Soft Tissue and Joint Mobility

- Passive or active-assistive ROM within limits of pain, including flexion/extension and pronation/supination
- Multiple-angle muscle setting of elbow flexors, extensors, pronators, and supinators and wrist flexors and extensors in pain-free positions

Maintain Integrity and Function of Related Areas

- Shoulder, wrist, and hand ROM and activities should be encouraged within the tolerance of the individual.
- If edema develops in the hand, the arm should be elevated whenever possible and distal-to-proximal massage techniques applied.

Joint Hypomobility: Management— Controlled Motion Phase

If joint hypomobility exists, ROM is increased by utilizing joint mobilization techniques as well as passive stretching and muscle inhibition techniques following the principles described in Chapters 4 and 5. Box 18.2 highlights several important precautions if joint restrictions are related to trauma.

Increase Soft Tissue and Joint Mobility

Initiate stretching cautiously and note the joint and tissue response. Vigorous stretching should not be undertaken

BOX 18.2 Precautions Following Traumatic Injury to the Elbow

- If the brachialis muscle is injured, ossification of the injured tissue is a potential complication, and stretching is contraindicated.
- After healing of fractures in the forearm, malunion is not unusual, preventing full range of pronation or supination. A bony block end-feel or an abnormal appearance of the forearm should alert the therapist to the cause of this impairment. X-ray films are helpful in verifying the problem. No amount of stretching or mobilizing changes the patient's range. Indiscriminate stretching may lead to hypermobility of related joints, which could cause additional trauma and pain.

until the chronic stage of healing. As noted in Box 18.2, high-intensity stretching of the elbow flexors is contraindicated following trauma because of the potential for development of heterotopic bone formation.

- Passive joint mobilization techniques.** Because several articulations are involved with each motion at the elbow, it is important to identify which of the articulations have reduced joint play prior to applying grade III sustained or grade IV oscillation techniques. See Figures 5.28 through 5.33 and their descriptions in Chapter 5 for specific techniques to use. Progress each technique by positioning the joint at the end of its available range before applying the mobilization technique.

To progress joint mobility in the terminal ranges of flexion and extension, it may be necessary to emphasize the accessory motions of varus and valgus, respectively. This is accomplished with medial and lateral gliding techniques or with a varus or valgus physiological stretch at the elbow.

- Mobilization to reduce a “pushed elbow.”** Proximal subluxation of the radius may result from falling on an outstretched hand. The radial head is pushed proximally in the annular ligament and impinges against the capitulum. This injury sometimes accompanies a fracture of the distal radius (Colles' fracture) or scaphoid and is not identified as an impairment until after the fracture has healed and the cast is removed. It is often overlooked because there is considerable soft tissue and joint restriction caused by the period of immobilization. Bilateral palpation of the joint spaces reveals the decreased space on the involved side. There may be limited flexion or extension of the elbow, limited wrist flexion, and limited pronation.

Technique. If acute (and no fracture), distal traction is applied to the radius to reposition the radial head. If chronic, repetitive stretching with sustained grade III distal traction to the radius is necessary (see Fig. 5.29) in addition to the soft tissue stretching and strengthening techniques needed for increasing motion.

- Manipulation to reduce a “pulled elbow.”** Distal subluxation of the radius is usually seen as an acute injury in children and is sometimes labeled “tennis elbow” when it occurs in adults. It occurs as a result of a forceful pull on the hand such as would occur when a child jerks away from a parent or caregiver or a person tries to pick up a heavy object with a jerking motion on the handle. The force causes the radius to move distalward with respect to the ulna. The head of the radius is unable to slide proximally in the annular ligament when supination is attempted, resulting in the person holding the forearm in pronation. Supination is either restricted, or the patient guards against the motion.

Technique. A quick compressive manipulation with supination is applied to the radius (see Fig. 5.31) to reposition the radial head. If it is an initial injury, there may be soft tissue trauma from the injury, which is treated with cold and compression.

- Manual stretching and self-stretching.** Use manual stretching and inhibition techniques to increase the flexibility of any periarticular tissues that are restricting mobility. Use of a cuff weight placed around the distal forearm with the patient carefully positioned for an effective stretch provides a low-intensity, long-duration stretch and is an alternative to manual passive stretching (see Fig. 18.7 in the exercise section). If elbow ROM does not steadily improve after acute symptoms have subsided, the patient may need to begin wearing an adjustable, dynamic splint that applies a low-intensity stretch force over an extended period of time. These stretching interventions are described in Chapter 4.

- Home instructions.** Teach the patient self-stretching maneuvers followed by active exercise that utilize the new range. Suggestions are provided in the last section of this chapter.

Improve Joint Tracking of the Elbow

A mobilization with movement (MWM) technique consisting of a lateral glide combined with the active movement of flexion or extension and pain-free passive overpressure may improve articular surface tracking by allowing the muscles to move the joint in a painfree manner.⁵¹ (Refer to the principles of MWM in Chapter 5.)

Technique. Patient position and maneuver: Supine with elbow either flexed or extended to the end of the available range. A mobilization belt is secured around the proximal forearm and your hips. Stabilize the distal humerus at the olecranon process with one hand and support the forearm with the other. Apply a gentle lateral glide to the proximal ulna with the belt by moving your hips. Have the patient produce an active elbow flexion or extension movement and apply a passive overpressure stretch at the end of the range (Fig. 18.3). This should not elicit any pain.

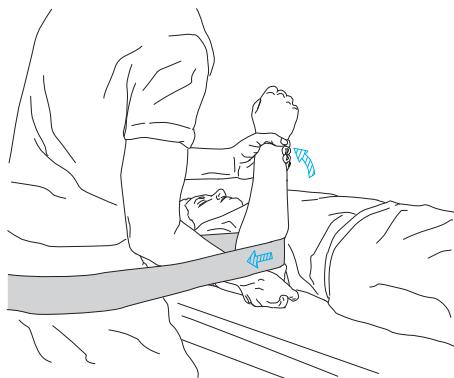

FIGURE 18.3 Mobilization with movement (MWM) to improve elbow flexion. A lateral glide is applied to the proximal ulna while the patient actively flexes, followed by a passive end-range stretch.

Improve Muscle Performance and Functional Abilities

Initiate active and light resistance exercises in open- and closed-chain positions to develop control, muscular endurance, and strength in the muscles of the elbow and forearm. As the patient improves, adapt the exercises to progress toward functional activities. Specific exercises are described in the exercise section of this chapter. Include the shoulder girdle, wrist, and hand in the exercise program as their flexibility and strength has an influence on the recovery of elbow function.

Joint Hypomobility: Management—Return to Function Phase

Improve Muscle Performance

Progress self-stretching and strengthening exercises as the joint tissue tolerates. Teach the patient safe progressions and exercise strategies that promote return to function. Use exercises that replicate the repetitions and demands of daily activities, such as pushing, pulling, lifting, carrying, and gripping, to prepare the joints and muscles for specific tasks. Chronic arthritic conditions may require modification of high-load activities to minimize deforming stresses.

Restore Functional Mobility of Joints and Soft Tissues

If restrictions remain, use vigorous manual or mechanical stretching and joint mobilization techniques.

JOINT SURGERY AND POSTOPERATIVE MANAGEMENT

Intra-articular or extra-articular surgical intervention is often necessary for management of severe fractures or dislocations that affect the joints of the elbow and surrounding soft tissues. These injuries may require open reduction with internal fixation or arthroscopic or open excision of bone fragments. In adults, the most common fracture in

the elbow region is a fracture of the head and neck of the radius. This type of fracture accounts for approximately one-third of all elbow fractures.⁹ This injury usually occurs when a person falls on an outstretched hand when the elbow is extended, causing a posterior dislocation and fracture of the radial head coupled with injury of elbow ligaments.²⁶

If the proximal radius is displaced and the radial head fracture is comminuted, either open or occasionally arthroscopically assisted reduction with internal fixation or a radial head excision (resection) with or without prosthetic implant is a surgical option.^{26,45,49,50} It has been suggested that rigid internal fixation (screws or plate fixation) of radial head fractures is indicated in the young, active adult, whereas excision of the radial head is more appropriate for the low-demand patient or if the fracture is severely comminuted and fixation is not possible.³⁴ Box 18.3 summarizes the advantages and disadvantages of surgical options for management of displaced fractures of the radial head. Radial head fractures are relatively uncommon in children. When they do occur, closed reduction is preferred.⁶⁸

BOX 18.3 Surgical Options for Displaced Fractures of the Radial Head

Open Reduction and Internal Fixation

- **Advantages:** Achieves stabilization and fixation of multiple fracture fragments with normal or near-normal alignment; ability to repair significant ligamentous damage; early postoperative motion permissible unless reconstruction of ligaments required
- **Disadvantages:** Extensive soft tissue disruption and arthrotomy required; not amenable to nonreconstructible fractures and less practical than radial head excision for severely comminuted fractures

Arthroscopic or Arthroscopically Assisted Reduction and Internal Fixation

- **Advantages:** Allows arthroscopic evaluation of the joint and débridement of fracture debris; if fully arthroscopic, no arthrotomy, less soft tissue disturbance, less postoperative pain, better cosmetic outcome
- **Disadvantages:** Limited to reduction and fixation of no more than two-part displaced fractures; not appropriate for radial neck fractures; if fully arthroscopic, fixation techniques more technically difficult (e.g., use of percutaneous screw fixation) than open procedure

Excision of the Radial Head

- **Advantages:** Only option for severely comminuted, non-reconstructible fractures; no potential for mechanical blockage of joint motion from malalignment of fracture fragments or internal fixation; early ROM permissible
- **Disadvantages:** Requires arthrotomy; may compromise joint stability if a prosthetic implant is not used

Early-stage or long-standing joint disease (RA, JRA, post-traumatic arthritis) associated with synovial proliferation and destruction of articular surfaces of the elbow joints and leading to pain, limitation of motion, and impaired upper extremity function also may need to be managed with extra-articular or intra-articular surgery. For example, with early-stage RA in which synovial proliferation is present but joint surfaces are still in good condition, *arthroscopic or open synovectomy* is the procedure of choice for relief of pain if medications have not controlled the disease.^{14,36,40} Occasionally, advanced arthritis is managed surgically by *interposition arthroplasty* (only in the young patient on a selective basis),^{18,62} *resection of the radial head* with or without prosthetic implant and concomitant synovectomy,^{17,25,50} or *arthrodesis*.⁶² However, today the most common surgical procedure used to manage severe destruction of the elbow joint is *total elbow arthroplasty*.^{14,17,18,25,41,51,62} Table 18.2 summarizes how the severity of joint disease and the extent of soft tissue involvement influence the choice of surgical procedure for the elbow complex.^{14,18,25}

The goals of surgery and postoperative rehabilitation of the elbow joint complex include^{18,54} (1) relief of pain, (2) restoration of bony alignment and joint stability, and (3) sufficient strength and ROM to allow functional use of the elbow and upper extremity. Surgical procedures done to relieve pain and improve elbow stability tend to be more successful than procedures done solely to increase ROM. Heterotopic bone formation, which leads to joint stiffness, is often a complication of elbow fractures, dislocations, and elbow joint surgery.⁴⁷ Therefore, the single goal of improving ROM is rarely an indication for surgery.^{18,45}

Excision of the Radial Head

Indications for Surgery

- Severe comminuted fractures of the distal humerus or fracture-dislocations of the head of the radius that cannot be reconstructed and held in place with internal fixation^{16,45,49}

- Chronic synovitis and mild deterioration of the articular surfaces associated with arthritis of the humeroradial and proximal radioulnar joints resulting in joint pain at rest or with motion, possible subluxation of the head of the radius, and significant loss of upper extremity function^{18,25,50}

Contraindication to surgery: Excision of the radial head is contraindicated in the growing child.⁶⁸

Procedure

Background

Selection of procedure. Depending on the integrity of the ligaments and stability of the joint, with a radial head excision procedure the head of the radius may or may not be replaced with a prosthetic implant. The use of a prosthetic implant is indicated when there is clinical instability of the elbow as the result of disruption of the supporting ligaments.^{25,49,50}

Implant design and material. Radial head implants originally were flexible and made of silicone (Silastic material).^{18,50} However, this material is no longer used because it has been associated with fatigue failure, particulate debris, and the development of adverse biological reactions, specifically inflammatory arthrosis (synovitis) of the humeroulnar joint.⁷² Today, rigid, modular (two-piece) implants, made of metal (cobalt-chrome and titanium), ceramics, or ultra-high molecular weight polyethylene, are being used and investigated.^{30,49,50} However, the optimal radial head implant has yet to be designed and fabricated.

Overview of Operative Procedure

A lateral triceps-sparing incision at the elbow and forearm is made into the joint (arthrotomy) just anterior to the lateral collateral ligament. The radial head is exposed, and a radial osteotomy is performed at the level of the annular ligament to resect the head. When exposing the operative field, effort is made not to detach intact ligaments. A concomitant synovectomy is done if proliferative synovitis is present (typically seen in RA and JRA).

TABLE 18.2 Severity of Elbow Joint Disease and Selection of Surgical Procedure

Severity of Joint Disease	Selection of Surgical Procedure
<ul style="list-style-type: none"> Mild synovitis; joint surfaces normal or minimally deteriorated; osteoporosis Moderate synovitis; some loss of articular cartilage; narrowing of joint space but joint contour maintained Moderate to severe synovitis; loss of articular cartilage; loss of joint space; intact collateral ligaments Severe synovitis; destruction of articular cartilage; complete loss of joint space (bone-to-bone articulation); significant joint instability; bone loss; ankylosis 	<ul style="list-style-type: none"> Nonoperative/medical management Arthroscopic synovectomy or resection of the radial head with synovectomy Resurfacing total elbow arthroplasty or, possibly in a growing child, an interpositional arthroplasty Semiconstrained total elbow arthroplasty

If an implant is to be inserted, the medullary canal of the radius is prepared to accept the stem of the prosthesis. If the elbow is unstable, ligamentous structures are repaired. If the lateral ulnar collateral ligament (LUCL) is insufficient, it may be reinforced with a palmaris longus autograft or allograft. To prevent injury to the ulnar nerve or if symptoms of compression are present, ulnar nerve transposition is also performed.^{25,49,50}

Postoperative Management

The goals and interventions, the rate of progression, and the length of the rehabilitation program, as well as final outcomes, are highly dependent on the extent of damage to soft tissues from injury or chronic inflammation, the integrity of repaired soft tissues particularly the supporting ligaments of the elbow complex, the philosophy of the surgeon, and the patient's expectations of the surgery and response to treatment.^{44,78}

Immobilization

The elbow is immobilized continuously in a well-padded posterior resting splint in a position of 90° of flexion and mid-position of the forearm after surgery.^{49,50} When elbow motion is permissible (often as early as 1 to 3 days after surgery or longer if significant reconstruction of ligaments was necessary), the splint is removed for exercise but is replaced after exercise and worn at night for an extended period of time to protect healing tissues. If the stability of the elbow is in question, the patient may need to wear a dynamic (hinged) splint for ROM exercises.

Exercise: Maximum Protection Phase

Goals and interventions.^{9,44,49,50,78} The first phase of rehabilitation focuses on patient education that emphasizes wound care, control of pain and peripheral edema, and exercises to offset the adverse effects of immobilization while protecting repaired soft tissues that maintain the stability of the elbow. The arm is elevated for comfort and to control edema distally.

- **Maintain mobility of unoperated joints.** Active ROM exercises of the shoulder, wrist, and hand immediately after surgery.
- **Maintain mobility of the elbow and forearm.** When permitted, have the patient remove the splint several times daily for self-ROM (passive or active-assisted) of the elbow and forearm within pain-free ranges. Active ROM is allowed within a week after exercises are initiated. As noted previously, some patients must wear a hinged splint for additional stability during ROM exercises.

PRECAUTION: Some specific motions initially may need to be restricted to prevent excessive stress on recon-

structed ligaments. Restrictions vary depending on the extent of ligament disruption and which ligaments were repaired. For example, if the lateral collateral complex was repaired, supination is limited to 20° during the early weeks of rehabilitation.²⁶

- **Minimize muscle atrophy.** Submaximal, pain-free, multiple-angle setting exercises of elbow and forearm musculature.

Exercise: Moderate and Minimum Protection Phases

Goals and interventions.⁹ The intermediate phase of rehabilitation begins when wound healing is satisfactory and active movements of the elbow are relatively pain-free. This phase and the final phase of rehabilitation are characterized by continued efforts to restore nearly full or at least sufficient ROM for functional activities while maintaining stability of the elbow. Exercises to improve upper extremity strength and muscular endurance and use of the involved elbow for light functional activities are introduced and progressed.

NOTE: Some surgeons and therapists prefer to improve strength and endurance solely through ADL, that is, without the use of specific resistance exercises.^{44,49,50}

- **Increase ROM,** particularly if contractures were noted preoperatively.
 - Gentle (low-intensity) manual stretching or self-stretching using inhibitory elongation techniques.
 - Grade II joint mobilization techniques initially, followed by grade III mobilizations after 6 weeks when the joint capsule is well healed.

CONTRAINDICATION: When applying joint mobilization techniques, do not perform valgus/varus stretches in terminal extension/flexion, particularly if the radial head was not replaced with a prosthetic implant or if the integrity of the supporting ligaments and stability of joints are questionable.

- Low-load, long-duration, dynamic splinting or alternating use of static splints in maximum flexion and extension.
- **Improve functional strength and muscular endurance.**
 - Low-load resistance exercises (maximum 1 to 2 lb), emphasizing high repetitions.
 - Use of the operated upper extremity for *light* ADL.

PRECAUTION: Be certain the patient knows to avoid using the involved upper extremity for moving or holding heavy objects.

Outcomes

The anticipated outcomes after resection of the radial head for a severely displaced and comminuted fracture or advanced arthritis are a stable elbow and pain-free movement (flexion/extension and pronation/supination) within functional ranges.^{26,49,50} Short-term postoperative results of excision arthroplasty with and without implant are similar with regard to relief of pain and functional motion. However, patients with preoperative instability necessitating an implant and those with a tenuous repair of ligamentous structures have less satisfactory results than those with a stable elbow. If preexisting contractures exists, ROM does not necessarily improve.

Some patients may develop complications causing elbow pain, such as a slight increase (about 5° to 10°) in valgus laxity of the elbow, without complaints of instability during functional activities if ligaments are intact. Others may develop pain and instability. In a recent study,³¹ posterolateral rotary instability was identified associated with a deficient lateral ulnar collateral ligament was identified at a mean of 44 months in only 16.6% of patients (7 of 42) who reported lateral elbow pain and a sense of instability or weakness after radial head resection (without implant). Another complication, slight proximal migration of the radius, may occur if resection does not include implantation of a prosthetic radial head. This complication may or may not be associated with wrist pain.⁴⁹

Most long-term studies of excision with prosthetic implant have evaluated the results of procedures using flexible components made of silicone, which, as previously noted, have been shown to be associated with material fatigue or inflammatory responses and have led to premature failure. Short-term outcomes after current-day procedures, using rigid implants, are promising, but long-term results are not yet available.⁵⁰ In patients with chronically active arthritis, synovitis eventually recurs necessitating another synovectomy or a total elbow arthroplasty. Regardless of the underlying pathology, patients who have undergone excision of the radial head with or without a prosthetic implant must permanently refrain from high-demand or high-impact, work-related or recreational activities.⁴⁴

Total Elbow Arthroplasty

Indications for Surgery

Since the early use of total elbow arthroplasty (TEA) several decades ago,²¹ the indications for this procedure have broadened considerably as the design of prosthetic implants and surgical techniques have evolved. The following are currently accepted indications for TEA.

- Severe joint pain and articular destruction of the humeroulnar and humeroradial joints, resulting in loss of functional use of the upper extremity.^{18,25,62} Underlying conditions managed with total elbow arthroplasty include RA (by far the most common pathology),^{19,25,26,28,41,48,51,53} JRA,¹⁷ and post-traumatic degenerative arthritis.^{19,52,65}
- Gross instability of the elbow.^{26,35,63}
- Acute intra-articular, comminuted fractures^{16,19} and nonunion fractures of the distal humerus.^{48,54}
- Failed interposition arthroplasty or radial head resection.⁶⁴
- Marked bilateral limitation of motion of the elbows.^{18,19,48}

Absolute and relative contraindications for total elbow arthroplasty are identified in Box 18.4.^{19,25,41,51} It is important to note, however, with the exception of active infection there is lack of agreement as to which contraindications are absolute versus relative.

BOX 18.4 Contraindications to Total Elbow Arthroplasty

Absolute

- The presence of active (acute or subacute) infection
- Inadequate control (paralysis) of elbow musculature, particularly the elbow flexors

Relative

- Irreparable supporting ligaments
- Inadequate control of elbow extensors
- Heterotopic ossification or pain-free ankylosis
- Insufficient bone stock
- A young patient, particularly one who needs to lift heavy loads

Procedure

Background

The complex structural relationships among the HU, HR, and proximal RU joints have made developing a prosthetic elbow joint a challenging task. Since the first cemented total replacement of the elbow in 1972,²¹ incremental improvements in design, materials, fixation, and surgical technique have contributed to increasingly predictable and successful outcomes.^{18,62} Elbow replacement systems include a humeral and an ulnar implant (Fig. 18.4), and some designs also include replacement of the head of the radius.^{41,48,51}

**A****B**

FIGURE 18.4 (A) Anteroposterior and (B) lateral radiographs following placement of a Conrad-Morrey (linked/semitconstrained) total elbow arthroplasty. (From Field and Savoie,²⁶ with permission.)

Implant design and selection considerations. Early designs were *hinged* (*linked*, *articulated*) and *fully constrained* metal-to-metal humeral and ulnar implants that allowed only flexion and extension of the elbow joint.^{18,51,62} These designs made no allowances for normal varus and valgus and rotational movements, and hence the implants rapidly loosened at the bone–cement interface. Metal fatigue at the linkage of the prosthetic components and joint dislocation were also common complications.^{7,18,29,62} As more accurate information about the biomechanical characteristics of the elbow joint became known, the design of prosthetic replacements evolved. In addition to an arc of flexion and extension, contemporary designs provide 5° to 10° of varus and valgus and a small degree of rotation (Fig. 18.5).⁵¹

The designs of total elbow replacement can be classified into two broad categories: *linked* (*articulated*) and *unlinked* (*nonarticulated*).⁷ Rather than being fully constrained, as the early components were, linked humeral and ulnar implants are now loosely constrained and, as such, are referred to as *semiconstrained* designs.^{28,48,51,65} Designs classified as unlinked are composed of two separate, nonarticulated implants and are often called *resurfacing* replacements.^{7,19,24,41} The most recent advance in implant design is the *hybrid* prosthesis, which can be inserted as either a linked or unlinked replacement system. Use of a hybrid replacement enables the surgeon to determine the

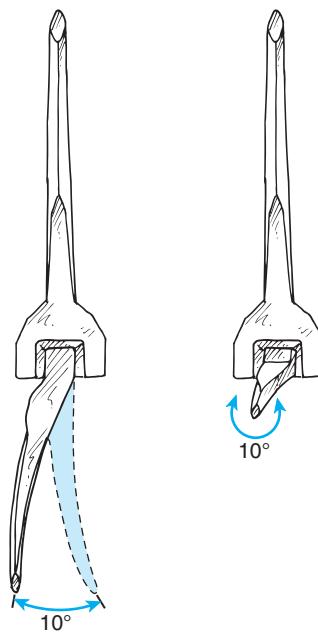

FIGURE 18.5 A linked, semiconstrained design is characterized by varus-valgus and axial rotation tolerances of several degrees at the articulation. (From Morrey, BF [ed] *The Elbow and Its Disorders*, ed 3. WB Saunders, Philadelphia, 2000, p 617, with permission from the Mayo Clinic Foundation.)

more appropriate design based on intraoperative observations and evaluation.⁷

The criteria for use of a linked or unlinked TEA is based in part on the characteristics of these designs with respect to stability. Linked designs derive inherent stability from one or two pins, which couple the humeral and ulnar components.⁴⁸ In addition, some semiconstrained designs have an anterior flange to enhance joint stability and decrease the risk of posterior dislocation.⁵¹ Unlinked implant systems, although sometimes referred to as non-constrained,⁴⁴ actually have varying degrees of constraint built into their designs based on the degree of congruency of the articulating surfaces.^{19,24,41} The less constraining the articular surfaces of the implants, the more reliant the replacement system is on the surrounding soft tissues, particularly the collateral ligaments, for joint stability.

Overall, linked designs, because of their inherent stability, are considered appropriate for use with a broader spectrum of patients, including those with unstable elbows, than unlinked designs. Although both linked and unlinked designs derive some degree of stability from the supporting capsuloligamentous structures and elbow musculature, the integrity of these soft tissues is far more critical for successful use of unlinked than linked designs.^{7,44,48}

In addition to considerations related to stability, the etiology and extent of joint destruction, the degree of deformity, the quality of the available bone stock, and the training and experience of the surgeon are factors that influence the type of replacement system used.

Materials and fixation. A stemmed titanium humeral component that has a cobalt-chrome alloy articulating surface interfaces with a high-density polyethylene articulating surface of a stemmed ulnar component.^{7,18} Currently, prosthetic components are cemented in place with polymethylmethacrylate, an acrylic cement. Some designs also have a porous-coated extramedullary flange for osseous ingrowth. To date, all-cementless fixation has not yet been developed for total elbow arthroplasty.^{18,62} Despite improvements in fixation, loosening of the implants at the bone–cement interface continues to be a cause of failure of elbow arthroplasty.⁸

Overview of Operative Procedure

The following is a brief overview of typical elements involved in a TEA.^{19,41,48,51,52,65} A longitudinal incision is made at the posterior aspect of the elbow, either slightly lateral or medial to the olecranon process. The distal attachment of the triceps is typically detached and reflected (*triceps-reflecting approach*) or split longitudinally and retracted along the midline (*triceps-splitting approach*).⁵¹ The more recently developed *triceps-sparing approach* is used occasionally. It involves incisions on the medial and lateral aspects of the elbow joint. This approach preserves

the attachment of the triceps tendon on the olecranon but makes insertion of the implants more technically difficult.⁸

As the procedure progresses, the ulnar nerve is isolated, temporarily displaced, protected throughout the procedure, and possibly transposed. Ligaments and other soft tissues are released as necessary; the posterior aspect of the capsule is incised and retracted; and the joint is dislocated. In preparation for the implants, small portions of the distal humerus and proximal ulna are resected. Depending on the status of the radial head, the integrity of the collateral ligaments, and the design of the prosthesis, the head of the radius may or may not be resected. Then the intramedullary canals of the humerus and ulna and possibly the radius are prepared, and the components are inserted and cemented in place. The available ROM and stability of the prosthetic joint is checked intraoperatively. The capsule and any ligaments that had ruptured prior to surgery or were released during the procedure are repaired to the extent possible or necessary based on the design of the prosthesis and the quality of the structures. The extensor mechanism, if detached or split, is securely reattached or meticulously repaired.

Complications

Although the incidence of complications has steadily declined over the past few decades as selection of patients, prosthetic design, and surgical technique have improved, complications after TEA continue to occur more frequently than after total hip, knee, or shoulder arthroplasty.⁸ Complications are categorized as intraoperative, early postoperative (before 6 weeks), and late postoperative (after 6 weeks).⁶¹

Intraoperative complications, such as fracture and component malposition, can occur with TEA and significantly affect short- and long-term outcomes. In addition to infection, which is a concern after any surgery, early complications, including joint instability, wound healing problems, and triceps insufficiency, are of particular concern during the early and intermediate phases of rehabilitation. These complications also can occur several months or even years later, as can fracture, aseptic (biomechanical) loosening of the prosthetic implants over time at the bone–cement interface, and mechanical failure or premature wear of the components. Another complication, ulnar neuropathy, either transient or permanent, can occur intraoperatively or during the early weeks after surgery.^{8,29,61}

It is important for a therapist to be familiar with the incidence and possible causes of complications after TEA in order to effectively structure and progress a postoperative rehabilitation program that decreases at least some of the risk factors associated with these complications. The incidence and characteristics of selected complications (joint instability, triceps insufficiency, prosthetic loosening) after TEA and factors that contribute to these complica-

BOX 18.5 Analysis of Three Potential Complications after Total Elbow Arthroplasty
Joint Instability

- **Incidence.** One of the more common complications after TEA; predominantly a problem in unlinked arthroplasty,⁸ higher incidence with prior radial head resection.⁶⁴ Rates of instability in unlinked implants reported at 4% to 15% (mean 8%)⁴¹ and in linked implants at 0% to 14% (mean 3.5%).^{28,38,65}
- **Characteristics.** Early or late dislocation or subluxation of the prosthetic elbow; associated with pain and loss of function.
 - Disruption of a repaired LCL → posterolateral, rotary, and varus instability; disruption of a repaired MCL → posteromedial and valgus instability.
 - Disruption of triceps mechanism → diminished dynamic compressive forces across the joint.
- **Contributing factors.** Excessive release or inadequate or failed soft tissue repair → deficient static or dynamic stabilizers (possibly due to inadequate postoperative immobilization and excessive postoperative stresses across the elbow, particularly during the early postoperative period before soft tissue repairs have healed), malpositioning of implants, and long-term polyethylene wear of the ulnar component increase the risk of instability.^{8,41,61}

Triceps Insufficiency

- **Incidence.** Primarily occurs after surgical approaches that disrupt the triceps mechanism; occurs in both linked and unlinked arthroplasty, usually during the first postoperative year. Examples of rates of occurrence in retrospective studies reported at 1.8% of 887 elbows,¹⁵ 4% of 78 elbows,²⁸ and 11% of 28 elbows.³⁸ Higher risk in patients with previous elbow surgery before TEA.¹⁵

tions are summarized in Box 18.5.^{8,29,61} Precautions to reduce the risk of these and other complications are addressed in the following section on postoperative management.

Postoperative Management

The overall goal of rehabilitation after total elbow arthroplasty is to achieve pain-free ROM of the elbow joints as well as strength of the upper extremity sufficient for functional activities while minimizing the risk of early or late postoperative complications. This goal is best achieved with an individualized rehabilitation program based on a thorough examination of each patient's postoperative status.

Immobilization

Immediately after surgery a soft compression dressing is applied, and the arm is elevated to control peripheral edema. A well padded posterior or anterior splint is used to immobilize the elbow to maintain stability and protect structures as they heal.

- **Characteristics.** Partial or complete rupture, or avulsion, of the extensor mechanism (during the early or late postoperative period) → weakness (particularly in terminal extension), often posterior elbow pain, and difficulty with pushing activities and overhead functions, such as combing one's hair.
- **Contributing factors.** Occasionally postoperative trauma but most commonly a failed surgical reattachment or repair of a poor quality tendon; premature or excessive ROM or loads on the extensor mechanism during early rehabilitation or during long-term functional use of the arm.⁴¹

Implant Loosening

- **Incidence.** Occurs in linked more than unlinked implants. Overall rates are low but remain higher than after hip, knee, and shoulder arthroplasty.⁶¹ The more constrained the design, the greater the risk of loosening.
- Rate of clinical loosening of contemporary implants up to a 6-year follow-up has been reported to range from 0% to 6%.^{29,38,53,65}
- Rates of 0% reported in patients with RA over a mean follow-up of 3.8 years⁵³ and in patients with post-traumatic arthritis with a mean follow-up of 5 years.⁶⁵
- The incidence of radiologic loosening is consistently higher than clinical loosening (where the patient becomes symptomatic).
- **Characteristics.** Aseptic (biomechanical) loosening, a late complication, occurs at the bone–cement interface; clinical loosening associated with pain. Excludes loosening caused by infection.⁸
- **Contributing factors.** Inadequate cementing technique, implant malpositioning, and lack of adherence to postoperative activity modification. High-load, high-impact activities place patient at higher risk of loosening.

Position. The position of immobilization varies based on a number of factors, including the surgical approach, the implant design, and which soft tissues were repaired and require protection.^{6,19,25,44} If, for example, a triceps-reflecting approach was used for a linked TEA, the position typically selected is full or almost full elbow extension to protect the reattached triceps tendon and a neutral position of the forearm.^{6,19,48,51} In contrast, with an unlinked TEA, which typically requires repair of the lateral ligament complex because of preoperative damage or release for operative exposure of the joint, the position of immobilization is a moderate degree of flexion with limitation of full forearm supination to lessen stress on the repaired ligaments.^{6,61} If a patient had a significant preoperative elbow flexion contracture that was surgically released, an anterior splint may be selected with the elbow placed in the available amount of extension. An extended position is also indicated if symptoms of ulnar neuropathy are present to alleviate pressure in the cubital tunnel.^{48,51,61}

Duration. The period of continuous immobilization after surgery, which is kept as short as possible to avoid stiffness, also varies widely, ranging from 1 to 2 days to several weeks. This time period depends on the design of the prosthesis, the surgical approach, the integrity of ligamentous structures, wound healing, and intraoperative observations by the surgeon. In general, unlinked/resurfacing designs, which have little inherent stability, require a longer period of immobilization than linked/semiconstrained designs.^{8,25,44}

If there is increased risk of delayed wound healing because of poor skin quality or a patient's history of diabetes, smoking, or use of steroids, the elbow may be continuously maintained in extension for 10 to 14 days postoperatively to limit stress on the posterior incision.^{48,51,61} Even after it is permissible to remove the splint for exercise or self-care, the patient is advised to continue to wear the splint at night for protection for up to 6 weeks.^{6,44} If there was a preoperative flexion contracture, an adjustable splint that maintains the elbow in extension is worn periodically during the day for a prolonged stretch, and a static (resting) splint is worn at night to hold the arm in a comfortably extended position. This regimen may be followed for 8 to 12 weeks postoperatively to prevent recurrence of the contracture.^{44,48,51}

Exercise

The progression of a postoperative exercise program after a TEA varies considerably based on many factors. Key factors and their impact on postoperative rehabilitation are identified in Table 18.3.^{6,19,44,78} The rehabilitation process

proceeds most rapidly when a triceps-sparing approach has been used to insert a linked replacement in a patient whose incision is healing well. On the other end of the spectrum, in which rehabilitation must progress most cautiously, is the use of a triceps-reflecting approach for an unlinked replacement requiring release and repair of the lateral ligament complex in a patient with poor skin quality.

Just as the progression of exercise is based on the unique features of each patient's surgery, precautions are determined in a similar manner. It is particularly important for the therapist to know the status of repaired soft tissues to incorporate the necessary precautions into the exercise program. Information in the operative report and close communication with the surgeon are the best sources for these details. Specific precautions for exercise and functional use of the operated upper extremity are summarized in Box 18.6.^{6,44,48,78} Patient education about these precautions should occur throughout the rehabilitation program. A patient's adherence to precautions ensures more positive outcomes and lessens the likelihood of short- or long-term postoperative complications related to exercise and use of the operated arm for functional activities.

Exercise: Maximum Protection Phase

Goals and interventions. The focus during the first phase of rehabilitation, which extends approximately over a 4-week period, includes control of inflammation, pain, and edema with use of medication as needed, application of cold (often with a Cryocuff[®]) and regular elevation of the operated arm. Emphasis is also placed on careful inspec-

TABLE 18.3 Factors That Influence the Progression of Exercise After Total Elbow Arthroplasty

Factors	Impact on Rehabilitation
• Design of prosthesis: linked/semiconstrained vs. unlinked/resurfacing	• Earlier ROM and use of the operated upper extremity for light ADL with linked/semiconstrained replacements, which typically do not require ligament repair for joint stability
• Surgical approach: triceps-sparing vs. triceps-splitting or triceps-reflecting	• More protected, controlled motion during exercise and delayed use for ADL with unlinked/resurfacing replacements, which typically require repair of supporting ligaments for stability
• Preoperative and postoperative status of supporting ligaments of the elbow	• Initial postoperative ROM permissible through a greater range of flexion and earlier active antigravity elbow extension, low-load resistance exercise, and light ADL with triceps-sparing approach
• Wound healing	• Earlier and less protected motion during exercise, less protected use during ADL, and less time in splint during the day and at night if ligaments were intact preoperatively and did not undergo a release and repair during arthroplasty
• Ulnar neuropathy	• Longer duration of immobilization of the elbow in an extension splint or delayed end-range flexion if posterior skin quality is poor and healing of the incision is likely to be delayed
• Surgical release of elbow flexion contracture	• May require extended immobilization in an extension splint or delay of exercises to regain elbow flexion • May require use of extension splint at night for a prolonged period of time

BOX 18.6 Specific Precautions After Total Elbow Arthroplasty

ROM Exercise

- Perform ROM exercises only within the arc of motion achieved during surgery.
- To reduce postoperative stress on a repaired triceps mechanism, avoid end-range flexion during assisted ROM and active, antigravity elbow extension for 3 to 4 weeks.
- If elbow stability is questionable after an unlinked TEA, limit full extension of the elbow and rotation of the forearm, particularly supination past neutral, to avoid over-load on repaired lateral ligaments for 4 weeks. With an unlinked replacement, the greatest risk of instability is when the elbow is extended beyond 40° to 50°.⁶
- If symptoms of ulnar nerve compression are noted, avoid prolonged positioning or stretching into end-range flexion.^{2,11}

Strengthening Exercises

- Postpone resisted elbow extension for 6 weeks (or as long as 12 weeks) if a triceps-reflecting approach was used.
- When strengthening the shoulder, apply resistance above the elbow to eliminate stresses across the elbow joint.
- Weight training using moderate and high loads is not appropriate after TEA.

Functional Activities

- Avoid moving or carrying objects with the operated extremity for 6 weeks.
- If the triceps mechanism was detached and repaired, avoid pushing motions for at least 6 weeks, including propelling a wheelchair, pushing up from a chair, and using a walker, crutches (other than forearm platform design), or a cane.
- If an unlinked replacement was implanted, do not lift weighted objects during daily tasks with the elbow extended to avoid shear forces across the lateral ligament repair, which could contribute to postero-lateral instability.
- Limit repetitive lifting to 1 lb for the first 3 months, 2 lb for the first 6 months, and no more than 5 lb thereafter. Never lift more than 10 to 15 lb in a single lift.^{6,19,41,44,51}
- Do not participate in recreational activities, such as golf and tennis, that place high loads or impact across the elbow.

tion of the wound, protection of repaired soft tissues as they begin to heal, and early ROM exercises to offset the adverse effects of immobilization without jeopardizing the stability of the prosthetic joint. Assisted ROM as tolerated and within the ranges achieved intraoperatively typically is initiated 2 to 3 days after linked TEA and a few days later after unlinked TEA if the elbow is stable.^{6,44,78}

NOTE: If there was significant preoperative instability of the elbow or if the repair of ligaments released during surgery is in question, ROM typically is delayed for more than a week; and when it is initiated, the patient may need to wear a hinged splint for 4 to 5 weeks that allows only flexion and extension and restricts rotation of the forearm.^{6,44}

The goals and exercise interventions during this first phase include the following.^{6,19,22,41,44,48,51,78}

● *Maintain mobility of the shoulder, wrist, and hand.*

- Active ROM of these regions during the immediate postoperative period. This is particularly important for the patient with RA or JRA involving these joints.

● *Regain motion of the elbow and forearm.*

- After a linked TEA or if the elbow is stable after an unlinked TEA, start with gentle self-assisted elbow flexion/extension and pronation/supination with the elbow comfortably flexed and the forearm in mid-position, progressing to active ROM as tolerated. As acute symptoms subside, have the patient maintain the end-range position to apply a very low-intensity stretch.
- If the triceps mechanism was reflected and repaired, limit assisted flexion to 90° to 100° for the first 3 to 4 weeks to avoid excessive stretch on the repaired triceps tendon. Perform active elbow flexion/extension in a seated or standing, rather than supine, position for the same time frame to avoid antigravity extension, which also could cause excessive stress to the reattached triceps mechanism and subsequent insufficiency.^{6,19,44} While sitting and standing, elbow extension is gravity-assisted; extension is controlled by an eccentric contraction of the elbow flexors.
- If a linked replacement was implanted using a triceps-sparing approach, there is little to no risk of early post-operative instability or disruption of the triceps mechanism. Therefore, active ROM in all planes of motion is permissible immediately.

NOTE: It is important to point out that some sources recommend that after linked arthroplasty involving a triceps-reflecting approach—and if secure reattachment of the triceps tendon was achieved—ROM exercises progress as tolerated without restrictions.^{26,51}

● *Minimize atrophy of upper extremity musculature.*

- Gentle, pain-free muscle-setting exercises of elbow musculature (against no resistance) while in the splint and, later, multiple-angle setting exercises when the splint can be removed.
- Low-intensity, isometric resistance exercises of the shoulder, wrist, and hand.
- Use of the hand for light functional activities as early as 1 to 2 week postoperatively if a linked replacement was inserted but several weeks later after an unlinked TEA.^{48,51}

Exercise: Moderate and Minimum Protection Phases By about 4 to 6 weeks postoperatively soft tissues have healed sufficiently to withstand increasing stresses. By 12 weeks, barring complications, only minimum protection is necessary; and a patient typically can resume most functional activities with some imposed restrictions (see Box 18.6). However, the recommended timeline for return to a reasonably full level of activity varies from 6 weeks^{19,41,48} to 3 to 4 months.^{6,22,44}

Goals and interventions. The focus of rehabilitation during the intermediate and final phases is to improve ROM to the extent achieved intraoperatively, regain strength and endurance of elbow musculature, and use the operated arm for gradually demanding functional activities. However, these goals must be reached without disrupting repaired soft tissues and compromising the stability of the prosthetic elbow. Strength and muscular endurance usually continues to improve up to 6 to 12 months postoperatively by cautious use of the operated arm for functional activities.

Patient education, especially with regard to the resumption of functional activities, is ongoing until the patient is discharged from therapy. The following goals and interventions are added during the moderate and minimum protection phases of rehabilitation.^{6,22,44}

● Increase ROM of the elbow.

NOTE: It is the opinion of the authors that use of joint mobilization techniques to increase ROM of the elbow or forearm is inappropriate after TEA, particularly with linked implants or if the stability of the elbow is questionable. If selected as a stretching technique, it should be implemented only after specific consultation with the surgeon to determine its appropriateness. It is a more prudent choice to forego full motion than to jeopardize the stability of the joint.

- Low-intensity manual self-stretching.
- Low-load, long-duration dynamic splinting,^{12,32,44} as described and illustrated in Chapter 4 (see Fig. 4.13), or alternating use of static splints, each fabricated in maximum but comfortable extension and flexion.

PRECAUTIONS: Emphasize end-range extension before end-range flexion to protect the posterior capsule and the triceps mechanism. If symptoms of cubital tunnel syndrome are present (aching along the medial forearm and hand, paresthesia, or hyperesthesia due to compression or entrapment of the ulnar nerve), avoid prolonged or repeated end-range positioning or stretching to increase elbow flexion.^{2,11}

● Regain functional strength and muscular endurance of the operated extremity.

NOTE: Some sources advocate progressive use of the operated upper extremity to regain strength and muscular endurance rather than an exercise program.^{26,41,48,51}

- Resisted, multiple-angle isometric exercises at 5 weeks if not initiated previously.
- *Light ADL* (initially < 1 lb of weight) performed with the arm positioned along the side of the trunk and the elbow flexed. If a triceps-reflecting approach was used, incorporate activities that require elbow flexion before elbow extension. Initially modify activities to avoid those that require lifting with the elbow extended and pushing motions, such as pushing up from a chair or using a walker, axillary crutches, or a cane.
- Dynamic, open-chain resistance exercises no earlier than 6 weeks and often later using a light-weight (1 lb) or light-grade elastic resistance. Emphasize gradually increasing repetitions rather than resistance.
- Repetitive lifting during exercise and functional activities limited to 1 lb for the first 3 months and 2 lb for the next 3 months. Permanently limit repetitive lifting to no more than 5 lb and a single lift to no more than 10 to 15 lb.^{6,19,41,44,48,51} Refer to Box 18.5 for additional restrictions to strengthening exercises and functional activities.
- Low-load, closed-chain activities, such as wall push-ups after 6 weeks or later (when the triceps mechanism and posterior capsule have healed).
- Upper extremity ergometry.

CONTRAINdications: High-load progressive resistive exercise (PRE), heavy lifting during home- and work-related activities, and recreational activities that place high loads or impact on the upper extremities (e.g., racquet and throwing sports or golf) are not allowed after TEA. These activities must be permanently avoided to reduce the risk of complications, such as elbow instability, implant loosening, and polyethylene wear.^{6,22,41,44,51}

Outcomes

Although the results of the early use of TEA during the 1970s were quite unsatisfactory, improvements in prosthetic design and fixation, surgical techniques, postoperative management, and criteria for patient selection have made this procedure an important treatment option for pain relief, improving physical function, and preventing eventual disability. Relatively recent long-term studies of patients with RA, for example, have indicated that the “survival rate” (the point at which revision arthroplasty is necessary) of contemporary implants is 94% at a mean of 7.6 years³⁸ and 92.4% at a minimum of 10 years²⁸ after linked arthroplasty and 87% at a mean of 12 years⁷¹ and 90% at 16 years⁷⁰ after unlinked arthroplasty. These rates are dramatically better than those for the early, constrained implants in which upward of 70% failed within 10 years and are even better than the 82% survival rate of 5.5 years reported in an analysis of studies published worldwide from 1986 to 1992.²⁹ For the best long-term results, a patient must be selective in the type of work-

related or recreational activities performed, modifying some activities and eliminating those that impose high loads and high impact on the elbow.

Outcomes typically are assessed by a combination of patient self-report instruments that address pain relief, function, and quality of life (e.g., the Patient Related Elbow Evaluation form), and physician-administered tools (e.g., the American Shoulder and Elbow Surgeons Questionnaire, which also includes measurements of ROM, strength, and specific shoulder and elbow functions).⁵ Because of the variety of tools used, comparison among studies is often difficult.

As noted at the beginning of this discussion on TEA, although the indications have broadened over the past three decades, elbow arthroplasty continues to be used most frequently in patients with RA followed by patients with post-traumatic arthritis. Follow-up studies of patients with these and other underlying pathologies who have undergone linked or unlinked TEA indicate an overall high rate of patient satisfaction, with 80% to 100% of patients reporting “good” or “excellent” results after linked^{16,28,38,63,65} and unlinked^{24,41} TEA.

Pain relief. Complete or nearly complete relief of pain is the most consistently positive and predictable outcome after elbow arthroplasty, occurring in more than 85% to 95% of patients.^{17,28,41,63}

ROM and functional use of the upper extremity. Improvements in elbow ROM after TEA are less significant than relief of pain. In addition, maintaining stability of the prosthetic elbow postoperatively is a higher priority than gaining full ROM. However, results of most studies of linked^{28,38,52,65} and unlinked^{24,70,71,76} arthroplasty indicate some increase in the arc of elbow extension/flexion and forearm rotation in patients with late-stage post-traumatic,^{52,65} rheumatoid,^{24,28,38,70,71} and juvenile¹⁷ arthritis. Anecdotal evidence suggests that most gains are achieved within 6 to 12 weeks but occasionally up to 6 months postoperatively. Patients with little active movement of the elbow because of preoperative instability have exhibited marked improvement of active motion postoperatively.^{35,63}

Many resources suggest or report supporting preoperative and postoperative data to show that greater improvement occurs in elbow flexion than extension after TEA.^{19,24,38,41,65,70,71} Some typical examples of the arc of extension/flexion achieved after TEA are 30° to 135°,²⁴ 26° to 131°,²⁸ 19° to 140°,³⁸ and 27° to 131°.⁶⁵ Remember that arcs of 100° (from 30° to 130° of extension/flexion and 50° each of pronation/supination) are necessary for most functional activities.^{55,56} Therefore, in all of these studies functional ROM for extension and flexion was achieved.

It is important to note that when reviewing the literature for this summary of outcomes there were no studies found that compared outcomes after different approaches to rehabilitation.

MYOSITIS OSSIFICANS

The terms *myositis ossificans* and *heterotopic or ectopic bone formation* are often used interchangeably to describe the formation of bone in atypical locations of the body. Some references^{33,45,47} use the term myositis ossificans to denote only ossification of muscle. More often, the term is used generally to characterize heterotopic bone formation in the muscle-tendon unit, capsule, or ligamentous structures. In this text, the terms myositis ossificans and heterotopic bone formation are used synonymously.

Etiology of Symptoms

Although not a common phenomenon, the sites most frequently involved are the elbow region and thigh. In the elbow, heterotopic bone formation most often develops in the brachialis muscle or joint capsule as the result of trauma, such as a comminuted fracture of the radial head, a fracture-dislocation (supracondylar or radial head fracture) of the elbow, or a tear of the brachialis tendon.^{20,33,47,49} Patients with neurological impairments, specifically traumatic brain injury or spinal cord injury, and patients with burns to the extremities are also prone to develop this complication.⁴⁷ It may also develop as the result of aggressive stretching of the elbow flexors after injury and a period of immobilization.²⁰

Myositis ossificans is distinguished from traumatic arthritis of the humeroulnar joint in that passive extension is more limited than flexion, resisted elbow flexion causes pain, flexion is limited and painful when the inflamed muscle is pinched between the humerus and ulna, and resisted flexion in mid-range causes pain in the brachialis muscle. Palpation of the distal brachialis muscle is tender.^{20,33} After the acute inflammatory period, heterotopic bone formation is laid down in muscle between, not within, individual muscle fibers or around the joint capsule within a 2- to 4-week period. This makes the muscle extremely firm to touch. Although this condition can permanently restrict elbow motion, in most cases the heterotopic bone, to a large extent, is reabsorbed over several months, and motion usually returns to near normal.⁴⁵

Management

Massage, passive stretching, and resistive exercise are contraindicated if the brachialis muscle is implicated after trauma. The elbow should be kept at rest in a splint, which should be removed only periodically during the day for active, pain-free ROM. Rest should continue until the bony mass matures and then resorbs. Surgical excision of heterotopic bone from muscle or TEA, if the capsule is also involved, is necessary only in rare instances.^{45,47}

OVERUSE SYNDROMES: REPETITIVE TRAUMA SYNDROMES

Overuse can occur in any muscle in the elbow region, including the flexors and extensors of the elbow, but it most commonly occurs in the muscles attached to the lateral or medial epicondyles in response to repetitive stressful wrist motions. Problems anterior or posterior to the elbow are frequently caused by excessive extension or flexion strain in sporting activities.⁴

Related Pathologies

Medial and lateral epicondylitis commonly occurs with repetitive activities of the wrist and hand. Other repetitive trauma in the elbow includes distal biceps tendonitis, triceps tendonitis, and olecranon bursitis.

Lateral Epicondylitis (Tennis Elbow)

With lateral epicondylitis, there is pain in the common wrist extensor tendons along the lateral epicondyle and radiohumeral joint with gripping activities. Activities such as the backhand stroke in tennis, requiring firm wrist stability, or repetitive work tasks such as computer keyboarding or pulling weeds in a garden, which requires repeated wrist extension, can stress the musculotendinous unit and cause symptoms. The highest incidence is in the musculotendinous junction of the extensor carpi radialis brevis.^{20,23,33,60} Symptoms also occur when the annular ligament is stressed.

Positive tests of provocation include palpation tenderness on or near the lateral epicondyle, pain with resisted wrist extension performed with the elbow extended, pain with resisted middle finger extension performed with the elbow extended, and pain with passive wrist flexion with elbow extended and forearm pronated.^{20,58,75}

NOTE : Pulled elbow, pushed elbow, rotated elbow, radial head fracture, pinched synovial fringe, meniscal lock, radial tunnel syndrome, tendinosis,³⁹ and periosteal bruise are also possible sources of pain at the elbow and are sometimes erroneously called tennis elbow.⁴²

Medial Epicondylitis (Golfer's Elbow)

Medial epicondylitis involves the common flexor/pronator tendon at the tenoperiosteal junction near the medial epicondyle. It is associated with repetitive movements into wrist flexion such as swinging a golf club, pitching a ball, or work-related grasping, shuffling papers, and lifting heavy objects. Concomitant ulnar neuropathy is often an associated finding.^{27,33}

Positive tests of provocation include palpation tenderness on or near the medial epicondyle, pain with resisted wrist flexion performed with the elbow extended, and pain with passive wrist extension performed with the elbow extended.

Etiology of Symptoms

The most common cause of epicondylitis is excessive repetitive use or eccentric strain of the wrist or forearm muscles. The result is microdamage and partial tears, usually near the musculotendinous junction when the strain exceeds the strength of the tissues and when the demand exceeds the repair process. With continued irritation, chronic inflammation develops.

Inflammation of the periosteum may develop with formation of granulation tissue and adhesions.⁶⁰ Recurring problems are seen because the resulting immobile or immature scar is redamaged when returning to activities before there is sufficient healing or mobility in the surrounding tissue.

Common Impairments

- Gradually increasing pain in the elbow region after excessive activity of the wrist and hand.
- Pain when the involved muscle is stretched or when it contracts against resistance.
- Decreased muscle strength and endurance for the demand.
- Decreased grip strength, limited by pain.
- Tenderness with palpation at the site of inflammation, such as over the lateral or medial epicondyle, head of the radius, or in the muscle belly.

Common Functional Limitations/Disabilities

- Inability to participate in provoking activities, such as racket sports, throwing, or golf
- Difficulty with repetitive forearm/wrist tasks, such as sorting or assembling small parts, typing on a keyboard or using a mouse, gripping activities, using a hammer, turning a screwdriver, shuffling papers, or playing a percussion instrument

Nonoperative Management of Overuse Syndromes: Protection Phase

Decrease Pain, Edema, or Spasm

- **Immobilization.** Rest the muscles by immobilizing the wrist in a splint such as a cock-up splint, where the elbow and fingers are free to move.
- **Avoid provoking activities.** Instruct the patient to avoid all aggravating activities, such as strong or repetitive gripping actions.
- **Cryotherapy.** Use ice to help control edema and swelling.

Develop Soft Tissue and Joint Mobility

- **Multiple-angle muscle setting (low-intensity isometrics).** Have the patient remove the splint several times a day and perform gentle multiple-angle setting tech-

niques to the involved muscle followed by pain-free ROM.

- **Technique for wrist extensor muscles.**

Patient position and procedure: Sitting with the elbow flexed, forearm pronated and resting on a table, and the wrist in extension. Begin with gentle isometric contractions with the wrist extensors in the shortened position. Resist wrist extension, hold the contraction to the count of 6, relax, and repeat several times; then move the wrist toward flexion and repeat the isometric resistance. Do not move into the painful range or provide resistance that causes a painful contraction.

When full wrist flexion is obtained without pain in the lateral epicondyle region, progress by placing the elbow in greater degrees of extension and repeat the isometric resistance sequence to the wrist extensors. Progress until gentle resistance can be applied to the wrist extensors in the position of elbow extension and wrist flexion. It may take several weeks to reach this position.

- **Technique for wrist flexor muscles.**

Patient position and procedure: Sitting with the elbow flexed, forearm resting on a table, and the wrist in flexion. Begin with gentle isometric contractions with the wrist flexors in the shortened position. Resist wrist flexion, hold the contraction to the count of 6, relax, and repeat several times; then move the wrist toward extension and repeat the isometric resistance. Do not move into the painful range or provide resistance that causes a painful contraction.

When full wrist extension is obtained without pain in the medial epicondyle region, progress by placing the elbow in greater degrees of extension and supination and repeat the isometric resistance sequence to the wrist flexors. As stated above, it may take several weeks to reach the full range of elbow extension, forearm supination, and wrist extension and to be able to tolerate gentle resistance.

- **Cross-fiber massage.** Apply gentle cross-fiber massage within tolerance at the site of the lesion. Teach the patient to self-administer the submaximal isometric and cross-fiber massage techniques in a home exercise program.

Maintain Upper Extremity Function

- **Active ROM.** Have the patient perform ROM to joints not immobilized to maintain the integrity of the rest of the upper extremity.
- **Resistive exercises.** Have the patient perform shoulder and scapular ROM exercises with the resistance applied proximal to the elbow.

Nonoperative Management: Controlled Motion and Return to Function Phases

NOTE: Progress to this stage when signs of inflammation are under control.

Increase Muscle Flexibility and Scar Mobility

● **Manual stretching techniques.** Use agonist contraction, hold-relax, and passive stretching techniques to elongate the tight muscle to the end of its range (principles for application of these techniques are described in Chapter 4). Use an intensity of muscle contraction and stretch that causes a stretching sensation but not increased pain. For both the wrist flexors and wrist extensors, the elbow must be extended. Then, to stretch the wrist extensors, pronate the forearm, flex and ulnarily deviate the wrist, and flex the fingers. To stretch the wrist flexors, supinate the forearm, extend and radially deviate the wrist, and extend the fingers.

● **Self-stretching techniques.** The patient may use a wall (see Fig. 18.10) and slide the hand along the wall until a stretch force is experienced, or the patient may use the opposite hand to apply the stretch force. These techniques are described in the self-stretching section later in the chapter.

● **Cross-fiber (friction) massage.** Palpate to localize the scar, then apply pressure and cross-fiber massage. Increase the intensity of massage as the inflammation decreases.

Restore Joint Tracking of the RU Joint

● **Mobilization with movement (MWM).** Mobilization with movement techniques are used to restore normal tracking of the radius on the capitulum so the forearm muscles can be strengthened without painful symptoms.⁵⁷ Several researchers have reported decreased pain and increased grip strength during or shortly after MWM at the elbow.^{46,73,74} One researcher observed decreased shoulder rotation in patients with lateral epicondylalgia and demonstrated significant improvement in shoulder range after MWM at the elbow. He proposed that the mechanism was mediated neurophysiologically.¹ Refer to Chapter 5 for principles of application. The following techniques are used if the patient experiences pain when making a fist or with resisted wrist extension. *Patient position and procedure:* Supine with the forearm pronated. Place a mobilization belt around the patient's proximal forearm and across your shoulders and stabilize the distal humerus with one hand. Apply a lateral glide to the forearm through the belt and then have the patient do repeated wrist extension against manual resistance applied by your other hand (Fig. 18.6A).

Alternative method: Apply the lateral glide force against the proximal forearm with your distal hand and have the patient do repeated gripping by squeezing a ball or inflatable bulb (Fig. 18.6B). Both the lateral glide force and the muscle contraction must be pain-free.

● **Self-mobilization:** The patient stands with the humerus of the involved elbow stabilized against a doorframe and the forearm in the opening and then applies lateral glide force against the proximal forearm with the contralateral hand. The patient then does repetitive gripping or squeezing against a resistive force such as a pneumatic bulb or squeezable ball (Fig. 18.6C).

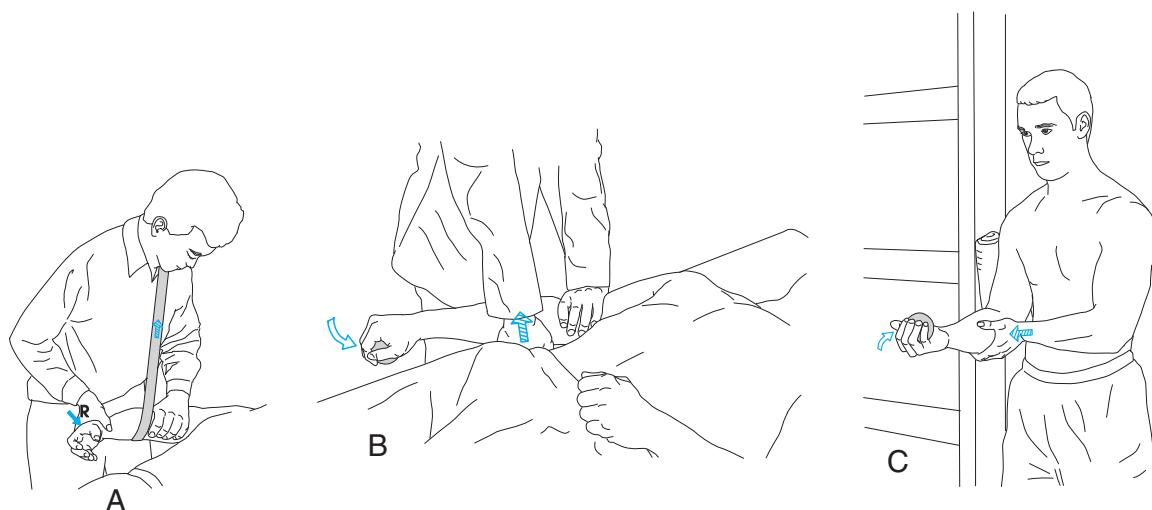

FIGURE 18.6 MWM for lateral epicondylitis. Lateral glide is applied to the proximal forearm (A) with resistance added to wrist extension, (B) with patient squeezing a ball to bring in the wrist extensors, and (C) self-treatment.

Improve Muscle Performance and Function

- **Isometrics.** Progress the isometric exercises by applying resistance in various pain-free positions.
- **Dynamic exercise.** Progress the exercises to using free weights and elastic resistance through pain-free ranges. Initially use low-intensity resistance with multiple repetitions for muscular endurance, then progress to more intense resistance to strengthen the muscles in preparation for functional demands.
- **Functional patterns.** As flexibility and strength improve and the pain is under control, incorporate functional training utilizing functional patterns into the exercises. Emphasize control of the resistance through the pattern. If pain or deviation of the pattern with substitute motions occurs, have the patient rest before resuming additional repetitions.
- **General strengthening and conditioning.** Incorporate any unused or underused part of the extremity or trunk into the training program prior to returning to the stressful activity.
- **Simulation.** Exercises simulating the desired activity are progressed from slow, controlled motions to high speeds with low resistance to improve timing (see Fig. 18.21).
- **Plyometric exercises.** Add plyometrics to the program if the patient's goals include returning to sport activities or occupational activities that require elbow and forearm power. Suggestions include:
 - Bouncing a tennis ball on a short-handled racket; progress to a long-handled racket.
 - Rapid eccentric/concentric elbow and forearm motions with an elastic resistance.
 - Rapid chest passes or overhead passes using a weighted plyometric ball.
- **Activity modification.** It may be necessary to modify the patient's activity or technique before returning to the stressful activity. For example, it may require taking tennis lessons to correct improper tennis techniques,

adapting use of a hammer or other equipment if used, or making ergonomic modifications of a computer workstation.^{23,33,58,60,75}

Patient Education

- Education includes advice and techniques on prevention, recognition of provoking factors, and identification of warning symptoms.
- Teach the patient how to reduce the overload forces that caused the problem and retrain the patient in proper techniques.^{23,33,58}
- In addition to exercises, include home instructions on the application of friction massage and stretching the involved muscle prior to using it.

Focus on Evidence

In a descriptive study of 60 subjects with lateral epicondylalgia who were followed for 6 months after initiating physical therapy intervention, Waugh et al.⁷⁵ reported that 80% of the participants continued to improve but only 33% had complete resolution of symptoms. The therapy intervention consisted of 8 weeks of ultrasound, deep transverse friction massage, and a stretching/strengthening program for the wrist extensor muscles; 37% of the participants also received treatment for the cervical spine or shoulder. Altogether, 50% continued with some form of therapeutic intervention after the initial 8 weeks. Those with poorer outcomes had repetitive work duties, with 92% of the repetitive duties involving computer work. This study also reported that women who have positive cervical signs as well as repetitive job duties involving computer usage had a poorer prognosis. This was observed at both 8 weeks and 6 months. Ergonomic recommendations for postural adaptations when using a computer included having forearm support, smooth movements, and relaxed shoulders.⁷⁵

NOTE: Additional information on ergonomic recommendations for computer workstations are described in Chapter 14.

EXERCISE INTERVENTIONS FOR THE ELBOW AND FOREARM

EXERCISE TECHNIQUES TO INCREASE FLEXIBILITY AND RANGE OF MOTION

Prior to initiating a muscle stretching program, be sure the joint capsule is not restricting motion. Techniques to increase joint play in the elbow and forearm articulations are discussed earlier in the chapter. Principles and techniques for applying joint mobilization techniques are presented in Chapter 5.

In addition to the description of principles and techniques of stretching presented in Chapter 4, manual, mechanical, and self-stretching techniques directed to the elbow are described in this section. When teaching the patient self-stretching, emphasize the importance of maintaining a low-intensity, prolonged stretch and not bouncing at the end of the range.

Manual, Mechanical, and Self-Stretching Techniques

To Increase Elbow Extension

NOTE: Of the three muscles that flex the elbow, only one, the biceps brachii, crosses two joints (the elbow and the shoulder). Therefore, techniques to fully elongate the biceps brachii must be done with the shoulder extended.

Mechanical Stretch—Mild Flexion Contracture

Patient position and procedure: Supine with the arm supported on the treatment table and a folded towel under the distal humerus as a fulcrum. Place a cuff weight around the distal forearm. Position the forearm in pronation, mid-position, and then supination to affect each of the flexor muscles. Have the patient stabilize the proximal humerus with the other hand or place a sandbag or belt across the proximal humerus to stabilize it. Instruct the patient to maintain the stretch for an extended period of time.⁷⁷

Mechanical Stretch—Dynamic Splinting

Apply a low-intensity, long-duration mechanical stretch force with a dynamic splint to reduce a long-standing elbow flexion contracture by affecting the soft tissue properties of creep and stress-relaxation.^{12,32}

Manual Stretch—Biceps Brachii

Patient position and procedure: Prone with the elbow in end-range but comfortable extension and forearm in pronation. Stabilize the scapula and passively extend the shoulder.

Mechanical Stretch—Biceps Brachii

Patient position and procedure: Supine with a cuff weight around the distal forearm. The elbow is in extension and the forearm is in pronation. Have the patient stabilize the proximal humerus with the opposite hand and then place the arm over the side of the table. Allow the elbow and shoulder to extend as far as possible and sustain the stretch position for an extended period of time (Fig. 18.7A).

Self-Stretch—Biceps Brachii

Patient position and procedure: Standing at the side of a table. Have the patient grasp the edge of the table and walk forward, causing shoulder extension with elbow extension (Fig. 18.7B). It is important to note that this stretching position does not include forearm pronation.

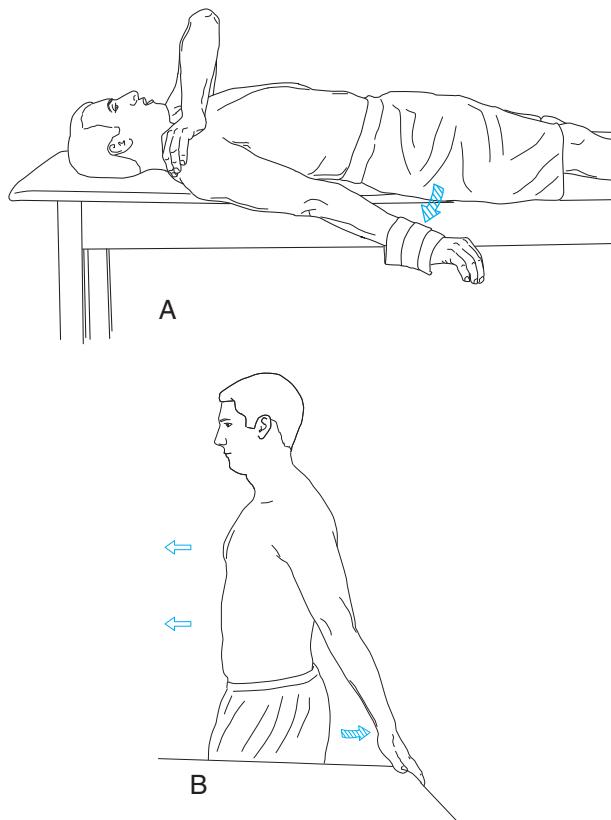

FIGURE 18.7 Self-stretching the biceps brachii musculotendinous unit includes stretching the long head across the shoulder joint (A) supine and (B) standing.

To Increase Elbow Flexion

Self-Stretch—Mild Extension Contracture

- **Patient position and procedure:** Prone-lying and propped up on elbows with forearms resting on the exercise mat. Have the patient lower the chest as far as elbow flexion allows and maintain the position as long as tolerated.
- **Patient position and procedure:** Sitting with elbow flexed as far as possible. Have the patient press against the distal forearm with the opposite hand to provide the stretch force into flexion.

Self-Stretch Long Head of Triceps

Patient position and procedure: Sitting or standing. Have the patient flex the elbow and shoulder as far as possible. The other hand can either push on the forearm to flex the elbow, or push the shoulder into more flexion (Fig. 18.8). Hold the stretch position as long as tolerated.

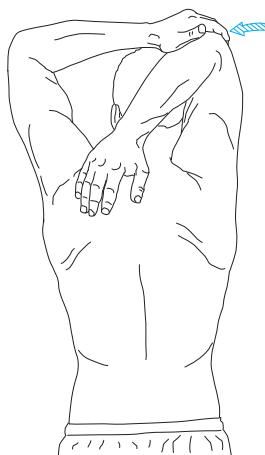

FIGURE 18.8 Self-stretching the triceps brachii musculotendinous unit includes stretching the long head across the shoulder joint.

To Increase Forearm Pronation and Supination

Patient position: Sitting with the elbow flexed to 90° and the elbow resting on a padded table or stabilized against the side of the trunk.

Self-Stretch to Increase Pronation

Have the patient grasp the dorsal surface of the involved forearm so the heel of the unininvolved hand is against the radius just proximal to the wrist and so the fingers wrap around the ulna. Then have the patient pronate the forearm and sustain the stretch as long as tolerated. The force is applied against the radius so there is no trauma to the wrist.

Self-Stretch to Increase Supination

Have the patient place the heel of the unininvolved hand against the volar aspect of the involved radius just prox-

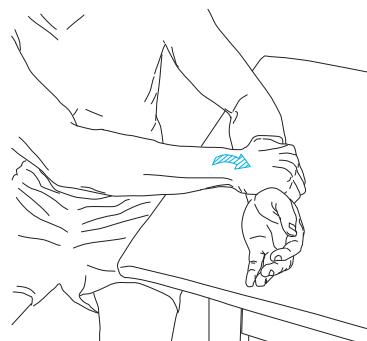

FIGURE 18.9 Self-stretching the forearm into supination. It is important that the stretch force is against the radius, not the hand.

mal to the wrist, supinate the forearm, and sustain the stretch as long as tolerated (Fig. 18.9).

Self-Stretching Techniques—Muscles of the Medial and Lateral Epicondyles

To Stretch the Wrist Extensor Muscles (From the Lateral Epicondyle)

- **Patient position and procedure:** Sitting or standing with the elbow extended and forearm pronated. While holding this position have the patient ulnarily deviate the wrist and flex the wrist and fingers; then apply a gentle stretch force against the dorsum of the hand. The patient should feel a stretching sensation along the lateral epicondyle or proximal forearm.
- **Patient position and procedure:** Standing with elbow extended, forearm pronated, and back of the hand against a wall (fingers pointing down). Have the patient then slide the back of the hand up the wall⁶⁶ (Fig. 18.10). For additional stretch have the patient actively flex the fingers.

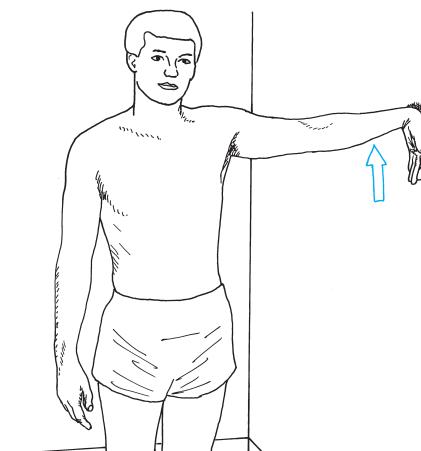

FIGURE 18.10 Self-stretching of the muscles of the lateral epicondyle.

To Stretch the Wrist Flexor Muscles (from the Medial Epicondyle)

- **Patient position and procedure:** Sitting or standing with the elbow extended and forearm supinated. While holding this position have the patient radially deviate and extend the wrist and apply a gentle stretch force with the other hand against the palm of the hand. A stretch sensation should be felt along the medial epicondyle or proximal forearm.
- **Patient position and procedure:** Standing with the elbow extended and forearm supinated. Have the patient place the palm of the hand against a wall, fingers pointing down, and then move the hand up the wall until a stretch sensation is felt in the wrist flexor muscles.⁶⁶

EXERCISES TO DEVELOP AND IMPROVE MUSCLE PERFORMANCE AND FUNCTIONAL CONTROL

In addition to the conditions already described in this chapter, imbalances in length and strength of muscles crossing the elbow and forearm can be the result of a variety of causes, such as nerve injury or after surgery, trauma, disuse, or immobilization. Appropriate exercises to develop neuromuscular control, increase strength, and improve endurance for return to functional activities can be selected from the following exercises as well as the techniques described in Chapter 6.

For patients with elbow impairments, exercises for the regions above (shoulder girdle) and below (wrist and hand) should also be incorporated into the therapeutic program to prevent complications and restore proper function in the entire upper quarter. The general principles of managing acute soft tissue lesions are discussed in Chapter 10. The exercises described in this section are for use during the controlled motion and return to function phases of intervention when tissues are in the subacute and chronic stages of healing and require only moderate to minimum protection.

Isometric Exercises

Multiple-Angle Isometric Exercises

Use manual or mechanical resistance at various positions throughout the available ROM of elbow flexion and extension and forearm rotation. Isolate the key musculature. Apply resistance at the distal forearm, not at the hand, to avoid forces across the wrist joints.

Angle-Specific Training

During isometric exercises emphasize joint positions that simulate use of the elbow for anticipated functional activities. For example, to simulate carrying large boxes close to the chest, strengthen the elbow flexors in a 70° to 90° position with the forearm in mid-position.

Endurance

Emphasize holding objects for extended periods of time to increase muscular endurance.

Alternating Isometrics and Rhythmic Stabilization

Open-Chain Exercises

Use alternating isometric contractions by means of manual resistance between antagonists at multiple angles of elbow flexion/extension and forearm pronation/supination. Stabilize the humerus and apply the resistance against the forearm.

Once the patient has learned to respond to the resistance at various elbow and forearm positions and at varying speeds of alternation, progress to alternating isometrics using total upper extremity patterns.

Closed-Chain Exercises

Patient positions include standing with hands on a wall or a table, in the quadruped position, or in the prone push-up position (with knees as fulcrum or toes as fulcrum). Have the patient hold the desired elbow position and apply alternating isometrics and rhythmic stabilization by means of manual resistance against the shoulders and trunk.

Dynamic Strengthening and Endurance Exercises

Many muscles that cross the elbow joint are multijoint muscles, such as the biceps, long head of the triceps, and wrist flexors and extensors. It is particularly important to consider the position of the shoulder and forearm during resistance training at the elbow.⁶⁷ Dynamic strengthening and endurance activities for the *prime movers* of the elbow, forearm, and wrist using manual or mechanical resistance are noted in this section. Combined patterns of motion during open- and closed-chain activities are described in the next section.

Elbow Flexion

Muscles include the biceps brachii, brachialis, and brachioradialis.

- **Patient position and procedure:** Sitting or standing, with the humerus at the side of the chest (arm perpendicular to the floor). Have the patient hold a weight or grasp a piece of elastic resistance material (secured under the foot or to the floor), and flex and extend the elbow. This strengthens the elbow flexors concentrically and eccentrically throughout the available ROM to simulate functional lifting and lowering. Perform this motion with the forearm supinated, pronated, and in mid-position.

- **Patient position and procedure:** Supine or prone, with the humerus supported on the treatment table. When the patient is supine, the resistive force from a free weight or gravity has a greater effect on the muscles near end-range extension and has little to no effect as the elbow reaches 90°. To provide resistance with the patient prone with the forearm over the side of the bed, a pulley sys-

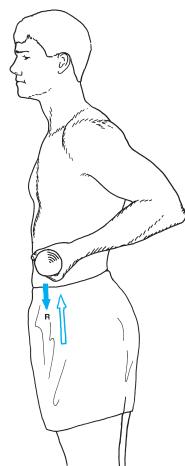

FIGURE 18.11 Resisting elbow flexion with emphasis on the biceps brachii. The shoulder extends as the elbow flexes with the forearm in supination. This combined action lengthens the proximal portion of the musculotendinous unit across the shoulder while it contracts to move the elbow, thus maintaining a more optimal length-tension relationship through a greater ROM.

tem or elastic resistance is necessary to provide resistance to the elbow flexors.

- **Patient position and procedure:** Standing or sitting while holding a weight with the forearm supinated. Have the patient extend the shoulder as the elbow flexes (Fig. 18.11). This combined motion elongates the biceps brachii over the shoulder as the muscle is shortening to move the elbow and thus most efficiently maintains optimal length for development of maximum tension in the *biceps*. This combined motion develops control for carrying objects at the side.

Elbow Extension

Muscles include the triceps and anconeus.

- **Patient position and procedure:** Prone, humerus abducted to 90° and supported on a rolled towel on a treatment table. Have the patient extend the elbow while holding a weight or pulling against elastic resistance. This position strengthens the elbow extensors from only 90° of flexion to terminal extension.
- **Patient position and procedure:** Supine with the shoulder flexed 90°, holding a weight in the hand. Have the patient begin with the elbow flexed and the weight either at the ipsilateral or contralateral shoulder (external or internal rotation of the shoulder); then extend and flex the elbow (lift and lower the weight) to strengthen the elbow extensors concentrically and eccentrically. To help maintain the shoulder in a stable position, have the patient stabilize the humerus in the 90° position with the opposite hand.

Long Head of Triceps with Elbow Extension

Patient position and procedure: Sitting or standing with the arm held overhead (shoulder flexed) and elbow flexed so the weight is near the shoulder (Fig. 18.12). Have the

FIGURE 18.12 Resisting elbow extension, beginning with the long head of the triceps brachii on a stretch.

patient lift the weight overhead and then lower the weight for a concentric and eccentric contraction. The patient may support the humerus with the opposite hand. Perform this exercise only if the patient has sufficient control of the shoulder.

Pronation and Supination

Muscles of pronation are the pronator teres and quadratus; muscles of supination are the supinator and biceps brachii. **Patient position:** Sitting or standing with the elbow flexed to 90°. When sitting, the forearm may be on a table for support.

- **Free weights.** When using a free weight to strengthen the pronators and supinators, the weight must be placed to one side or the other of the hand (Fig. 18.13). If a person holds a dumbbell with weight equal on each side of the hand, one side of the weight is assistive and the other is resistive, in essence canceling out the resistive force. Note also the position of the thumb for each exercise so it is not lifting the bar. The weight can also be turned through a downward arc by placing the resistance on the ulnar side of the hand.

- **Elastic resistance.** Have the patient grasp one end of the elastic resistance with the normal hand, or secure it by standing on it. Have the patient grasp the other end with the involved extremity and turn the forearm against the resistance. For greater resistance, secure the end of the resistance around the end of a short rod and have the patient pull against the resistance force.

- **Functional activity.** Have the patient stand facing a doorknob with the arm kept at the side and the elbow

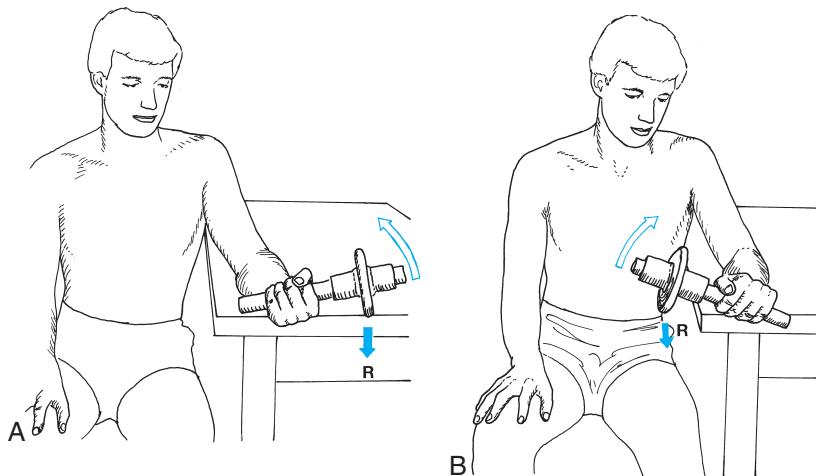

FIGURE 18.13 Mechanical resistance exercise using a small bar with asymmetrically placed weights for strengthening (A) forearm pronators and (B) supinators. The bar can also be rotated through a downward arc to affect the other half of the range for each muscle by placing the weight on the ulnar side of the hand.

flexed to 90° to avoid substituting with shoulder rotation. Have the patient turn the knob.

Wrist Flexion and Extension

Wrist flexion involves muscles of the medial epicondyle; extension involves muscles of the lateral epicondyle.

- **Free weights.** *Patient position and procedure:* Sitting, with forearm resting on a table and hand over the edge of the table holding a small weight. When the forearm is pronated, resistance is against the wrist extensors (Fig. 18.14); when supinated, the resistance is against the wrist flexors. Elastic resistance can be applied by secur-

ing a loop of material under the patient's foot and holding the other end in the hand.

- **Wrist roller.** *Patient position and procedure:* Sitting or standing, with the elbows flexed or extended and the forearms pronated or supinated. Tie a 2- to 4-ft cord to the middle of a short rod; secure a weight to the other end of the cord. Have the patient hold each end of the rod and with an alternating wrist action, turn the rod causing the cord to wind around the rod and elevate the weight. The weight is then lowered with a reverse motion (Fig. 18.15).

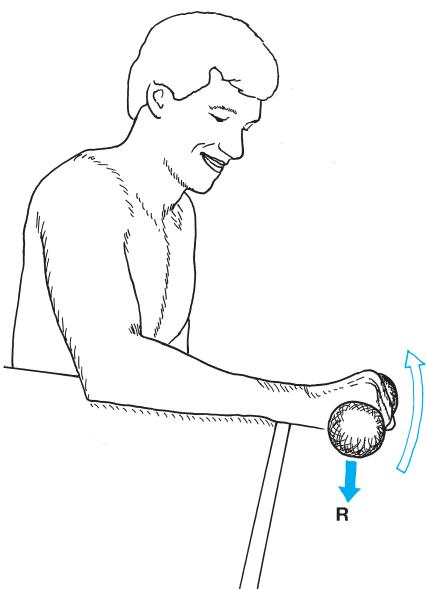

FIGURE 18.14 Mechanical resistance exercise using a handheld weight for strengthening the muscles of the lateral epicondyle (wrist extensors).

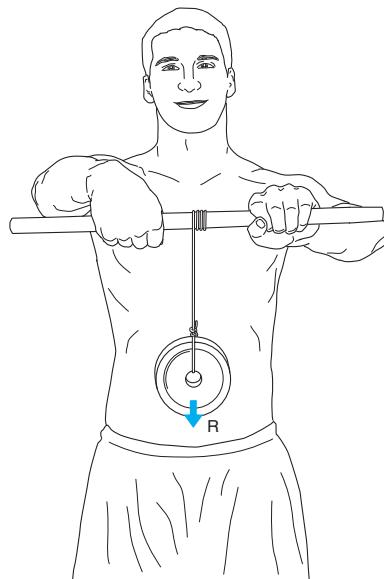

FIGURE 18.15 Wrist roller exercise to strengthen grip and develop muscles of the lateral epicondyle. This exercise requires stabilization in the shoulder girdle and elbow muscles. The elbows may be flexed or the forearms supinated to emphasize the elbow flexors or muscles of the medial epicondyle, respectively.

Functional Exercises

NOTE: Because the elbow primarily functions during activities that also involve the shoulder and hand, use combined patterns that strengthen the entire upper extremity. Be careful that substitute motions do not occur to compensate for a weak link in the chain. Include exercises to progressively improve strength, power, and endurance. Isokinetic exercises may also be used to address specific patterns of motion.

Diagonal Patterns

PNF patterns against manual or mechanical resistance. Use unilateral or bilateral diagonal (proprioceptive neuromuscular facilitation, or PNF) patterns as described in Chapter 6. Use manual resistance, free weights, elastic resistance, a weight-pulley system, or an isokinetic dynamometer to provide the resistance as the patient moves through the diagonal patterns. Gradually increase resistance, speed (if appropriate with the choice of equipment), and repetitions.

Combined Pulling Motions

Elbow flexors are used in pulling, lifting, and carrying activities in open- and closed-chain activities. These upper extremity actions also require strength in the scapular retractors, shoulder extensors, and wrist and hand musculature. Many of the exercises that are described for the shoulder in Chapter 17 also involve resisted elbow flexion and therefore can be used to strengthen muscle groups during pulling motions. Additional suggestions include:

- Bilateral pull-ups against elastic resistance (Fig. 18.16)

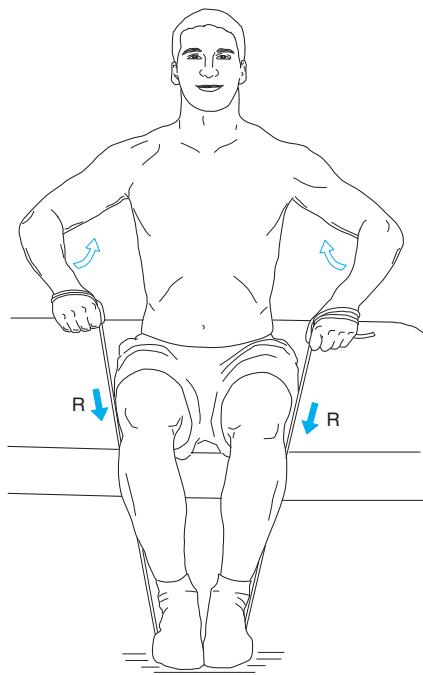

FIGURE 18.16 Bilateral pull-ups against elastic resistance.

- Closed-chain chin-ups or modified pull-ups on an overhead bar (Fig. 18.17)

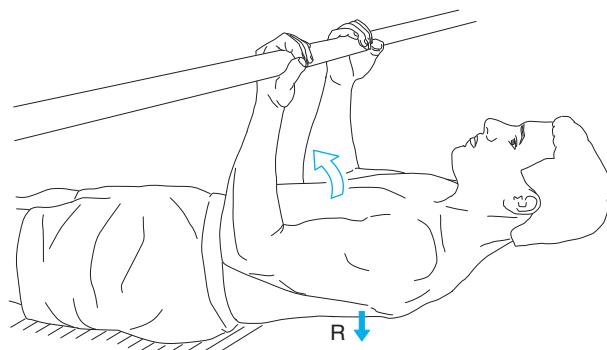

FIGURE 18.17 Closed-chain modified chin-ups using top half of body weight for resistance to strengthen the elbow flexors. This exercise may be performed in a bed with an overhead trapeze.

- Bilateral or unilateral rowing motions, such as using a rowing machine or simulating starting a lawn mower (Fig. 18.18)

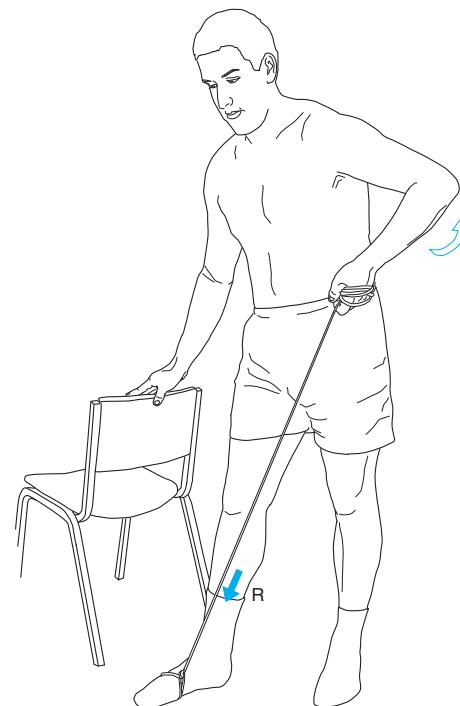

FIGURE 18.18 Simulation of a "lawn mower pull" for functional strengthening of the upper extremity.

- Pulling a variety of weighted objects with one or both arms, emphasizing elbow flexion and proper body mechanics.

Combined Pushing Motions

The triceps muscle is involved in pushing motions. Pushing also involves variations of shoulder flexion and scapular

protraction or depression so muscles controlling these motions are functioning with the triceps. Many of the exercises described in Chapter 17 for the shoulder also involve resisted elbow extension and may be used to strengthen muscle groups used in pushing patterns. Additional suggestions include:

- Military press (see Fig. 17.52).
- Bench press.
- Upper extremity ergometry (see Fig. 6.54).
- Wall push-ups, semiprone or prone push-ups (Fig. 18.19A).
- Push-ups from a chair or on parallel bars (Fig. 18.19B).

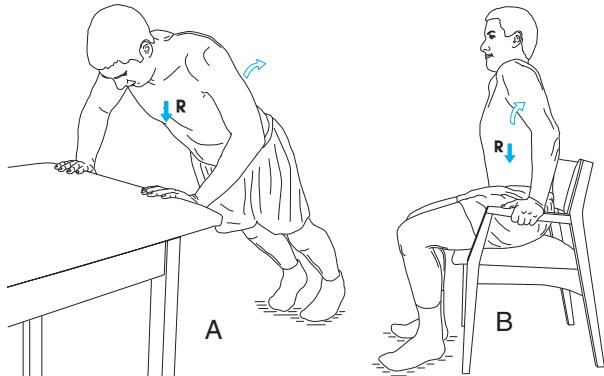

FIGURE 18.19 Closed-chain strengthening of the triceps. (A) Modified push-ups. (B) Seated push-ups.

- Stepping/stair-climbing machine with hands on the “steps.” Emphasize elbow extension.
- Pushing a variety of weighted objects with one or both arms using dynamic elbow extension (Fig. 18.20).

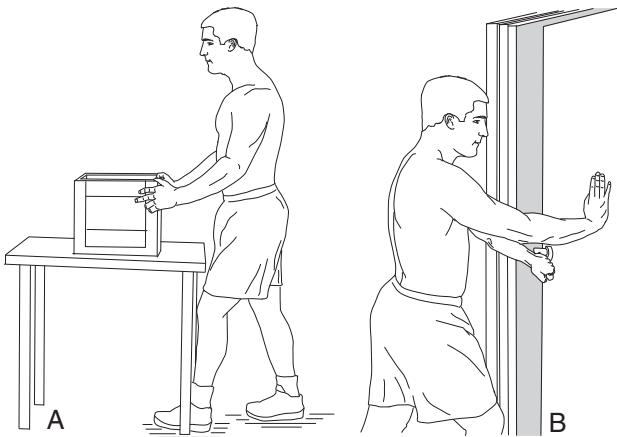

FIGURE 18.20 Strengthening the triceps with pushing activities. (A) Pushing weighted objects across a table. (B) Depressing a door handle and pushing open a door.

Stretch-Shortening Drills (Plyometrics)

Suggestions for increasing power using plyometric exercises⁷⁷:

- Have the patient perform elbow flexion and extension exercises against elastic resistance, emphasizing rapid reversal between eccentric and concentric motions.
- Use a weighted ball and have the patient catch and then quickly throw it back. Emphasize elbow motions with overhead passes, chest passes, and lateral passes.
- Have the patient bounce a tennis ball on a racket with the forearm pronated and with it supinated.

Simulated Tasks and Activities

Determine the component motions of the patient’s desired functional activities as well as occupational or recreational tasks. Have the patient simulate these motions and practice the entire task. Activities could involve lifting, lowering, carrying, pushing, pulling, twisting, turning, catching, throwing, or swinging. For example, if the patient is recovering from repetitive trauma to the muscles of the lateral epicondyle (“tennis elbow”), have the patient practice the various strokes using a wall pulley (Fig. 18.21). Impose controlled forces to challenge the patient by increasing the time or repetitions, speed, or resistance.⁷⁷

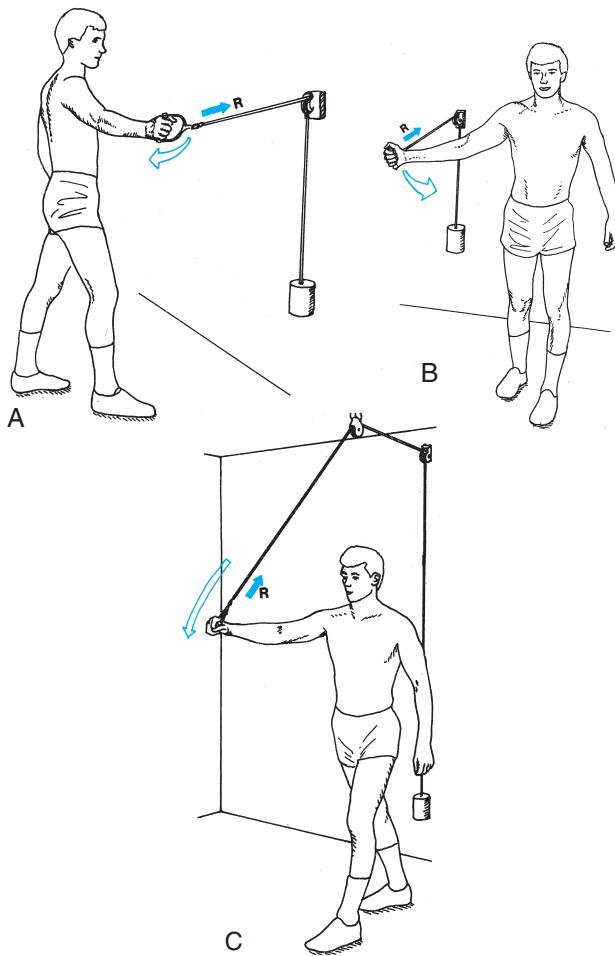

FIGURE 18.21 Mechanical resistance exercise using wall pulleys to simulate tennis swings. (A) Backhand stroke. (B) Forehand stroke. (C) Serve.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Differentiate between the etiology, signs and symptoms, and management of lateral and medial epicondylitis. Note the similarities and differences.
2. Develop, compare, and contrast the postoperative management after two types of total elbow arthroplasty: (1) a semiconstrained implant/triceps-reflecting approach and (2) a resurfacing implant/triceps-splitting approach.
3. The goal is to increase muscle performance and function in the elbow flexors that are currently functioning at a 3/5 strength level and endurance of four repetitions. Identify exercises that could be used at each increment of strength, including exercises for strength, endurance, power, control, stability, and function. Identify parameters for progression of each exercise and any precautions.
4. Do the same sequence of analysis and identification to increase muscle performance and function of the elbow extensors.
5. Analyze the following household, occupational, or sports-related activities. Identify the components and sequence of motions related to each of these motor tasks; pay particular attention to elbow and forearm motions during these tasks. Design a sequence of upper extremity exercises and simulated activities that could be incorporated into a late-stage rehabilitation program to prepare a patient to return to the desired task after an elbow injury.
 - Housecleaning
 - Gardening
 - Grocery store stocking
 - Carpentry
 - Volleyball
 - Tennis
 - Throwing sports

● Laboratory Practice

1. Apply mobilization techniques to a laboratory partner to increase the following elbow and forearm motions: mid- and end-range elbow flexion; mid- and end-range elbow extension; forearm pronation and supination (proximal and distal articulations).

2. Demonstrate passive stretching and hold-relax techniques to elongate the following muscles that cross the elbow: brachialis, brachioradialis, biceps, long head of the triceps, extensor communis digitorum, flexor carpi ulnaris, flexor carpi radialis.

3. Using the following pieces of resistance equipment demonstrate at least two methods (setups) to strengthen the elbow flexors/extensors and forearm rotators: free weights, weight-pulley system, and elastic resistance. Then demonstrate a progressive sequence of resistance exercise to strengthen the same muscle groups using self-resistance (body weight or manual resistance).

● Case Studies

1. Describe the mechanical problem causing impairments in the elbow and forearm in the following scenario and what techniques could be used for intervention. A patient is referred to you 4 weeks after sustaining a fracture of the distal radius with immobilization in a cast following a fall on an outstretched hand. She has limited elbow, forearm, and wrist motions. On palpation you note a decreased space between the lateral aspect of the head of the radius and capitellum as well as decreased joint play at all articulations of the elbow, forearm, and wrist.
2. A 15-year-old patient with a 5-year history of polyarticular JRA just underwent open synovectomy and excision of the head of the radius with implant for late-stage joint disease of the elbow. Prior to surgery, the patient had severe pain in the elbow region, lacked full elbow flexion/extension and forearm rotation, and had limited use of the arm for functional activities. Continuous passive motion (CPM) was implemented during the patient's hospitalization (3 days). On the day prior to discharge the patient was referred to physical therapy for a home program. Design an exercise program for this teenager. Prioritize and describe each exercise you want the patient to do for the first week at home. Outline a program of exercises for later use in the rehabilitation process. The patient plans to return to school within a week of discharge from the hospital. Indicate whether you recommend outpatient therapy; if so, indicate the frequency and duration; justify the need for this recommendation.

Functional Activities 638

● INDEPENDENT LEARNING ACTIVITIES 638

The wrist is the final link of joints that positions the hand for functional activities. It has the significant function of controlling the length-tension relationship of the multiarticular muscles of the hand as they adjust to various activities and grips.⁵ The hand is a valuable tool through which we control and manipulate our environment and express ideas and talents. It also has an important sensory function of providing feedback to the brain.

This chapter is divided into three major sections. The first section briefly reviews the rather complex structure and function of the wrist and hand—information that is important to know in order to effectively treat hand problems. The second section describes common disorders and guidelines for conservative and postoperative management. The last section describes exercise techniques commonly used to meet the goals of treatment during the stages of tissue healing and phases of rehabilitation.

STRUCTURE AND FUNCTION OF THE WRIST AND HAND

The bones of the wrist consist of the distal radius, scaphoid (S), lunate (L), triquetrum (Tri), pisiform (P), trapezium (Tm), trapezoid (Tz), capitate (C), and hamate (H). Five metacarpals and 14 phalanges make up the hand and the five digits (Fig. 19.1).

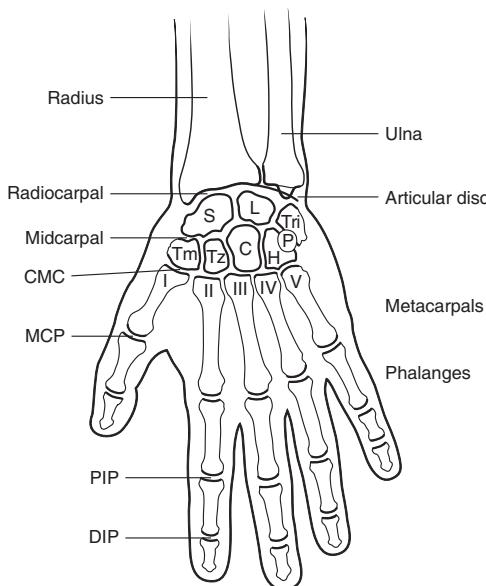

FIGURE 19.1 Bones of the wrist and hand complex.

JOINTS OF THE WRIST AND HAND

Wrist Joint—Characteristics and Arthrokinematics

The distal radioulnar (RU) joint is not part of the wrist joint, although pain and impairments in this forearm articulation are often described by the patient as wrist pain. Its structure and function are described in Chapter 18.

The wrist joint is multiarticular and is made up of two compound joints. It is biaxial, allowing flexion (volar flexion), extension (dorsiflexion), radial deviation (abduction), and ulnar deviation (adduction). Stability is provided by numerous ligaments: the ulnar and radial collateral, the dorsal and volar (palmar) radiocarpal, the ulnocarpal, and the intercarpal.

The pisiform is categorized as a carpal and is aligned volar to the triquetrum in the proximal row of carpal bones. It is not part of the wrist joint per se but functions as a sesamoid bone in the flexor carpi ulnaris tendon.

Radiocarpal Joint

Characteristics. The radiocarpal (RC) joint is enclosed in a loose but strong capsule that is reinforced by the ligaments

shared with the midcarpal joint. The biconcave articulating surface is the distal end of the radius and radioulnar disk (discus articularis); it is angled slightly volarward and ulnarward. The biconvex articulating surface is the combined proximal surface of the scaphoid, lunate, and triquetrum. The triquetrum primarily articulates with the disk. These three carpal bones are bound together with numerous interosseous ligaments.

Arthrokinematics. With motions of the wrist, the convex proximal row of carpal bones slides in the direction opposite the physiological motion of the hand. The arthrokinematics are summarized in Box 19.1.

Midcarpal Joint

Characteristics. The midcarpal joint is a compound joint between the two rows of carpal bones. It has a capsule that is also continuous with the intercarpal articulations. The combined distal surfaces of the scaphoid, lunate, and triquetrum articulate with the combined proximal surfaces of the trapezium, trapezoid, capitate, and hamate.

Arthrokinematics. The articulating surfaces of the capitate and hamate are, in essence, convex and slide on the concave articulating surfaces of a portion of the scaphoid, lunate, and triquetrum so with flexion and extension, as well as radial and ulnar deviation, their combined surfaces slide opposite the physiological motion.

The articulating surfaces of the trapezium and trapezoid are concave and slide on the convex distal surface of the scaphoid so with flexion and extension their combined surfaces slide in the same direction as the physiological motion. Because the trapezoid is bound to the capitate, they cannot slide in opposite directions during radial and ulnar deviation. The trapezii (the trapezium and trapezoid) therefore slide in a dorsal direction on the scaphoid during radial deviation and in a volar direction during ulnar deviation.⁵⁹

Physiological motions of the wrist result in a complex motion between the proximal and distal row of carpal bones. Because the concave trapezii slide in a dorsal direction on the scaphoid and the convex capitate and hamate slide in a volar direction on the lunate and triquetrum during extension and radial deviation, the resulting motion is a supination twist of the distal row on the proximal row. A pronation twist occurs during flexion and ulnar deviation as the trapezii slide volarly and the capitate and hamate slide dorsally.⁵

These arthrokinematic relationships are summarized in Box 19.1.

Hand Joints—Characteristics and Arthrokinematics

Carpometacarpal Joints of Digits 2 through 5

Characteristics. The carpometacarpal (CMC) joints are enclosed in a common joint cavity and include the articulations of each metacarpal with the distal row of carpal bones and the articulations between the bases of each metacarpal.

BOX 19.1 Arthrokinematics of the Wrist and Hand Joints

Physiological Motion	Roll	Slide
Radiocarpal joint: motion of proximal row of carpal s		
Flexion of wrist	Volar	Dorsal
Extension of wrist	Dorsal	Volar
Radial deviation	Radial	Ulnar
Ulnar deviation	Ulnar	Radial
Midcarpal joints: motion of distal row of carpal s		
Flexion of wrist	Volar	C and H dorsal Tm and Tz volar
Extension of wrist	Dorsal	C and H volar Tm and Tz dorsal
Radial deviation	Radial	C and H ulnar Rm and Tz dorsal
Ulnar deviation	Ulnar	C and H radial Tm and Tz volar
Carpometacarpal joints of digits 2–5: motion of proximal phalanx		
Flexion (increased arch)	Volar	Volar
Extension (decreased arch)	Dorsal	Dorsal
Carpometacarpal joint of thumb: motion of 1st metacarpal		
Flexion	Ulnar	Ulnar
Extension	Radial	Radial
Abduction	Volar	Dorsal
Adduction	Dorsal	Volar
Metacarpophalangeal joints of digits 2–5: motion of phalanx		
Flexion	Volar	Volar
Extension	Dorsal	Dorsal
Abduction	Away from center of hand	
Adduction	Toward center of hand	
Interphalangeal joints and MCP joint of thumb: motion of phalanx		
Flexion	Volar	Volar
Extension	Dorsal	Dorsal

The joints of digits 2, 3, and 4 are plane uniaxial joints; the joint of digit 5 is biaxial. They are supported by transverse and longitudinal ligaments. The fifth metacarpal is most mobile, with the fourth being the next most mobile. Flexion of the metacarpals and additional adduction of the fifth contribute to cupping (arching) of the hand, which improves the ability of the hand to grasp objects of various sizes. Extension of the metacarpals contributes to flattening of the hand, which improves the ability to release objects.

Arthrokinematics. The proximal surfaces slide in a volar direction with flexion and in a dorsal direction with extension motions in the hand (see Box 19.1).

Carpometacarpal Joint of the Thumb (Digit 1)

Characteristics. The CMC joint of the thumb is a saddle-shaped (sellar) biaxial joint between the trapezium and base of the first metacarpal. It has a lax capsule and wide range of motion (ROM), which allows the thumb to move

away from the palm of the hand for opposition in prehension activities.

Arthrokinematics. For flexion/extension of the thumb (components of opposition/reposition, respectively), occurring in the frontal plane, the surface of the trapezium is convex and the base of the metacarpal is concave; therefore, its surface slides in the same direction as the angulating bone. For abduction/adduction, occurring in the sagittal plane, the trapezium surface is concave and the metacarpal is convex; therefore, the surface of the metacarpal slides in the opposite direction of the physiological motion (see Box 19.1).

Metacarpophalangeal Joints of Digits 2 through 5

Characteristics. The metacarpophalangeal (MCP) joints are biaxial condyloid joints. Each joint is supported by a volar and two collateral ligaments. The collaterals become taut in full flexion and prevent abduction and adduction in this position.

Arthrokinematics. The distal end of each metacarpal is convex and the proximal phalanx concave. The proximal surface of the proximal phalanx rolls and slides in the same direction as the physiological motion (see Box 19.1).

Interphalangeal Joints and MCP Joint of the Thumb

Characteristics. There is a proximal (PIP) and distal (DIP) interphalangeal joint for each digit, 2 through 5. The thumb has only one interphalangeal joint, although the MCP joint of the thumb is uniaxial and therefore functions similarly to the IP joints. The MCP joint of the thumb differs in that it is reinforced by two sesamoid bones on the volar surface, which improve the leverage of the flexor pollicis brevis muscle. Each of these joints is a uniaxial hinge joint.

The capsule of each joint is reinforced with collateral ligaments, which are taut in extension. Going radial to ulnar in digits 2 through 5, there is increasing flexion/extension range in the joints. This allows for greater opposition of the ulnar fingers to the thumb and also causes a potentially tighter grip on the ulnar side of the hand.

Arthrokinematics. The articulating surface at the distal end of each phalanx is convex; the articulating surface at the proximal end of each phalanx is concave. Therefore, the proximal surface of each phalanx rolls and slides in the same direction as the physiological motion (see Box 19.1).

Length-Tension Relationships

The position of the wrist controls the length of the extrinsic muscles of the digits. As the fingers or thumb flex, the wrist must be stabilized by the wrist extensor muscles to prevent the flexor digitorum profundus and flexor digitorum superficialis or the flexor pollicis longus from simultaneously flexing the wrist. As the grip becomes stronger, synchronous wrist extension lengthens the extrinsic flexor tendons across the wrist and maintains a more favorable overall length of the musculotendinous unit for a stronger contraction.

For strong finger or thumb extension, the wrist flexor muscles stabilize or flex the wrist so the extensor digitorum communis, extensor indicis, extensor digiti minimi, or extensor pollicis longus muscles can function more efficiently. In addition, there is ulnar deviation; the flexor and extensor carpi ulnaris muscles are both active as the hand opens.⁶⁹

Extensor Mechanism

Structurally, the extensor hood (extensor expansion) is made up of the extensor digitorum communis tendon, its connective tissue expansion, and fibers from the tendons of the dorsal and volar interossei and lumbricales (Fig. 19.3).⁵ Each structure that is a part of the hood has an effect on the extensor mechanism.

- An isolated contraction of the extensor digitorum produces clawing of the fingers (MCP hyperextension with IP flexion from passive pull of the extrinsic flexor tendons, also called the hook position).
- PIP and DIP extension occurs concurrently and can be caused by the interossei or lumbrical muscles through their pull on the extensor hood.
- There must be tension in the extensor digitorum communis tendon for there to be interphalangeal extension. This occurs either by active contraction of the muscle, causing MCP extension concurrently as the intrinsic muscles contract, or by stretch of the tendon, which occurs with MCP flexion.

HAND FUNCTION

Muscles of the Wrist and Hand

The complex function of the hand occurs as a result of an intricate balance and control of forces between the extrinsic and intrinsic muscles of the wrist and hand. The muscles are depicted in Figure 19.2.

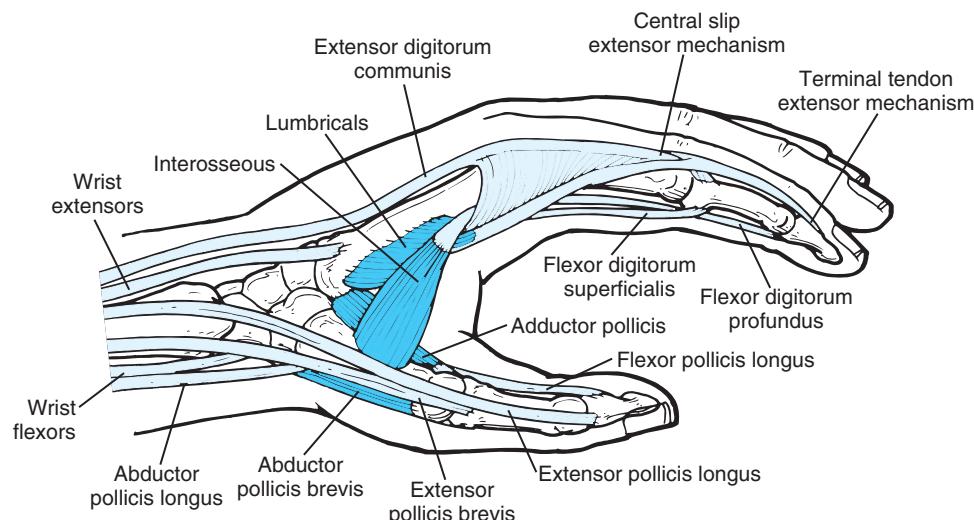

FIGURE 19.2 The extrinsic and intrinsic muscles of the wrist and hand create a balance of forces that affect hand function.

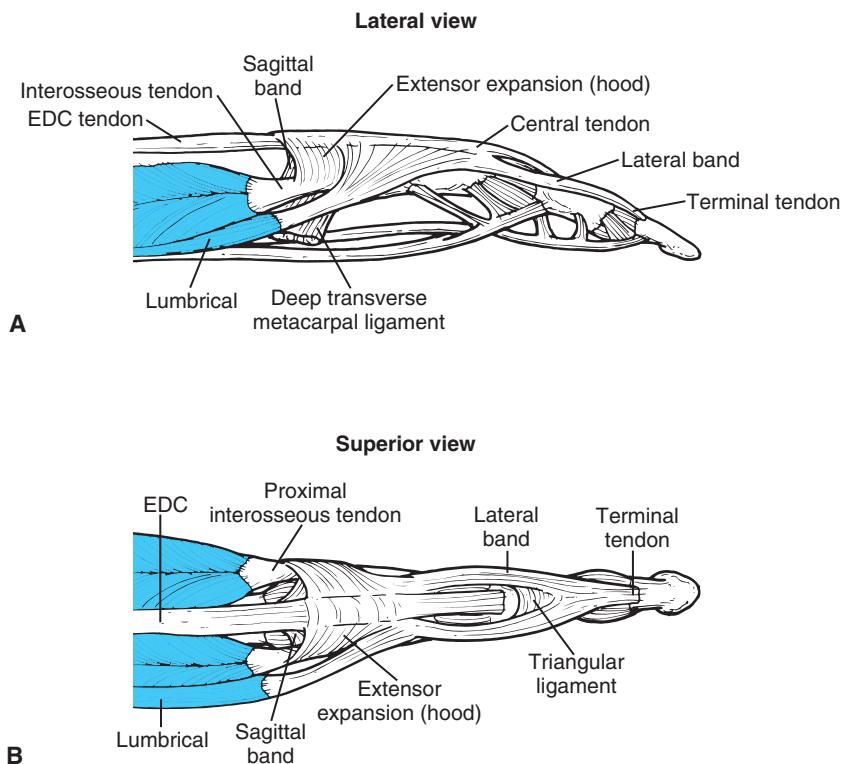

FIGURE 19.3 Anatomical structures of the extensor mechanism: (A) lateral view and (B) dorsal view. See text for description of functional relationships.

Control of the Unloaded (Free) Hand

Anatomical factors, muscular contraction, and viscoelastic properties of the muscles influence finger motion.^{5,69}

- When only the extrinsic muscles contract, clawing motions occur in the digits.
- Closing motions can occur only with extrinsic muscle contractions but also require the viscoelastic force of the biarticular interossei.
- Opening motions require synergistic contraction of the extrinsic extensor and the lumbrical muscles.
- Reciprocal motion of MCP flexion and IP extension is caused by the interossei. The lumbrical removes the viscoelastic tension from the profundus tendon and assists IP extension.

Grips and Prehension Patterns

The nature of the intended activity dictates the type of grip used.^{5,68,69,82}

Power Grips

Description. Power grips involve clamping an object with partially flexed fingers against the palm of the hand and with counter pressure from the adducted thumb. Power grips are primarily isometric functions. The fingers are flexed, laterally rotated, and ulnarily deviated. The amount of flexion varies with the object held. The thumb reinforces the fingers and helps make small adjustments to control the direction of the force.

Varieties include cylindrical grip, spherical grip, hook grip, and lateral prehension.

Muscle control. The muscles primarily function with isometric contractions^{5,108}

- Extrinsic finger flexors provide the major gripping force.
- The extensor digitorum provides a compressive force to the MCP joints, which increases stability and also provides a balancing force for the flexors.
- Interossei rotate the first phalanx for positioning to compress the external object and also flex the MCP joint.
- Lumbricales do not participate in the power grip (except the fourth).
- The thenar muscles and adductor pollicis provide compressive forces against the object being gripped.

Precision Patterns

Description. Prehension patterns involve manipulating an object that is not in contact with the palm of the hand between the opposing abducted thumb and fingers. The muscles primarily function isotonically. The sensory surfaces of the digits are used for maximum sensory input to influence delicate adjustments. With small objects, precise handling occurs primarily between the thumb and index finger. Varieties include pad-to-pad, tip-to-tip, and pad-to-side prehension.

Muscle control. The primary dynamic function of the muscles includes the following.^{5,108}

- Extrinsic muscles provide the compressive force to hold the objects between the fingers and thumb.
- For manipulation of an object, the interossei abduct and adduct the fingers, the thenar muscles control movement of the thumb, and the lumbricales help move the object away from the palm of the hand. The amount of participation of each muscle varies with the amount and direction of motion.

Combined Grips

Description. Combined grips involve digits 1 and 2 (and sometimes 3) performing precision activities, whereas digits 3 through 5 supplement with power.

Pinch. Pinch requires holding an object between the thumb and index or middle finger, as in precision handling, but may require primarily an isometric hold. Compression between the thumb and fingers is provided by the thenar eminence muscles, the adductor pollicis, the interossei, and extrinsic flexors. The lumbricales also participate.⁵

MAJOR NERVES SUBJECT TO PRESSURE AND TRAUMA AT THE WRIST AND HAND

For a detailed description of peripheral nerve injuries and Entrapments in the wrist and hand region, as well as complex regional pain syndromes (including reflex sympathetic dystrophy) and their management, see Chapter 13.

Nerve Disorders in the Wrist

Median nerve. The most common site for compression of the median nerve is the carpal tunnel.

Ulnar nerve. The most common site for compression of the ulnar nerve is in the ulnar tunnel (Guyon's canal).

Referred Pain and Sensory Patterns

The hand is the terminal point for the C6, C7, and C8 nerve roots coursing through the median, ulnar, and radial nerves (see Figs. 13.5, 13.6, and 13.7). Injury or entrapment of these nerves may occur anywhere along their course, from the cervical spine to their termination. What the patient perceives as pain or a sensory disturbance in the hand may be from injury of the nerve anywhere along its course, or the pain may derive from irritation of tissue of common segmental origin such as the zygapophyseal facet joints of the spine. For treatment to be effective, it must be directed to the source of the problem, not to the site where the patient perceives the pain or sensory changes. Therefore, a thorough history is taken and examination of the entire upper quarter must be done, including the cervical spine when referred pain patterns or sensory changes are reported by the patient.^{36,72}

MANAGEMENT OF WRIST AND HAND DISORDERS AND SURGERIES

To make sound clinical decisions when treating patients with wrist and hand disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting impairments, functional limitations, and possible disabilities. In this section, common pathologies and surgeries are presented and are related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*² (Table 19.1). Conservative and postoperative management of these conditions are also described in this section.

JOINT HYPOMOBILITY: NONOPERATIVE MANAGEMENT

Pathologies such as rheumatoid arthritis (RA) and degenerative joint disease (DJD) affect the joints of the wrist and hand and may have a significant effect on the functional abilities of an individual as a result of pain, impaired mobility, and potential joint deformities. Impaired joint, tendon, and muscle mobility also occurs any time joints are immobilized due to fractures, trauma, or surgery. Chapter 11 describes the etiology and general guidelines for management of impairments due to these joint pathologies. This section focuses on specific interventions for the wrist and hand.

Common Joint Pathologies and Associated Impairments

Rheumatoid Arthritis

The following is a summary of signs and symptoms and resulting impairments typically seen in the wrist and hand with RA.^{3,13,74,83,90}

Acute stage. There is pain, swelling, warmth, and limited motion from synovial inflammation (synovitis) and tissue proliferation, most commonly in the MCP, PIP, and wrist joints bilaterally. There is also inflammation (tenosynovitis) and synovial proliferation in the extrinsic tendons and tendon sheaths. In addition:

- Progressive muscle weakness and imbalances in length and strength between agonists and antagonists and between intrinsic and extrinsic muscles occur.
- Carpal tunnel syndrome may occur in conjunction with tenosynovitis due to compression of the median nerve from the swollen tissue.
- General systemic as well as muscular fatigue occurs.

Advanced stages. Joint capsule weakening, cartilage destruction, bone erosion, and tendon rupture, as well as imbalances in musculotendinous forces, lead to joint instabilities, subluxations, and deformities (Fig. 19.4). Typical deformities and the pathomechanics in the hand include:

TABLE 19.1 Wrist and Hand Pathologies/Surgical Procedures and Preferred Practice Patterns

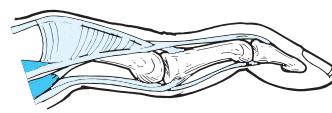

PATHOLOGY/SURGICAL PROCEDURE	PREFERRED PRACTICE PATTERN AND ASSOCIATED IMPAIRMENTS ²
<ul style="list-style-type: none"> • Arthritis (osteoarthritis, rheumatoid arthritis, post-traumatic arthritis) • Synovitis • Postimmobilization arthritis (stiffness) • Tendon adhesions 	Pattern 4D—Impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
<ul style="list-style-type: none"> • Acute arthritis • Acute sprain, tendonitis 	Pattern 4E—Impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
<ul style="list-style-type: none"> • Interposition arthroplasty (flexible silicone spacer, soft tissue implant) • Total joint replacement arthroplasty 	Pattern 4H—Impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
<ul style="list-style-type: none"> • Synovectomy and tenosynovectomy • Repair, reconstruction, or transfer of a ruptured or lacerated tendon • Soft tissue release (capsule, ligament, or tendon) • Open reduction and internal fixation of a fracture or fracture-dislocation • Bone resection (distal styloidectomy of the ulna, proximal row carpectomy) • Arthrodesis 	Pattern 4I—Impaired joint mobility, motor function, muscle performance, and ROM associated with bony or soft tissue surgery
<ul style="list-style-type: none"> • Carpal tunnel syndrome (median nerve) • Tunnel of Guyon syndrome (ulnar nerve) 	Pattern 5F—Impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury.

- *Volar subluxation of the triquetrum on the articular disk and ulna.* The extensor carpi ulnaris tendon displaces volarly and causes a flexor force at the wrist joint.
- *Ulnar subluxation of the carpal.* This causes radial deviation of the wrist.
- *Ulnar drift of the fingers and volar subluxation of the proximal phalanx.* There is stretching or rupture of the collateral ligaments at the MCP joints and a bowstringing effect from the extrinsic tendons.¹³

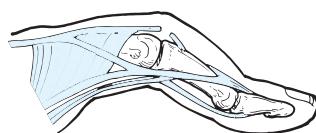

FIGURE 19.4 Joint deformities seen in the hand of a patient with rheumatoid arthritis. Note the hypertrophy of the IP joints, rheumatoid nodules, and volar subluxation of the triquetrum. This patient had fusion of the wrist joints due to pain and complete destruction of the joints, which has helped prevent the deforming bowstringing effect of the extrinsic tendons on the MCP joints. (Courtesy of Turtle Services Limited, www.turtleserviceslimited.org/.)

- *Swan-neck deformity.* Laxity of the PIP joint with an overstretched palmar plate and bowstringing of the lateral bands of the extensor hood result in hyperextension of the PIP and flexion of the DIP joints (Fig. 19.5A). Tight or overactive interossei muscles pulling on the extensor tendon reinforces the hyperextension of the hypermobile PIP joints, and increased passive tension in the flexor digitorum profundus tendon causes flexion of the DIP joint.
- *Boutonnière deformity.* Rupture of the central band (central slip) of the extensor hood results in the lateral bands of the extensor apparatus (extensor hood) slipping in a volar direction to the PIP joint, causing PIP flexion and DIP extension (Fig. 19.5B).

A Swan neck deformity

B Boutonnière deformity

FIGURE 19.5 (A) Swan-neck and (B) Boutonnière deformities. See text for description of the pathomechanics.

- **Zigzag deformity of the thumb.** Muscle imbalances and ligamentous laxity lead to metacarpal dislocation of the thumb and deformities similar to swan-neck or boutonnière deformity. Tightness in the adductor pollicis contributes to deformities in the thumb.⁸³

Osteoarthritis and Post-traumatic Arthritis

Age and repetitive joint trauma lead to degenerative cartilaginous and bony changes in susceptible joints. Osteoarthritis (OA) most commonly involves the trapezioscapoid articulation, CMC joint of the thumb, and DIP joints of the digits, although the effects of trauma can occur in any joint.

Post-traumatic arthritis can develop in any joint of the wrist or hand as the result of a severe intra-articular fracture or fracture-dislocation. At the wrist, for example, deficiency of the scapholunate interosseus ligament, as the result of a severe wrist sprain, can alter joint alignment, which can cause articular degeneration over time. In the fingers, the PIP joint is a common site of articular fracture and subsequent joint degeneration.

The following is a summary of signs and symptoms and resulting impairments commonly seen in OA or post-traumatic arthritis.¹²³

Acute stage. During the early stages of OA the symptoms include achiness and feelings of stiffness, which abate with movement. Following stressful activities or trauma, joint swelling, warmth, and restricted and painful motion occur.

Advanced stages. With degeneration there is capsular laxity resulting in hypermobility or instability; with progression, contractures and limited motion develop. Affected joints may become enlarged or sublux (Fig. 19.6). Limitation of both flexion and extension with a firm capsular end-feel develops in the affected joints. There is general muscle weakness, weak grip strength, and poor muscular endurance. Pain may also be a limiting factor in pinch and gripping activities.

FIGURE 19.6 Advanced stages of osteoarthritis in the hands of an 86-year-old pianist. Note the carpometacarpal joint subluxation at the base of each thumb. Atrophy of the first dorsal interossei as well as nodules and joint enlargements are apparent, but the individual is still functional.

PRECAUTION: After trauma, the therapist must be alert to signs of a fracture in the wrist or hand because small bone fractures may not show on radiographs for up to 2 weeks. Signs include swelling, muscle spasm when passive motion is attempted, increased pain when the involved bone is stressed (e.g., deviation toward the involved bone), and tenderness on palpation over the fracture site.^{36,77}

Postimmobilization Hypomobility

Immobilization may be necessary following a fracture, surgery, or trauma; or it may be used to rest a part when an individual sustains repetitive stress. Impairments and functional limitations may occur from the lack of motion and muscle contraction, including:

- Decreased ROM and decreased joint play with firm end-feel and pain on overpressure.
- Tendon adhesions. This is a significant complication if there was any inflammation in a tendon or its sheath.
- Decreased muscle performance including muscle weakness, weak grip strength, decreased flexibility, and decreased muscle endurance.

Common Functional Limitations/Disabilities with Joint Pathologies

When joint pathology is acute, many prehension activities are painful, interfering with activities of daily living (ADL and IADL), such as dressing, eating, grooming, and toileting or almost any functional activity that requires gripping and fine-finger dexterity, including writing and typing.

Depending on which joints are involved, the amount of restricted movement and residual weakness, fatigue, or dexterity loss, and the type of grip or amount of precision handling required, functional loss may be minor or significant.

Joint Hypomobility: Management—Protection Phase

General guidelines for managing acute joint lesions are described in Chapter 11, with special concerns for patients with RA and OA summarized in Boxes 11.2 and 11.4, respectively.

Control Pain and Protect Joints

Patient education. Teach the patient how to protect involved joints and control pain with activity modification, ROM exercises, and appropriate use of a splint.

Pain management. In addition to physician-prescribed medications or nonsteroidal anti-inflammatories and modalities, gentle grade I or II distraction and oscillation techniques may inhibit pain and move synovial fluid for nutrition in the involved joints.

Splinting. Use a splint to rest and protect the involved joints. Instruct the patient to remove the splint for brief periods of nonstressful motion throughout the day.

BOX 19.2 Joint Protection in the Wrist and Hand

Purpose. Performance of daily activities with minimal pain, stress to joints, and energy expenditure. Most of these principles are applicable to any arthritic problem in the hand but are especially important in the hand affected by rheumatoid arthritis.^{90,91}

Respect pain. Monitor activities; stop when fatigue or discomfort begins to develop. Modify or discontinue any activity or exercise that causes pain that lasts longer than 1 hour after stopping the activity.

Maintain strength and ROM. Integrate exercises into daily activities.

- Look for early signs of muscle tightness in the intrinsic muscles. If tight, initiate stretching. One cause of swan-neck deformity is tight interossei muscles pulling on the extensor tendon, leading to hyperextension of hypermobile PIP joints.
- Strengthen radial deviation of the MP joints of the fingers to counter the ulnar drifting of the fingers that occur in many functional activities.

Balance activity level and rest. More rest than normal is required during the active phases of the disease of RA.

Conserve energy and perform activities in the most economic way or do the most important activities first.

Avoid deforming positions or one position for prolonged periods.

Avoid using strong grasping activities that facilitate the deforming force. Typical joint deformities with RA include radial deviation and extension of the wrist and ulnar deviation and volar subluxation of the MP joints. Adaptive suggestions include:

- Open jars with the left hand or with an assistive device.
- Cut food with the blade of the knife protruding from the ulnar side of the hand.
- Stir food with spoon on the ulnar side of the hand.
- Build up the handles of eating utensils.
- Use stronger, larger joints whenever feasible. For example, carry items in a shoulder bag or over the forearm or with two hands rather than with one hand.
- Avoid twisting or wringing motions with the fingers. Press water out of a rag by opposing the palms of both hands together.

Activity modification. Analyze the patient's daily activities and recommend adaptations or assistive devices to minimize repetitive or excessive stresses on the joints. This is particularly important for patients with chronic arthritic disorders to prevent repetitive trauma and to minimize joint-deforming forces. Examples are summarized in Box 19.2.

Maintain Joint and Tendon Mobility and Muscle Integrity

Passive, assistive, or active ROM. It is important to move the joints as tolerated because immobility of the hand quickly leads to muscle imbalance and contracture formation or further articular deterioration. Aquatic therapy is an effective method of combining nonstressful, non-weight-bearing exercises with therapeutic heat.

Tendon-gliding exercises. Have the patient perform full motion in the uninvolved joints and as much motion as possible in the involved joints to prevent adhesions between the long tendons or between the tendons and their synovial sheaths.⁵⁰ Tendon-gliding exercises are described in the exercise section of this chapter.

Multiple-angle muscle setting exercises. Do gentle isometrics to all wrist and hand musculature. Resistive ROM exercises are usually not tolerated if there is joint effusion or inflammation; therefore isometric resistance within the tolerance of pain, is performed.

Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

With joint pathology, increase ROM by utilizing joint mobilization techniques to stretch the capsule⁹³ as well

as passive stretching and muscle inhibition techniques to elongate the periarticular connective tissue and musculotendinous units following the principles described in Chapters 4 and 5. It is also critical to determine if scar tissue has formed in the long tendon sheaths in the hand, and, if so, attempt to re-establish smooth tendon gliding. Tendon gliding techniques are described in the Exercise Intervention section of this chapter.

Increase Joint Play and Accessory Motions

Joint mobilization techniques. Determine which of the articulations of the distal RU, wrist, hand, or digits are restricted because of decreased joint play, and apply grade III sustained or grade IV oscillation techniques to stretch the capsules. See Figures 5.33 through 5.43 for mobilizing restricted joints of the distal forearm, wrist, hand, and digits.

PRECAUTIONS: For patients with RA, modify the intensity of joint mobilization and stretching techniques that are used to counter any restrictions. This is necessary because the disease process and steroid therapy weaken the tensile quality of the connective tissue, and consequently they are more easily torn.

Unlock a subluxated ulnomeniscal-triquetral joint. The mechanism of the dysfunction is not clear, but some patients describe locking in the wrist and an inability to supinate the forearm. The meniscus may be displaced and be the cause of the blocked motion. The following techniques may free up the motion.

- Apply a volar glide to the ulna on a stabilized triquetrum (similar to Fig. 5.38).

- **Self-mobilization.** Have the patient grasp the distal ulna with the fingers of the opposite hand, place the thumb on the palmar surface of the triquetrum just medial to the pisiform, and then press with the thumb, causing a dorsal glide of the triquetrum on the radioulnar disk and ulna (Fig. 19.7).

FIGURE 19.7 Self-mobilization of the ulnomeniscal-triquetal (UMI) joint.

Improve Joint Tracking and Pain-Free Motion

Mobilization with movement (MWM) techniques may be applied to increase ROM and/or decrease the pain associated with movement.⁷⁸ (The principles of MWM are described in Chapter 5.)

MWM of the wrist. Have the patient seated with the elbow flexed and forearm supinated (patient's palm facing towards his or her face); stabilize the distal radius with your hand placed around the lateral aspect of the forearm. Apply a pain-free lateral glide to the proximal row of carpal bones utilizing the web space of your other hand. Have the patient then perform active wrist extension or flexion to the end of the available range, and with his or her free hand apply a passive stretch at the end of the range (Fig. 19.8).

An internal or external rotation of the carpal bones relative to the radius may need to be combined with the glide to achieve pain-free, end-range loading.

The intercarpal joint may require specific anterior-posterior gliding of one proximal row of carpal bones relative to its distal row neighbor combined with active physiologic motion to the end of the range. The mobilization and movement are pain-free. While holding the mobilization force, ask the patient to do repetitive gripping activities or resisted wrist motions.

MWM of the MCP and IP joints of the digits. Medially or laterally glide the involved phalanx in a painless direction,

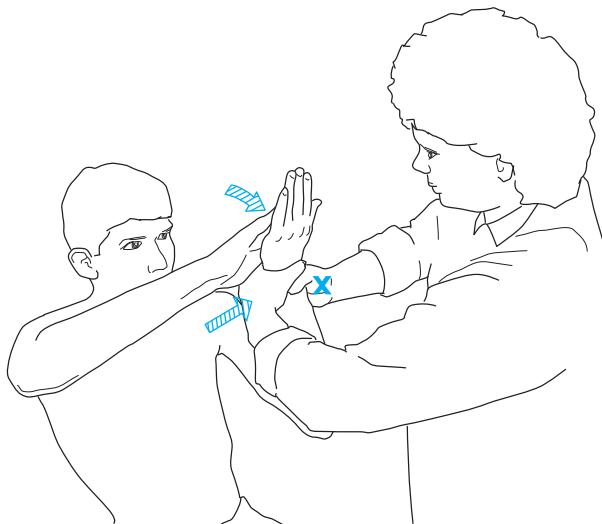

FIGURE 19.8 Mobilization with movement (MWM) to increase wrist flexion or extension. Apply a lateral glide while the patient actively flexes or extends the wrist and then applies a passive stretch force with the other hand at the end of the range.

then have the patient actively flex or extend the finger and apply a pain-free, end-range stretch. Internal or external rotation of the more distal phalanx may be required in conjunction with the medial or lateral glide to achieve painless end-range overpressure.⁷⁸

Improve Mobility, Strength, and Function

Carefully examine the multijoint and intrinsic muscles for restricted motion due to contractures or adhesions and poor movement patterns due to weakness or imbalances in strength. Stretching, tendon gliding, and strengthening exercises are described in the exercise sections of this chapter. Utilize techniques that specifically address the impairments the patient has. Once range is gained, it is critical that the patient uses the new range with active ROM and functional activities.

Neuromuscular control and strength. Progress exercises with controlled and nondestructive forces to increase strength and muscle balance between antagonists and progress endurance training. With pathological joints, use caution when applying weights so as not to stress the joints beyond the capability of the stabilizing tissues.

Functional activities. Develop exercises that prepare the patient for functional activities. Consider prehension patterns that are required for the patient's job, recreational, and daily activities. Include exercises that require coordination and fine finger dexterity.

Conditioning exercises. Initiate physical conditioning exercises using activities that do not provoke joint symptoms, such as aquatic exercises or cycling.

Joint protection. Reinforce use of joint protection techniques as summarized in Box 19.2.

Focus on Evidence

In a systematic literature review of randomized, controlled trials of adult patients with RA, the reviewers concluded that there is evidence to support the idea that low-intensity therapeutic exercise is beneficial for reducing pain and improving functional status (including hand grip strength) in patients with RA, whereas high-intensity exercise programs may exacerbate symptoms.⁸⁷

JOINT SURGERY AND POSTOPERATIVE MANAGEMENT

Long-standing RA, OA, or post-traumatic arthritis that affects the joints and soft tissues of the wrist and hand can lead to chronic pain, instability and deformity of joints, restricted ROM, loss of strength in the hand, and impaired function of the upper extremity. When nonoperative management is not sufficient, surgical intervention coupled with individually designed and carefully supervised postoperative rehabilitation is indicated to improve and restore function.

Some of the more common surgical options for management of arthritis are listed in Box 19.3. Refer to Table 19.1 to see the groupings of impairments typically associated with each of these surgeries.

Soft tissue procedures, such as synovectomy, tenosynovectomy for chronic tenosynovitis of the extensor and flexor tendons of the wrist, repair of ruptured tendons, capsulotomy or release of other soft tissues for correcting

a deformity, or muscle balancing of the wrist or finger joints are employed independently or concomitantly when articular surfaces of the involved joints remain reasonably intact.^{16,20,37,50,132,133} If joint deterioration is significant, resection arthroplasty, such as resection of the distal ulna (Darrach procedure) or proximal row carpectomy, arthrodesis, or implant arthroplasty, performed in conjunction with soft tissue repair or reconstruction, are surgical options for advanced joint deterioration.^{12,16,20}

Some procedures are selected to relieve pain and others to minimize or delay further deformity. For example, if medical management of RA of the wrist does not adequately control synovitis, tenosynovectomy is performed to remove proliferated synovium from tendon sheaths and prevent erosion or rupture of tendons before significant deformity and loss of active control of the wrist and fingers occur.¹³² If rupture occurs, tendon repairs and transfers can improve function of the hand and delay or prevent subluxation and dislocation of joints or fixed deformities.^{50,51}

Partial or complete arthrodesis of the wrist or arthrodesis of an individual joint of a digit, such as the CMC joint of the thumb, are procedures that yield predictable and durable results. Fusion corrects deformity and gives the patient stability and relief of pain with only some compromise of function despite the loss of joint motion.^{49,50,80} If fusion is inappropriate and pain-free functional mobility is necessary, implant arthroplasty, either interposition arthroplasty or total joint replacement, are possible options. In many instances, a combination of joint and soft tissue procedures is indicated.^{10,11,16,30} For the most part, however, arthroplasty is reserved for the patient who requires only low-demand use of the hand.

The goals of surgery and postoperative management of advanced arthritis and associated deformities of the wrist and hand include^{10,16,57,95,121} (1) relief of pain, (2) restoration of normal or sufficient function of the wrist and hand, (3) correction of instability or deformity, (4) restoration of ROM, and (5) improved strength of the wrist and fingers for functional grasp and pinch.

A discussion of several types of arthroplasty and general guidelines for postoperative management follow. Information on surgical management and postoperative rehabilitation of tendon repairs and transfers associated with RA is then outlined. Given the complexity of hand rehabilitation, suggested phase-specific guidelines for exercise, founded on principles of tissue healing, must be individualized for each patient and determined by the patient's level of participation in the rehabilitation process and response to exercise.

Successful outcomes are contingent upon close communication among the surgeon, therapist, and patient or patient's family. An effective postoperative rehabilitation program combines early, supervised therapy with patient education and progresses to long-term self-management by the patient. Although rehabilitation is deemed essential after each of the surgical interventions covered in this section, postoperative protocols vary and have not been com-

BOX 19.3 Surgical Intervention for RA or DJD of the Wrist and Hand

Soft Tissue Procedures

- Synovectomy
- Tenosynovectomy
- Tendon repair, graft, or transfer/realignment
- Nerve decompression
- Capsuloligamentous reconstruction
- Contracture release
 - Capsulectomy/capsulotomy
 - Tendon release
- Soft tissue arthroplasty

Joint and Bony Procedures

- Excision/resection arthroplasty
 - Styloidectomy
 - Proximal row carpectomy
- Tendon interposition/trapezial resection arthroplasty
- Interposition, flexible implant arthroplasty
- Total joint arthroplasty
- Arthrodesis

pared for each type of procedure, making it difficult to suggest that there is one best approach to postoperative management.

Wrist Arthroplasty

Although arthrodesis of the wrist continues to be the most common surgical intervention for late-stage RA of the wrist, arthroplasty has become an acceptable alternative, particularly for patients with arthritis and impaired mobility of other joints of the extremities. Although wrist arthrodesis has not been shown to limit upper extremity function in daily living activities in patients with post-traumatic arthritis of the wrist but without arthritis of other upper extremity joints, it is thought that loss of wrist motion may adversely affect functions such as personal care in patients with RA who also have impaired mobility of other upper extremity joints.¹³¹ For these patients, wrist arthroplasty—total joint replacement or flexible implant (interposition) arthroplasty—is an option that provides relief of symptoms while retaining some wrist mobility.

Indications for Surgery

The following are common indications for arthroplasty of the wrist.^{10,12,16,95,119}

- Severe pain in the wrist region as the result of deterioration of the articular surfaces of the distal radius, carpal, and distal ulna from chronic arthritis (usually RA, but also OA and post-traumatic arthritis) that compromises hand and upper extremity function.
- Deformity and marked limitation of the wrist that causes muscle-tendon imbalances of the digits.
- Subluxation or dislocation of the radiocarpal joint.
- Appropriate for *low-demand* upper extremity functional needs.
- Appropriate for patients with bilateral wrist involvement where arthrodesis of both wrists would limit rather than improve overall function.
- Also appropriate for patients with significant stiffness of the ipsilateral shoulder, elbow, or finger joints in whom unilateral arthrodesis of the wrist would further limit rather than improve functional use of the upper extremity.

Box 19.4 identifies some absolute and relative contraindications to wrist arthroplasty and arthroplasty of the joints of the fingers and thumb.^{10–12,16}

Procedures

Implant designs, materials, and fixation. Because partial or total arthrodesis of the wrist is often considered the procedure of choice (not just a salvage procedure) for patients with severe pain and instability of the wrist^{49,80} and because resection arthroplasty of the distal radius and proximal row carpectomy³⁷ are also suitable options that relieve pain but retain some mobility of the wrist, the use of joint replacement surgery for patients with late-stage arthritis of the wrist has been somewhat limited.²⁰ Never-

BOX 19.4 Contraindications to Arthroplasty of the Wrist or Digits

Absolute

- Active infection
- Expected high-demand use of the hand (e.g., manual labor) or high-impact sport activities (e.g., tennis and volleyball)
- Inadequate motor control of the wrist or hand as the result of neurological damage
- Rupture of the radial wrist extensors
- Limited ROM without pain

Relative

- Severe and irreparable deformity of the wrist or digits
- Rupture of multiple extensor tendons of the digits
- Inadequate, poor quality bone stock
- Need for ambulation aids (e.g., crutches or a walker) that place significant forces across the wrist and hand
- Compromised immune system

theless, designs of implants and operative techniques for arthroplasty of the wrist have gradually evolved.

During the late 1960s, Swanson first used a one-piece, uncemented, double-stemmed, flexible (“hinged”) implant made of silicone for the radiocarpal joint, primarily for use in patients with RA.^{119,122} The prosthesis, which is inserted between the distal radius, through the capitate, and into the intramedullary canal of the third metacarpal (after a proximal row carpectomy), is designed to act as a *dynamic spacer* to maintain joint alignment during healing. Over time the implant becomes encapsulated, forming a new fibrous capsule.^{12,119,122} Although the procedure provides pain relief and some degree of stability and ROM (approximately a 60° arc of flexion/extension and a total of 10° of radial and ulnar deviation), its use has been associated with a high rate of failure as the result of excessive wear of the prosthesis or cystic changes in bone and eventual fracture or loosening of the prosthesis.^{10–12,16} It has also been suggested that as a silicone implant gradually wears (abrades), and it may give rise to *particulate synovitis* (silicone synovitis).⁵⁸ Design changes have been made to reinforce the silicone implant with bone-shielding devices (titanium grommets) to improve the long-term durability of the prosthesis.^{10,12,119} Development of flexible materials as alternatives to silicone is also being investigated.¹¹⁹ Despite improvements, with the increased use of rigid implants for wrist arthroplasty, flexible interposition implant arthroplasty now plays a limited role, with its use reserved for the low-demand, older (> 60 years) patient with RA.¹⁶

Numerous designs of total wrist replacement arthroplasty (Fig. 19.9) have been developed and consistently refined over the past few decades, making arthroplasty available not only to patients with late-stage joint disease but also those with severe deformity and collapse of the wrist joint.^{10,11,76} Total wrist arthroplasty typically involves inserting a two-piece system with elliptical (convex-

FIGURE 19.9 Total wrist arthroplasty. (From Wadsworth C, Steyers C, Adams B: Postoperative Management of the Wrist and Hand. Independent Study Course 15.2. Post-operative Management of Orthopedic Surgeries. Orthopedic Section, APTA, La Crosse, WI, 2005:25, with permission.)

concave) surfaces that are loosely constrained or non-constrained. Components are made of rigid materials (cobalt-chrome or titanium and high-density polyethylene). The implants are sometimes porous-coated along the stems for bio-ingrowth,⁹⁶ and a combination of cement and screws is employed for additional fixation.^{10,12,16} Most total wrist systems are designed to allow a combined 90° arc of flexion and extension.

Operative procedures. Total wrist arthroplasty requires a longitudinal incision along the dorsal aspect of the wrist in line with the third metacarpal.^{10–12,16} Concomitant *dorsal clearance* (synovectomy of the wrist and tenosynovectomy of the extensor tendons) is often necessary. The retinaculum is incised and reflected, and the digital extensor tendons are retracted for access to the joint capsule.

The distal portions of the radius and ulna, some of the carpal, and a small portion of the proximal aspect of the third and often the second and fourth metacarpals are resected. The rigid, stemmed prosthetic components are then tightly fit into the reamed intramedullary canals of the necessary metacarpals and the distal radius.^{10,11,50} In patients with instability and subluxation of the radiocarpal joint, capsule and ligament reconstruction is typically performed to improve wrist stability. Soft tissue balancing is critical for satisfactory results.

After closure of the dorsal incision, the hand is placed in a long-arm or short-arm bulky compression dressing and elevated several days postoperatively to control edema.

Postoperative Management

Immobilization

After total wrist replacement, the wrist is continuously immobilized in a neutral position for several days to 2 weeks. After the bulky, postoperative dressing is removed, the wrist and forearm are placed in a short-arm volar wrist splint with the wrist positioned in about 10° to 15° extension. The splint allows full finger ROM and opposition of the thumb. The timeframe for removal of the splint for exercise varies from 1 to 4 weeks, depending on the extent of soft tissue reconstruction and bone stock quality.^{11,16,70,96}

If a concomitant repair of the extensor tendons was performed, the immobilizer is fitted with outriggers that have elastic slings to hold the fingers in extension. Even after wrist exercises are initiated, the immobilizer is worn for protection between exercise sessions. A static resting splint is worn at night for 6 to 8 weeks postoperatively.⁵¹

Generally, flexible implant arthroplasty requires a longer period of immobilization than total wrist replacement, with a duration as short as 3 to 4 weeks or as long as 6 to 8 weeks, to allow time for encapsulation of the prosthetic spacer to occur.^{48,119}

Exercise

As with arthroplasty of other large or small joints, the goals and progression of exercise during each successive phase of rehabilitation after wrist arthroplasty (both total wrist or interposition arthroplasties) are based on the stages of soft tissue healing. The stability of the wrist always takes precedence over restoration of wrist mobility. If concomitant extensor tendon repairs were also done, the guidelines and timeframe for exercise are adjusted and special precautions are taken, as discussed in a later section of the chapter on repair of extensor tendon ruptures in RA.

For protection of the wrist after arthroplasty, precautions, identified in Box 19.5, must be incorporated into postoperative exercises and functional activities during and after rehabilitation.^{70,118}

Exercise: Maximum and Moderate Protection Phases

The focus of rehabilitation during the maximum protection phase is to control pain and peripheral edema, protect the

BOX 19.5 Precautions After Wrist Arthroplasty

- Avoid weight bearing on the operated hand during transfers, ambulation with assistive devices, or other daily living activities.
- If ambulation aids are required because of lower extremity joint involvement, use forearm-support crutches or walker.
- Avoid functional activities that place more than 5- to 10-lb loads on the wrist.
- Wear a wrist splint for additional protection during functional activities.
- Permanently refrain from high-impact vocational or recreational activities, such as heavy labor or racquet sports.

wrist, and prevent stiffness of the rest of the upper extremity. When the immobilizer can be removed for wrist exercises, protection of the wrist is still essential.

The emphasis during the moderate protection (controlled motion) phase, which typically begins about 4 to 8 weeks postoperatively, is to gradually restore active control and mobility of the digits, wrist, and forearm motion without jeopardizing wrist stability.^{11,48,57,70,119}

● **Maintain and later improve mobility of unoperated joints.**

- Begin active ROM exercises of the digits, elbow, and shoulder while the wrist is immobilized and the use of the hand is restricted.
- Around 6 weeks postoperatively, if there was limitation of finger mobility preoperatively, selectively use low-load, dynamic finger splint(s) during the day or gentle passive stretching *initially with the wrist maintained in a neutral position* to increase mobility for a sufficient level of hand function.
- Grade II and possibly grade III joint mobilizations are appropriate if the joints of the digits are not inflamed.

● **Restore control and mobility of the wrist.**

- Include active ROM, emphasizing wrist extension more than flexion, and tendon-gliding exercises with the wrist in neutral (see Fig. 19.17A–E).

PRECAUTIONS: Postpone radial and ulnar deviation if wrist stability is questionable.⁵⁷ When performing radial and ulnar deviation, avoid wrist flexion with ulnar deviation (the position of wrist deformity).

● **Regain use of wrist, finger, and thumb musculature.**

- Start with gentle setting exercises and progress to low-intensity, isometric resistance exercises of the wrist and finger musculature.
- After total wrist arthroplasty, begin to use the hand for light (minimum-load) functional activities around 6 to 8 weeks.⁹⁶
- After flexible implant arthroplasty, this may be delayed until about 12 weeks postoperatively.¹¹⁹

Exercise: Minimum Protection/

Return to Function Phase

During the minimum protection phase, which usually does not begin until 8 to 12 weeks postoperatively, regaining sufficient strength and muscular endurance of the entire upper extremity for appropriate functional activities is the priority.⁷⁰ In the wrist, emphasize strengthening the wrist extensors more so than the wrist flexors. Patient education focuses on incorporating joint protection during functional activities (refer to Box 19.2). Use of a cock-up resting splint is advisable at night, particularly if a wrist flexion contracture persists. Although 15° of wrist extension is preferable for a strong functional grasp, the use of manual stretching procedures to increase wrist extension is not consistently advocated so as not to compromise wrist stability.¹¹⁹

● **Regain functional strength of the hand and wrist.**

- Transition to low-intensity dynamic resistance (about 1 lb) exercises of the hand and wrist.⁷⁰
- Emphasize simulated functional movement patterns, such as various types of grasping activities, being certain to reinforce principles of joint protection.⁹¹ If not previously initiated, begin to use the hand for light functional activities.
- By 12 weeks after total wrist arthroplasty or flexible implant arthroplasty, the patient may use the hand for most low-load functional activities.^{48,96}

● **Increase ROM of the wrist to a functional level.**

- Continue active ROM and gentle stretching exercises as dictated by the stability of the wrist.
- Use low-load dynamic splinting of the wrist, emphasizing wrist extension to at least 15°.
- In patients who exhibit significant postoperative stiffness of the wrist soon after surgery, stretching activities may be initiated earlier than during the minimum protection phase, possibly at 6 weeks postoperatively.⁴⁸

Outcomes

A successful outcome after wrist arthroplasty gives the patient a stable, pain-free wrist with functional ROM. Postoperative outcomes typically measured are pain relief, use of the hand for functional activities, wrist and forearm ROM, and grip strength. Instruments, such as the Disabilities of the Arm, Shoulder and Hand (DASH) questionnaire and the Patient-Rated Wrist Evaluation, are used to assess pain, function, and satisfaction.⁷⁹

Pain relief. Barring complications, short- and long-term relief of pain after flexible implant arthroplasty^{61,112,119} and total wrist arthroplasty^{10,11,16} is a consistent finding. For example, in a retrospective study that followed 14 patients (12 with RA) with arthritis of the wrist, who underwent 17 primary semiconstrained total wrist replacements, preoperatively 88% of wrists (15/17) were ranked as being moderately to severely painful. Postoperatively, all wrists were less painful, with 15 ranked as pain-free and 2 mildly painful.⁹⁶ Another author indicated that about 75% of patients experience complete pain relief after total wrist arthroplasty.¹⁶

In a long-term study, patients with RA who underwent Swanson silicone wrist arthroplasty were followed for a minimum of 10 years (mean follow-up 15 years) and reported “good” or “very good” outcomes, primarily due to adequate pain relief.⁶¹

Wrist and forearm ROM, strength, and function.

Improvement in ROM is less predictable than pain relief. ROM of the wrist achieved postoperatively is usually about 15° to 30° each of wrist flexion and extension, 5° to 10° each of radial and ulnar deviation, and at least a 100° arc of pronation and supination.^{11,119} A functional level of active wrist ROM appears to be retained over an extended number of years. For example, 10 years or more after implantation of the Swanson silicone prosthesis, a group of patients (all with RA) in a follow-up study had 28°

flexion and 15° extension (i.e., a total flexion/extension arc of 43°).⁶¹

In studies comparing pre- and postoperative results of newer designs of total wrist arthroplasty, the postoperative ROM reported was even greater for most motions.^{40,79,96} However, actual *improvements* in ROM after arthroplasty have⁴⁰ and have not⁹⁶ been statistically significant. As a point of interest, the results of biomechanical studies of normal individuals performing a variety of functional activities have indicated that no more than 35° each of wrist flexion and extension was used.^{88,98}

Grip strength⁹⁶ and use of the operated hand for functional activities^{40,79} routinely improve after wrist arthroplasty. Relief of pain has an obvious impact on hand function. Concomitant soft tissue repair, such as repair of ruptured tendons, also contribute to improved function. Furthermore, arthroplasty provides some additional length to the wrist, which in turn improves the length-tension relationship of the muscle-tendon units that cross the wrist.¹⁰

Complications. Complications rates have always been higher for wrist arthroplasty, particularly the early designs, than replacement arthroplasty of larger joints, such as the shoulder, hip, and knee.^{11,12} One author has suggested that one in five wrist arthroplasties require revision within 5 years.¹⁰ After flexible implant arthroplasty, prosthetic fracture rates 5 to 10 years postoperatively have been reported at 20%⁵⁰ and 22%.¹¹⁰ Loosening of the distal component and dislocation are frequently reported complications associated with total wrist arthroplasty,^{10,16} particularly the early designs.⁷⁶ Early results of recent modifications to implant designs appear to be decreasing the rate of loosening.^{16,40,79,96}

Complications may require an alternative procedure or revision arthroplasty. If a silicone implant arthroplasty fails, total wrist replacement is still possible; if a total wrist arthroplasty fails because of mechanical loosening or component failure, revision arthroplasty and wrist arthrodesis are still viable alternatives.^{10,12,49,80}

Metacarpophalangeal Implant Arthroplasty

Arthroplasty of the MCP joints of fingers (digits 2 to 5), combined with necessary reconstruction of soft tissues, is the most common surgical procedure performed to manage impaired function and progressive deformity as the result of late-stage RA of the hand.^{29,30} However, arthroplasty is also an option for patients with idiopathic OA and post-traumatic arthritis of the MCP joints.^{30,94} For MCP arthroplasty to be successful, a patient must have intact extensor digitorum communis tendons, or repair of these tendons must be performed. The two procedures may be staged, one prior to the other, or performed simultaneously as determined by the surgeon. Other procedures to balance soft tissues must also accompany MCP arthroplasty for improved hand function postoperatively.^{30,73,115}

If joints other than the MCP joints are involved, which is often the case in patients with RA, surgeries are carefully

sequenced. For example, if the wrist is involved, a radiolunate or total wrist arthrodesis for pain-free wrist stability in a functional position may be necessary prior to MCP arthroplasty. In contrast, a swan-neck deformity of a finger is managed with PIP fusion in 30° to 40° of flexion, but typically it is done after, not before, MCP arthroplasty.^{30,118}

The goals of this surgery and postoperative management are to relieve pain, correct alignment of the fingers, improve active hand opening and grasp, and improve the cosmetic appearance of the hand.^{73,118}

Indications for Surgery

The following are common indications for arthroplasty of the MCP joint(s).^{12,30,73,95,115,121}

- Pain at the MCP joint(s) of the hand and diminished hand function as the result of deterioration of the articular surfaces, usually because of RA but sometimes as the result of OA or post-traumatic arthritis.
- Instability, often coupled with volar subluxation, and deformity (flexion and ulnar drift) of the MCP joint(s) that cannot be corrected with soft tissue releases and reconstruction alone.
- Stiffness and decreased active ROM of the MCP joints, often associated with a deficient extensor mechanism, causing inability to open the hand to grasp large objects.
- Poor appearance of the hand.

Procedures

Implant design, materials, and fixation. MCP joint arthroplasty is designed to provide a balance of stability and mobility to the MCP joints for patients with late-stage arthritis. There are several designs using different materials and methods of fixation that have evolved over the past few decades. Swanson developed a one-piece, flexible, double-stemmed prosthesis made of silicone (Fig. 19.10)

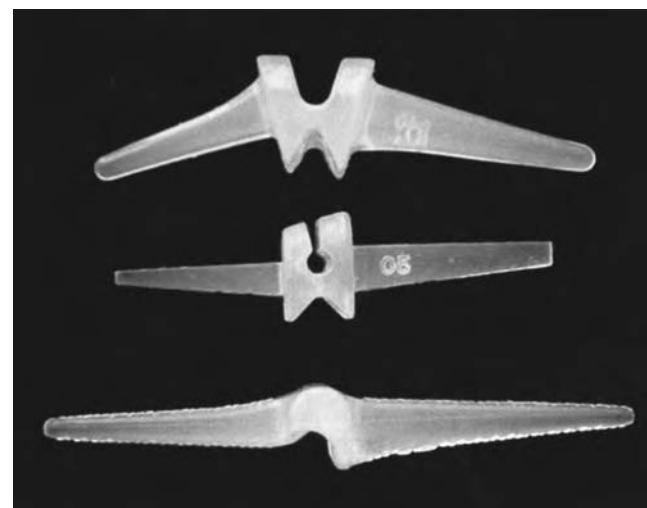

FIGURE 19.10 Lateral view of the three most common silicone-based implants: Neuflex (top), Avanta (middle), Swanson (bottom). Note that the Avanta and Swanson implants are of a 0° bend type. (From Manuel, JLM, Weiss, A-PC: Silicone metacarpophalangeal joint arthroplasty. In Strickland JW, Graham, TJ [eds] Master Techniques in Orthopedic Surgery—The Hand, ed 2. Lippincott Williams & Wilkins, Philadelphia, 2005, p 393, with permission.)

that is uncemented; it serves as a dynamic spacer and an internal joint mold as it becomes encapsulated during the healing process.^{12,15,30,81,121} The implant maintains internal alignment of the joint during healing and allows early postoperative joint motion. As with radiocarpal flexible implants, the MCP silicone implant sometimes is reinforced with circumferential titanium grommets to minimize long-term component wear or fracture and the possibility of silicone synovitis.¹²¹ Although the original Swanson implant has undergone some minor design changes, it has been a highly reliable design and remains the most widely used MCP implant for patients with RA.^{30,115} The Swanson implant has also been used successfully in patients with OA⁹⁴ and post-traumatic arthritis.³⁰

Other silicone implants have been developed as alternatives to the Swanson implant. One such design is the Neuflex implant (see Fig. 19.10), which is preformed in 30° of flexion to replicate the position of the MCP joints when the hand is at rest. The design is intended to improve ROM.^{39,73}

Total MCP joint replacement, sometimes referred to as resurfacing arthroplasty, is an alternative to flexible implant arthroplasty.³⁰ Surface replacements typically are two-component, convex-concave designs made of either metal and high-density polyethylene or pyrolytic carbon with highly polished articular surfaces. The metal-plastic designs are usually cemented in place, but bio-ingrowth fixation is being investigated as an alternative. The pyrolytic carbon implants, because of the nature of the material, exclusively rely on bio-ingrowth fixation.^{29,30}

Unlike the one-piece flexible implant designs, resurfacing replacements have little to no inherent stability and therefore must rely on intact or repairable collateral ligaments for joint stability. Consequently, MCP resurfacing arthroplasty is used less frequently in patients with RA—in whom there tends to be poor quality soft tissues as the result of long-standing inflammation and deformity, making it difficult to repair the collateral ligaments—than in patients with OA or post-traumatic arthritis, whose collateral ligaments are either intact or can be repaired. One resource suggests that a silicone implant is indicated if there is an extensor lag (lack of active extension) of the MCP joints > 60° and ulnar deviation > 45°.³⁰

Operative procedures. MCP arthroplasty and related soft tissue balancing involve the following procedures.^{30,73,94,118,121} The involved MCP joints are approached by either a single, transverse incision over the dorsal aspect of the metacarpal heads or by double, longitudinal incisions made between the index and middle fingers and between the ring and little fingers. The joint capsule is exposed by carefully separating the extensor tendons, which are often ulnarily displaced, from the underlying capsule and longitudinally incising the extensor hood. The tendons are retracted; the ulnar and possibly the radial collateral ligaments, if intact, are reflected from the head of each metacarpal; and the dorsal aspect of the capsule is incised (capsulotomy). Every effort is made to preserve the radial collateral ligaments. A synovectomy is performed if necessary. If a sig-

nificant flexion contracture exists, the volar aspect of each capsule may also be incised to allow greater extension of the MCP joints.

The heads (distal aspect) of the metacarpals and proximal aspect of the first phalanges of the involved joints are excised, and the intramedullary canals of the metacarpals and proximal phalanges are widened to accept the prosthetic implants. After insertion of the implants, the ROM of the replaced joints is checked. The joint capsule, radial collateral ligament (if preserved), and extensor mechanism of each digit are repaired. The wound is then closed, and a bulky compression dressing and volar hand and forearm splint are placed on the hand. The hand is elevated to control edema.

Postoperative Management

As with arthroplasty of the wrist or other joints of the digits, the postoperative rehabilitation program is founded on the principles of soft tissue healing and includes phase-specific goals and interventions, including the use of dynamic and/or static splinting and a supervised home exercise program.

General postoperative guidelines from a number of resources for a progression of exercises combined with the use of splints to maintain alignment and protect soft tissues as they heal are summarized in this section.^{14,21,30,48,121,126} These guidelines must be individualized, based on the type of arthroplasty and soft tissue procedures performed and each patient's responses. Ongoing patient education and close communication with the surgeon are essential for effective outcomes. Postoperative rehabilitation continues for 3 to 6 months.

Immobilization

Initially, the wrist and hand are continuously immobilized in the bulky compression dressing and volar splint applied at the end of surgery, with the wrist positioned in neutral, the MCP joints in full extension and either neutral or slight radial deviation (opposite the position of deformity), and the distal joints (PIP and DIP) in slight flexion.^{30,70,121} In some instances the splint extends only to the level of the PIP joints.⁹⁴ The bulky dressing is later replaced with a light compression dressing.

Continuous immobilization is not lengthy but varies with the type of arthroplasty, the type and quality of the soft tissue repairs, and the stability of the reconstructed joints. If only an MCP implant was performed, the hand remains immobilized for only a few days. If, in addition to the MCP arthroplasty, ruptured extensor tendons also were repaired or transferred, the hand remains immobilized longer to protect the tendons.^{50,51}

Dynamic splinting. When the compression dressing is removed, the hand is placed in a dynamic MCP extension splint with an outrigger (Fig. 19.11). The splint is worn to protect healing structures, maintain alignment (to prevent recurrent flexion and ulnar drift deformities at the MCP joints), and control and guide the range and plane of motion during exercises as soft tissues heal.^{14,30,71,115,121,126,129}

FIGURE 19.11 A dynamic extension splint with rubber bands attached to a dorsal outrigger used after MCP arthroplasty permits active MCP flexion but at rest maintains the MCP joints in extension and sometimes slight radial deviation. (Courtesy of Janet Bailey, OTR/L, CHT.)

The dynamic splint holds the wrist in about 10° to 15° of extension and the MCP joints in full extension and slight radial deviation as well as supination of the index finger, but it does not control motion in the IP joints. Slings under the proximal phalanx of each finger with rubber bands attached to the outrigger of the splint hold the MCP joints in extension when the hand is at rest but still allow active flexion of the MCP joints within a functional range. The patient wears the dynamic splint throughout the day, including exercise sessions.

At 2 to 3 weeks, a dynamic MCP flexion splint may be indicated and worn intermittently or alternately during the day with the dynamic extension splint if sufficient MCP flexion has not yet been attained, particularly in digits 3, 4, and 5.^{12,14,48,70,121,126,129} By 6 weeks, but sometimes as late as 12 weeks postoperatively, dynamic splinting is gradually discontinued unless an active extensor lag or a flexion or extension contracture of the MCP joints persists.^{14,30,70,121,126,129}

Static splinting. If a dynamic splint is worn during the day, at night the patient wears a volar static (resting splint), which holds the wrist in 15° of extension and the fingers in full or almost full extension. A block along the ulnar border of the splint prevents ulnar deviation of the fingers. If a flexion contracture or active extensor lag of the MCP joints is present, night splinting is often continued for 3 to 4 months or as long as a year.^{12,14,70,118,126,129}

Although dynamic splinting is widely used after MCP arthroplasty, another option is the alternating use of two static splints, one that holds all of the finger joints in extension and another that holds the MCP joints in flexion and the PIP and DIP joints in almost full extension.²¹ Each splint is worn for 24 hours at a time. During the day the splint is removed frequently for gentle assisted ROM exercises. Some clinicians suggest that static splints are as effective as dynamic splints and are easier and less expensive to fabricate and modify, easier for patients to apply, and less cumbersome to wear because there is no need for

the high-profile outrigger and rubber band suspension slings used in a dynamic splint.²¹

Focus on Evidence

In a prospective study by Burr and colleagues²¹ designed to investigate the effectiveness of the use of an alternating static splinting regimen combined with postoperative exercises as an alternative to dynamic splinting, 15 patients with RA who underwent 51 MCP silicone implant arthroplasties were followed for 19 months. The results indicated that there was a significant improvement in the mean total arc of active flexion/extension when the preoperative ROM of all MCP joints (27.6°) was compared to the postoperative ROM (47.2°) at 19 months. In addition, there was a significant improvement in the total arc of active MCP flexion/extension for each of the four fingers. The mean active MCP extension deficit also improved significantly from 50° before surgery to 18° postoperatively. The degree of ulnar deviation also improved, decreasing from 30.4° to 9.7°.

Although this study did not include a dynamic splint comparison group, the investigators compared their findings to the results of other studies over a similar period of follow-up in which dynamic splinting had been used and found that the two approaches to splinting yielded similar results.

Exercise

Protected motion in a dynamic splint or out of a static splint is initiated as early as 3 to 5 days or as late as 10 to 14 days postoperatively when the bulky compression dressing is removed and splints have been fabricated.^{12,14,21,30,70,118,121,126} Timeframes vary with the type of procedures performed, the underlying pathology, and the stability of the joint. Even after the bulky dressing is removed, exercise may be delayed for several weeks for a patient with poor quality soft tissue repairs and potential joint instability or delayed wound healing.

The involved MCP joints of patients with OA or post-traumatic arthritis usually are stable postoperatively. Therefore, MCP exercises typically are begun earlier and progressed more rapidly in these patients than is permissible for patients with RA, whose joints tend to be less stable as the result of long-standing tissue inflammation and deformities.⁹⁴

A goal of a rehabilitation program, proposed by Swanson et al.,¹²¹ is to achieve full or almost full active extension and about 45° to 60° of flexion of the MCP joints of the index and middle fingers, respectively, and 70° in the ring and little fingers in patients with RA. Greater ROM may be possible in the patient with OA, particularly in the index and middle fingers. In addition to improving the overall excursion of each reconstructed joint, another goal of exercise is to *elevate* the arc of active MCP motion to a more functional range—that is, to decrease or eliminate the active extension deficit while increasing flexion to improve hand opening and grasp.^{21,52}

During the course of rehabilitation, active MCP flexion usually plateaus before active MCP extension, with flexion leveling off at about 3 to 4 months but extension often continuing to improve for up to a year.^{21,38}

Exercise: Maximum Protection Phase

For the first 4 to 6 weeks, the patient performs only assisted or active exercises and is not allowed to use the hand for functional activities. The focus of management is to protect healing structures while applying safe levels of stress to soft tissues to influence organized scar tissue formation and prevent adhesions through protected motion within limited ranges. Early motion also assists in controlling or reducing postoperative peripheral edema.

NOTE: Every effort should be made to obtain the desired degree of flexion, particularly in the ring and little fingers, by the end of the third week postoperatively, the time at which the reconstructed joint capsules become very tight. Otherwise, it becomes difficult to gain additional joint ROM.^{48,121,126}

The following goals and exercises are emphasized during the maximum protection phase.^{14,21,48,70,126,129}

- **Maintain mobility of the shoulder, elbow, and forearm.**

- Perform active shoulder, elbow, and forearm ROM. This is particularly important for patients whose RA is affecting multiple joints of the body.

- **Improve functional ROM of the fingers and maintain gliding of tendons within their sheaths.**

- Initiate active PIP and DIP flexion and extension, with the MCP joints held in extension by the dynamic splint. If static splinting is being used, remove the splint and teach the patient to manually stabilize the MCP joints in extension.
- Perform active, pain-free MCP flexion initially with the IP joints in extension followed by extension of the MCP joints assisted manually or by the dynamic splint. The dynamic splint usually allows no more than 60° to 70° of MCP flexion.^{70,126} Manually stabilize the IP joints in extension or temporarily splint them in extension with tape and tongue depressors during exercise sessions so the lumbricals act to flex the MCP joints. If multiple MCP joints have been replaced, which is usually the case in patients with RA, have the patient exercise one MCP joint at a time to be certain that flexion and extension increase in each of the MCP joints. If the patient is having difficulty actively flexing the MCP joint of the little finger, the fourth and fifth digits can be taped together some of the time to allow the ring finger to assist flexion of the little finger.^{14,21,70,126}
- If it is permissible to remove the splint for exercise, teach the patient how to perform active radial deviation of the MCP joints by placing the open hand palm-down on a table, stabilizing the dorsum of the hand with the opposite hand, and sliding (“walking”) the fingers toward the thumb.^{90,91}
- Include active composite finger flexion and opposition of the thumb to each digit, emphasizing pad-to-pad pinch rather than lateral pinch.

PRECAUTIONS: During exercise, avoid lateral pressure of the thumb against the digits, which could contribute to recurrence of an ulnar deviation deformity of the fingers. Carefully observe the incision during MCP flexion, being certain to avoid excessive tension on the skin and delayed wound closure.

- **Prevent adhesions along the healed incision.**

- Perform gentle mobilization of the scar when sutures have been removed.

Exercise: Moderate and Minimum Protection Phases

The goal of the *moderate protection phase*, which begins at about 3 to 4 weeks or as late as 6 weeks postoperatively, is to achieve full *active* extension of the MCP joints (no extensor lag) and continue to increase active MCP flexion as early as possible during this phase of rehabilitation for functional use of the hand.^{12,14,121,126,129}

Sometime after 3 or 4 weeks or by 6 weeks, it may be permissible to remove the dynamic extension splint for exercise if the MCP joints are stable. Very low-intensity strengthening exercises and light use of the hand for ADL also are initiated around 4 to 6 weeks. If the joints are stable and well aligned and there is sufficient MCP flexion and no active extension deficit, daytime splinting during general activity is gradually discontinued starting around 6 weeks or as late as 12 weeks if joint stability is in question.^{14,21,30,70}

During the *minimum protection phase*, which begins around 8 to 12 weeks postoperatively, progressive strengthening of the wrist and hand musculature and increasing use of the hand for functional activities while reinforcing principles of joint protection are emphasized. In most instances, a patient is allowed full use of the hand for light to moderate functional tasks by 12 weeks postoperatively.

Goals and interventions during the moderate and minimum protection phases include the following.^{14,21,30,70,118,121,126,129}

- **Continue to increase ROM and active control of the MCP joints.**

- Have the patient continue active flexion exercises in the dynamic splint or with the static splint removed and even after daytime splinting is discontinued. Add gentle passive stretching, one finger at a time, to increase flexion.
- Emphasize active MCP extension with the wrist in neutral and the IP joints flexed (the intrinsic minus/hook fist position of the hand) to reinforce the action of the extensor digitorum communis (EDC) muscle and minimize influence of the intrinsic finger extensors. This movement also promotes gliding of the extrinsic extensors in the tendon sheaths.
- Reinforce end-range MCP extension by maintaining the extended position briefly with each repetition.

- **Restore ROM of the wrist.**

- When the dynamic splint can be removed during exercise, initiate active ROM of the wrist, emphasizing wrist extension. Be sure that the fingers are relaxed during wrist motions.

● ***Improve functional strength in the hand and wrist.***

- Have the patient begin isometric flexion and extension against submaximal manual resistance or a solid object at 6 to 8 weeks postoperatively. Then transition to resisted dynamic finger flexion and extension using a variety of exercise devices, such as a small spring-loaded hand exerciser or exercise putty.
- Include resisted radial deviation of the digits. For example, have the patient place the hand on a table palm-down and stabilize the dorsum of the involved hand with the opposite hand. Abduct the index finger against the resistance of a rubber band or push against a coffee cup and slide it across the table.¹⁴

● ***Regain use of the hand for functional activities while protecting the operated joints to prevent recurrence of deformity.***

- Reinforce principles of joint protection and energy conservation through patient education (see Box 19.2). Emphasize avoidance of stresses on the fingers in an ulnar direction.
- Perform simulated functional grasping activities, beginning with light prehension activities. Use the hand for light to moderate functional activities by 8 to 12 weeks postoperatively.
- Modify activities of daily living that could contribute to deforming stresses on the MCP or other involved joints.^{70,90,91} Consider use of a commercially fabricated, hand-based, digital alignment splint made of neoprene during heavier, more stressful activities.¹⁴

Outcomes

A successful outcome provides the patient with pain-free, stable, properly aligned MCP joints combined with improved active extension of the digits while retaining or improving MCP flexion sufficient for functional grasp.¹¹⁸ Of these outcomes, pain relief is the primary value of MCP arthroplasty.

Pain relief and patient satisfaction. Pain relief is excellent or good for most patients, and correction of a flexion/ulnar drift deformity is consistently sufficient after silicone implant arthroplasty and resurfacing arthroplasty. Both of these outcomes contribute to patient satisfaction because they improve hand function and the cosmetic appearance of the hand.³⁰

ROM and hand function. As noted previously, approximately 70° of active flexion of the MCP joints of the ring and little fingers and 45° to 60° of flexion of the index and middle fingers, full active extension, and correction of ulnar drift of the fingers and pronation primarily of the index finger are considered an ideal overall result.¹²¹

This degree of mobility enables a patient to open the hand far enough to grasp large objects, touch the fingertips of the ulnar digits to the palm (which is necessary for grasping small objects), and touch the tips of the index finger and thumb for pinch. Less MCP flexion in the index and middle fingers is acceptable because limited motion of the MCP joints enhances stability and allows dexterity and pinch without compromising functional grasp.^{12,121}

In an early follow-up study¹⁵ of 28 patients with RA after 115 Swanson implant arthroplasties followed by a dynamic splinting program, the mean arc of active motion for all operated joints at 54 months was 43° (56° of flexion and a 13° active extension deficit). In a review of a number of short- and long-term studies of patients with various types of arthritis undergoing MCP arthroplasty, the postoperative range of MCP flexion/extension varied considerably from study to study, with the mean arc of active motion for all fingers reported to be 45° and a mean extensor lag of 15°.³⁰ In another review of studies in which only the Swanson silicone implant arthroplasty was used in patients with RA, the reviewers found that the mean postoperative arc of active motion was 50° with a range of flexion from 39° to 67° and an active extension deficit from 7° to 28°.³⁸ In the early study and in both reviews, the ROM outcomes are less than the potential ranges suggested by Swanson et al.¹²¹ However, postoperative ROM was not reported for individual fingers in any of these studies.

When comparing pre- and postoperative mobility, the total range of flexion/extension may increase only to a small or moderate extent, but the arc of active motion postoperatively often is elevated and becomes more functional. For example, in an 8-year follow-up study of 901 Swanson silicone MCP implants in 294 patients with RA, the mean total active ROM was 40° preoperatively and 50° postoperatively, an increase of only 10°. However, the preoperative active MCP extension deficit was 40° but only 10° postoperatively, creating a more functional range of active MCP movement (an arc from 10° to 60° of flexion) for hand closing and opening.⁵² Similar findings were reported in a follow-up study of two-piece, nonconstrained, pyrolytic carbon implants.²⁹ In this study the prosthetic joints were stable and pain-free, and the mean range of flexion/extension improved by just 13°, but the arc of motion was elevated by 16°.

Few studies have directly compared one type of prosthetic implant to another. However, a recent prospective, double-blind study of patients with RA, which followed patients for 2 years postoperatively, compared the results of two types of silicone implant, the Swanson and the Neuflex designs (see Fig. 19.10). The findings indicated that there was a significantly greater improvement in MCP flexion in patients who received the Neuflex design than in patients receiving the Swanson implant, but there was no significant difference in active MCP extension, ulnar deviation, or grip strength between the two groups.³⁹ Of interest in this study is that the Neuflex implant, which is pre-formed in 30° of flexion, did not adversely affect active MCP extension, which had been a concern of the investigators.

Although satisfactory improvement of MCP mobility is a predictable outcome after joint arthroplasty, grip and pinch strength do not seem to increase significantly or consistently, or they improve only modestly.³⁰

Complications. Approximately 70% of MCP silicone implants survive 10 years before revision is necessary as the result of a number of complications.³⁰ However, some

postoperative complications affect outcomes but do not necessitate additional surgery. Delayed wound healing is a short-term complication that may have an adverse effect on re-establishing adequate MCP flexion for functional grasp.¹¹⁸

As with the wrist, the most common long-term complication after silicone implant arthroplasty is fracture of the prosthesis,^{12,118,121} whereas mechanical loosening is most common after metal-plastic arthroplasty.^{29,30} It is believed that these long-term complications can be minimized with the practice of principles of joint protection by consistently avoiding heavy loads and deforming forces on the reconstructed joints.

Proximal Interphalangeal Implant Arthroplasty

There are a number of joint and soft tissue procedures for managing arthritis and associated deformities of the PIP joints. They include soft tissue release and reconstruction for swan-neck and boutonnière deformities¹¹⁸ and implant arthroplasty or arthrodesis when there is significant destruction of the articular surfaces.^{1,12,50,66,120,121} Arthroplasty may or may not be preferable to arthrodesis to improve functional use of the hand.

In the ulnar digits, where mobility of the PIP joints is particularly important for functional grasp, arthroplasty may be the procedure of choice.⁵⁰ However, in the index finger where stability of the PIP joint is a necessity for many functional activities, arthrodesis is often preferable.^{1,12,121} If the MCP and PIP joints are involved, as is often the case in patients with RA, the MCP joint is usually replaced, but the PIP joint deformity (usually a swan-neck deformity) is corrected by soft tissue reconstruction¹²¹ or fusion.¹

Indications for Surgery

- PIP joint pain and destruction of the articular surfaces (with or without joint subluxation) secondary to OA or post-traumatic arthritis; less frequently indicated for RA.^{1,12,70,120,121} In general, PIP implant arthroplasty is indicated for patients with *isolated* PIP involvement, particularly those who are free of MCP joint disease. Implant arthroplasty of contiguous joints (both the MCP and PIP joints) is not recommended.^{12,120,121}
- Joint stiffness and decreased ROM that cannot be managed with nonoperative treatment or corrected with soft tissue reconstruction.^{1,70}
- Only occasionally for isolated boutonnière deformity or swan-neck deformity^{12,50,121} if fusion is not a viable option.

NOTE: Lateral stability of the PIP joint is necessary for a successful outcome.

Procedure

Implant design, materials, and fixation. The type of arthroplasty of the PIP joint selected by the surgeon depends on the underlying pathology, the extent of associated impairments and deformities, and the experience of the

surgeon. As with the MCP joints, there are two categories of implant arthroplasty for the PIP joints: a one-piece, flexible silicone joint spacer^{12,120,121} or a two-component (nonarticulated), minimally constrained, surface (total joint) replacement system made of metal and plastic or pyrolytic carbon.^{1,66,118} The components of a surface replacement are secured by cement or press-fit fixation.

The silicone implant, designed by Swanson during the 1960s, remains in use today.^{120,121} Two-piece, surface replacement systems, first developed during the late 1970s, have undergone many design changes and improvements.^{1,12} A surface replacement design affords greater joint mobility than the one-piece silicone design but provides no inherent stability. Therefore, when PIP arthroplasty is deemed appropriate for patients with RA, who typically have compromised joint stability as the result of damage to periarticular soft tissues secondary to chronic synovitis, a one-piece silicone implant tends to be used to provide some stability to the joint. In contrast, surface replacement arthroplasty is used almost exclusively in patients with OA or post-traumatic arthritis because the collateral ligaments usually are intact or repairable.

Operative procedures. For both types of arthroplasty, a curved, longitudinal incision is made along the dorsal aspect of the PIP joint. Occasionally, a volar (palmar) or lateral approach is used. Either a *central slip-sparing approach* (which leaves the central tendon intact) or, when there is significant joint deformity, a *central slip-splitting approach* (where the central tendon is incised longitudinally) is used. The collateral ligaments are preserved or detached and repaired after insertion of the implant(s) whenever possible.^{1,9,66}

Portions of the head of the proximal phalanx and the base of the middle phalanx are resected. The intramedullary canals of the proximal and middle phalanges are reamed and prepared for the prosthetic implant(s), which is/are then inserted.

If necessary, the volar plate is released for a flexion contracture, and the extensor tendon mechanism is repaired. Then the joint capsule is repaired, the wound is closed, and a bulky compression dressing is placed on the hand. The hand is supported in a volar splint, which includes the forearm, and elevated in a sling above the level of the shoulder to minimize edema.

Postoperative Management

Immobilization

When the surgical dressing is removed, a custom static splint and possibly a dynamic extension splint with an outrigger are fabricated. These are hand-based splints that leave the wrist free. The position of PIP joint immobilization varies with the type of preoperative deformity that existed and the type of soft tissue reconstruction performed. Recommended positions of the immobilization are summarized in Table 19.2.^{1,12,121,127}

The duration of immobilization varies with the type of arthroplasty, whether extensor tendon or collateral ligament

TABLE 19.2 Position of Immobilization After PIP Arthroplasty

Preoperative Deformity	Postoperative Positioning in Splint
PIP flexion contracture	PIP extension
Boutonnière deformity	PIP extension and slight DIP flexion
Swan-neck deformity	–10° to 30° PIP flexion and full DIP extension

reconstruction of the fingers was part of the procedure, and the surgeon's philosophy.^{1,12,50,70,121,127} Protective splinting with frequent sessions of assisted or active exercises continues during the day for at least 6 to 8 weeks postoperatively and is gradually eliminated by 12 weeks. Night splinting may continue for 3 to 6 months or up to a year to protect the repaired joint(s).

Exercise

The sequence of exercises after PIP arthroplasty emphasizes early but protected motion of the operated and adjacent joints. The time frame for initiation of PIP exercises in the dynamic splint or out of the static splint varies from a few days^{1,50,70} to 10 to 14 days¹²⁷ postoperatively based on the type and extent of impairments of the fingers preoperatively and the type of reconstructive procedures used. For example, after a *central slip-sparing approach* (extensor mechanism remains intact), ROM exercises are initiated as soon as the bulky dressing has been removed (1 to 3 days postoperatively). After a *central slip-splitting approach* in a joint with no associated swan-neck or boutonnière deformity, ROM exercises are begun several days to a week to 10 days later.

The goals of exercise during each phase of rehabilitation after PIP arthroplasty are similar to those already detailed in this chapter for rehabilitation after MCP arthroplasty. Only guidelines and precautions unique to PIP arthroplasty or procedures for associated correction of specific soft tissue deformities of the PIP joints are addressed in this section.

Exercise: Maximum and Moderate Protection Phases

The primary goals of the maximum and moderate protection phases of rehabilitation after PIP arthroplasty are to control peripheral edema and restore functional mobility of the operated joint(s) without compromising the repair or reconstruction of soft tissues.

In most instances, the emphasis is to gradually increase PIP flexion by 10° to 15° per week¹ and to achieve approximately 70° of PIP flexion in the ring and little fingers, 60° in the middle finger, and at least 45° in the index finger with full or almost full PIP extension by the end of the moderate protection phase (by 6–8 weeks postoperatively).¹⁷ Dynamic flexion splinting may be instituted if adequate flexion is not achieved with exercise alone.

The following guidelines for exercise are recommended.^{12,50,70,120,121,127}

- **Maintain mobility of the wrist, MCP and DIP joints.**

- Immediately after surgery initiate active ROM of all joints not restricted by the bulky dressing.

- **Restore ROM of the operated joints.**

- Begin active PIP flexion in the dynamic splint or with the static splint removed and assisted flexion and extension of each PIP joint. Stabilize the MCP and DIP joints in neutral to direct motion to the PIP joint (promotes joint mobility and tendon gliding).

PRECAUTION: During ROM exercises avoid lateral stresses to the operated joints that could compromise the integrity of the collateral ligaments and joint stability.

- If a *boutonnière deformity* was corrected (which requires reconstruction of the extensor mechanism), follow the guidelines and precautions described in Box 19.6.^{118,127}
- If a *swan-neck deformity* was corrected, follow the guidelines and precautions noted in Box 19.7.^{50,118,127} A central slip-splitting approach is necessary for correcting a swan-neck deformity to allow the tension on the extensor mechanism to be adjusted and to allow greater excursion of the PIP joint into flexion.

Exercise: Minimum Protection/Return to Function Phase

The primary goal of the minimum protection phase shifts from restoration of functional ROM to improving strength

BOX 19.6 Postoperative Guidelines and Precautions after Correction of a Boutonnière Deformity

Exercise

- Maintain as much extension as possible of the PIP joint through splinting and exercise for 3 to 6 weeks postoperatively. Remove the splint only for exercise and wound care.
- Initiate early DIP flexion exercises with the PIP joint stabilized in extension to maintain the length of the oblique retinacular ligament.
- Begin active or assisted PIP flexion/extension exercises by 10 to 14 days or sooner postoperatively. Stabilize the MCP joint in neutral (on a book or at the edge of a table) during PIP movements.
- Emphasize PIP extension and DIP flexion during exercise.

Precautions

- Avoid hyperextension of the DIP joint.
- Because correction of a boutonnière deformity requires a central slip splitting approach and repair of the extensor mechanism, avoid resisted exercises and stretching of the extensor mechanism of the PIP joint for 6 to 8 weeks or as long as 12 weeks postoperatively.

BOX 19.7 Postoperative Guidelines and Precautions after Correction of a Swan-Neck Deformity
Exercise

- Maintain the PIP joint(s) in 10° to 20°¹²⁷ or 20° to 30°⁵⁰ of flexion and the DIP joint(s) in full extension with static digital splinting.
- Initiate active ROM exercises at the PIP and DIP joints several days⁵⁰ to 10 to 14 days¹²⁷ postoperatively.
- Perform DIP extension exercises with the PIP joint stabilized in slight flexion.
- Stabilize the DIP joint in neutral during PIP ROM exercises.
- Emphasize PIP flexion and DIP extension.

Precautions

- Limit PIP extension to 10° of flexion during exercise to avoid excessive stretch to the volar aspect of the capsule.
- Avoid extreme flexion of the DIP joint.

in the hand and wrist and gradually incorporating safe but progressive use of the hand into functional activities of daily living. This transition occurs around 6 to 8 weeks or as late as 12 weeks postoperatively. The status of the soft tissue repairs, particularly the extensor tendons, determines how early resisted exercises are initiated. For optimal results, rehabilitation may need to continue (through adherence to a home program) for 6 months or longer postoperatively.

As with MCP arthroplasty, low-intensity strengthening exercises can be performed with equipment specifically designed for hand rehabilitation, such as exercise putty, or through graded functional activities that involve resisted movements. Principles of joint protection (see Box 19.2) are integrated into daily living through patient education, with attention paid to continued avoidance of lateral stresses to the PIP joints.

Outcomes

After PIP joint arthroplasty, an optimal result provides the patient with a pain-free, mobile but stable and well-aligned joint for functional use of the hand.^{1,9,12,120,121} Pain relief is the most consistent outcome after PIP arthroplasty.¹ Outcomes usually are better in patients with OA than in those with post-traumatic arthritis or RA and in fingers without preoperative deformity.¹

Optimal ROM for functional use of the hand after arthroplasty of the PIP joint is 45° to 70° of active flexion (depending on the finger) and full or almost full active extension (no extensor lag). However, postoperative ROM reported in most studies is substantially less.¹ One surgeon¹²⁰ reported that the expected motion after flexible implant arthroplasty ranges from 0 to 10° extensor lag and 30° to 70° flexion but did not differentiate expected results for each finger. In a large follow-up series by Swanson et al.,¹²⁰ approximately two-thirds of

the replaced PIP joints had greater than 40° of motion. In a follow-up study after surface replacement arthroplasty primarily for OA, the average arc of motion was 47° (average 16° extensor lag and 63° of PIP flexion).⁶⁶

If the extensor tendon mechanism is intact and a central slip-sparing approach is used, which allows early initiation of mobility exercises, approximately 10° more PIP flexion can be expected than if a central slip-splitting approach is used or repair of extensor tendons is required.¹²¹ If a swan-neck deformity was corrected, a slight (up to 10°) flexion contracture at the PIP joint is acceptable to protect the volar aspect of the joint capsule and possibly avoid recurrence of the deformity.

Patients must continue to avoid forceful grasping and high-impact activities and must practice principles of joint protection for a lifetime to prevent common long-term complications, such as fracture of the implant.^{1,127}

Carpometacarpal Arthroplasty of the Thumb

Arthritis of the CMC joint, also called the trapeziometacarpal joint, of the thumb, leading to pain and stiffness, occurs with advancing age in women more often than men.⁸³ When this joint is involved, patients have difficulty with forceful grasp and pinch and wringing motions. If a patient remains symptomatic after a period of conservative management, including anti-inflammatory medications, splinting, activity modification, and exercise, one of several types of arthroplasty may be appropriate for relief of symptoms and improved function.³¹

Indications for Surgery

The following are common indications for CMC arthroplasty of the thumb.^{12,23,31,50,113,125}

- Disabling pain at the base of the thumb, specifically the CMC joint, as the result of osteoarthritis, post-traumatic arthritis, or RA. However, most CMC arthroplasties are performed for degenerative joint diseases and less often for synovium-based diseases.
- Dorsoradial instability (subluxation or dislocation) of the first metacarpal on the trapezium, leading to a hyperextension deformity at the MCP joint of the thumb.
- Stiffness and limited ROM (often an adduction contracture) of the thumb.
- Decreased pinch and grip strength because of CMC pain or subluxation.
- When arthrodesis of the CMC joint is inappropriate.

Procedures

Background and surgical options. The type of procedure selected depends on the degree of ligament laxity, the extent of destruction of the articular surfaces, the underlying pathology, and the expected demands that will be placed on the hands postoperatively.^{31,113} Arthrodesis, rather than arthroplasty, is an option for patients who use the hand for high-demand occupational activities. However, for the patient whose activities place less stress on the hand, there

are several soft tissue and bony procedures that relieve pain and restore joint stability but preserve functional mobility at the base of the thumb.^{31,83} Retaining some CMC joint mobility is particularly important for the patient with RA, who typically has loss of mobility of other joints of the hand and wrist.¹²⁵

Procedures for CMC arthroplasty fall into three broad categories: ligament reconstruction, trapezial resection/tendon interposition or suspension arthroplasty (usually with ligament reconstruction), and joint replacement arthroplasty (resurfacing or total joint replacement) of the CMC joint with prosthetic components that are cemented in place. Among these procedures, ligament reconstruction alone is used when there is pain and instability but little to no loss of articular cartilage.³¹ One of the many variations of trapezial resection/tendon interposition arthroplasty is by far the most widely used approach to treatment when there is joint subluxation and loss of the joint space due to deterioration of articular cartilage.^{9,12,23,31,50,64,113,125} Trapezial resection combined with ligament reconstruction but without tendon interposition also has been shown to be an effective surgical approach to treatment.⁶⁵

Joint replacement arthroplasty (resurfacing arthroplasty or total joint arthroplasty) with rigid prosthetic components is an alternative to trapezial resection/tendon interposition arthroplasty for a few selected patients with CMC OA, who require improved pinch but do not need to use the hand for high-load, high-impact activities.^{12,31,50} A patient must have good quality bone stock to be a candidate for joint replacement arthroplasty. If bone stock is poor, as often occurs in RA, cement fixation of the prosthetic components usually is not successful. Silicone implant arthroplasty, although considered a viable option in the past,³³ now is used infrequently because of the problems of joint dislocation and silicone wear.^{9,31}

Because instability (hyperextension) and arthritis of the MCP joint are frequently associated with CMC arthritis, concomitant stabilization with a temporary K-wire or arthrodesis of the MCP joint is performed in addition to reconstruction of the CMC joint.^{31,125}

Operative overview. For a tendon interposition arthroplasty, a dorsal incision is made at the base of the thumb, with careful attention paid to protecting the branches of the superficial radial nerve. The capsule is approached through the extensor tendons and incised longitudinally. All or a portion of the trapezium is resected (trapeziectomy), as is a small portion of the base of the first metacarpal. A tendon graft is harvested from a portion of the flexor carpi radialis, abductor pollicis longus, or palmaris longus and inserted into the trapezial space to act as a soft tissue spacer.^{9,12,23,31,50,64,113,125} The anterior oblique ligament may also be reconstructed with a portion of the tendon graft; and the abductor pollicis longus, if not used for the tendon graft, may be imbricated or advanced to enhance joint stability and function of the abductor postoperatively.⁵⁰ The capsule and adjacent soft tissues are then repaired, and the wound is closed.

For a resurfacing arthroplasty, a dorsal approach is also used to reach the capsule through a longitudinal incision between the abductor pollicis longus and the extensor pollicis brevis. For a total joint replacement arthroplasty, a volar approach is often used.³¹ After the capsule has been split longitudinally, portions of the distal trapezium and the base of the first metacarpal are resected. The trapezium and the intramedullary canal of the metacarpal are prepared, and the prosthetic components are inserted and cemented in place. The capsule is repaired; and as with soft tissue interposition arthroplasty, the abductor pollicis longus may be advanced to enhance joint stability. Joint stability and ROM are assessed prior to closure.

Postoperative Management

The goal of rehabilitation is to develop sufficient mobility of the thumb for functional activities while maintaining joint stability for strong pinch and grasp. It may take up to a year after surgery for a patient to achieve optimal results.

Immobilization

With all procedures, the thumb and hand are immobilized postoperatively in a bulky compression dressing and elevated for several days to a week to control edema.

After the postoperative dressing is removed, the hand is placed in a static, forearm-based thumb spica cast, which is later replaced with a removable splint, with the CMC joint immobilized in abduction (40° to 60°), the MCP joint in slight flexion, and the wrist in neutral to slight extension.^{12,31,50,83,100} The IP joint of the thumb and the fingers are left free.

The length of time the CMC joint is continuously immobilized depends on the surgery. The time frame varies from just 7 to 10 days after total joint arthroplasty³¹ to 3 to 5 weeks after ligament reconstruction/tendon interposition arthroplasty or resurfacing arthroplasty with prosthetic implants.^{12,31,48,50,83,100,125}

At 3 to 6 weeks after surgery the splint is removed frequently during the day for exercise. From 8 to 12 weeks, as the patient uses the hand for functional activities, daytime splinting is gradually discontinued. Use of a night splint to stabilize the thumb continues for 8 to 12 weeks or until the joint is stable and essentially pain-free.^{31,100,125}

Exercise

Progression of exercises varies with the type of arthroplasty. Guidelines presented in this section are for *ligament reconstruction/tendon interposition arthroplasty*, still the most common form of CMC arthroplasty. Management guidelines unique to joint replacement arthroplasty are also noted. Precautions after CMC arthroplasty are summarized in Box 19.8.^{31,83,100}

Exercise: Maximum Protection Phase

The focus of the first 6 weeks of rehabilitation is control of pain and edema, maintaining ROM in nonimmobilized joints, and initiating protected motion of the CMC joint when it is permissible to remove the thumb spica splint for exercise.^{31,83,100,125} The following are suggested goals and exercises.

BOX 19.8 Precautions after CMC Arthroplasty of the Thumb

- Initially refrain from full CMC flexion with adduction (sliding the thumb across the palm to the base of the fifth finger) as this motion places excessive stress on the dorsal aspect of the capsule and ligament reconstruction. Be certain it is possible to oppose the thumb to each fingertip before attempting to touch the base of the fifth finger.
- When stretching to increase CMC abduction or extension, apply the stretch force to the metacarpal, not the first phalanx, to avoid hyperextension or compromise stability of the MCP joint. Follow the same precaution during light resistance exercises.
- Avoid forceful pinch and grasp for at least 3 months after surgery.
- Modify activities of daily living to limit heavy lifting. If occasionally heavy lifting is necessary, advise the patient to wear a protective splint.

● Maintain mobility of the fingers and IP joint of the thumb.

- During the period of continuous immobilization of the wrist and CMC and MCP joints of the thumb, have the patient perform active ROM of the fingers and the IP joint of the thumb.
- Initiate protected mobility of the thumb and wrist.**
 - When permissible, begin active, controlled ROM of the thumb within protected ranges and the wrist.
 - After tendon interposition arthroplasty, protected ROM is not initiated until about 3 to 6 weeks after surgery to allow time for the reconstructed soft tissues to heal adequately.^{31,48,83,100,125}
 - After total joint arthroplasty, ROM may be initiated at about 1 week postoperatively because of the inherent stability of the cemented, ball-and-socket design prosthesis.³¹ When it is permissible to remove the splint for exercise, begin active wrist ROM in all directions and CMC ROM with active abduction and extension; then add opposition and circumduction. Also include active MCP flexion and extension, being certain to stabilize the CMC joint.

Exercise: Moderate and Minimum Protection Phases
● Re-establish functional mobility of the hand and wrist.

- Continue active ROM exercises using gradually increasing ranges.
- At about 8 weeks, begin gentle self-stretching exercises or dynamic splinting if limitations in functional ROM persist.

● Regain strength and functional use of the hand and wrist.

- At about 8 weeks postoperatively initiate isometric exercises against light resistance, emphasizing abduction and extension.

- If the CMC joint is stable and pain-free, progress to dynamic resistance exercises to regain pinch and grasp strength.
- Between 8 and 12 weeks, gradually begin to use the hand for light ADL with the splint removed, such as buttoning and unbuttoning.^{48,83,125}
- Incorporate principles of joint protection during strengthening exercises and ADL.
- Continue to increase use of the hand for light to moderate ADL over the next 4 to 6 weeks. A patient typically can return to light-duty work by 3 to 4 months and can resume most functional activities by 4 to 6 months.

Outcomes

Most of the studies reported in the literature have investigated outcomes of trapezial resection/tendon interposition arthroplasty with very limited data reported on the results of joint replacement arthroplasty. A successful overall outcome after CMC arthroplasty, based on data from a variety of instruments that measure pain, ROM, hand function, patient satisfaction, and quality of life, is pain-free motion of the basal joint of the thumb and improved hand function, such as dexterity, pinch, and grasp.^{12,23,31,113,125} The time required to achieve maximum benefit from the surgery is typically 6 to 12 months.^{12,48,100}

Among the procedures available, trapezial resection/tendon interposition arthroplasty with or without ligament reconstruction yields the most predictable and successful outcomes.³¹ In a review of tendon interposition arthroplasty, outcomes appear to be better when the procedure includes reconstruction of ligaments, possibly because the CMC joint is more stable with than without ligament reconstruction.³¹

Pain relief and patient satisfaction. Regardless of the type of CMC arthroplasty, the most consistent and predictable benefit of these procedures is relief of pain.^{12,23,31,33,50,64,65} For example, in a review of outcomes of a number of studies for patients with OA who had undergone tendon interposition arthroplasty with or without ligament reconstruction, 94% of patients reported long-term relief of pain.¹¹³ Although tendon interposition is designed to resurface the deteriorated joint to make motion more comfortable, in a prospective, randomized study of patients with OA investigators compared the results of trapezial resection and ligament reconstruction with and without the use of tendon interposition. They found that at a mean of 48 months after surgery, both groups had equally satisfactory pain relief.⁶⁵

The patients' quality of life also improves after CMC arthroplasty. In a follow-up study of 103 patients with OA, who had primary tendon interposition arthroplasty, participants completed several standardized self-assessment questionnaires at a mean of 6.2 years after surgery.⁴ In an overall rating, 79 of 103 reported their quality of life had improved greatly, and an additional 15 reported slight improvement.

ROM and hand function. Active ROM of the thumb, particularly opposition, and dexterity usually improve after CMC arthroplasty. Increased abduction and extension widen the web space, making it easier to open the hand to grasp large objects. However, the results of some studies of ligament reconstruction/tendon interposition arthroplasty indicate that preoperative and postoperative ROM essentially is unchanged. Although data are limited, total joint arthroplasty is thought to produce the most improvement in ROM compared to other procedures.³¹

One author has observed that it is not uncommon for patients to experience discomfort in the region of the CMC joint for up to 1 year after surgery as structures heal.⁴⁸ Consequently, hand functions that require some degree of force production, such as pinch and grasp, improve only gradually. Most studies that follow patients for several years after surgery, however, indicate that measurements of pinch and grasp strength as well as performance of functional tasks improve significantly.^{23,31} The most successful long-term functional outcomes have been reported for patients who use the hand primarily for low-demand activities. For example, after silicone implant arthroplasty, satisfactory results were reported for 80% of patients who typically used the hand for activities that placed only light to moderate loads on the thumb.³³

Complications. Complications vary with the type of CMC arthroplasty. Overall, however, the rate of complications is low, with inadequate pain relief or recurrence of joint instability the most common complications that necessitate revision arthroplasty. In a retrospective study of 606 primary tendon interposition-ligament reconstruction arthroplasties performed over a 16-year period, only 3.8% were known to have required a revision procedure for mechanically based pain.³² Neuropathic pain can also develop after CMC arthroplasty. The pain may be caused by damage to or impingement of the radial nerve (radial sensory neuritis), carpal tunnel syndrome, or complex regional pain syndrome (reflex sympathetic dystrophy).^{23,32}

For arthroplasties that include implantation of prosthetic components, loosening and dislocation are the most common complications. Loosening has been identified after silicone implant arthroplasty³³ as well as joint replacement arthroplasty.³¹

Tendon Rupture Associated with RA: Surgical and Postoperative Management

Background and Indications for Surgery

Ruptures of tendons of the hand are common in patients with chronic tenosynovitis of the tendons of the wrist and hand associated with RA. The actual site of the rupture may be in the wrist or the hand. When a tendon ruptures, there is a sudden loss of active control of one or more of the digits. Rupture of a single or multiple tendons is usually painless and occurs during unremarkable use of the hand.^{9,50,51,132} Such ruptures are evidence of severely diseased tendons.

The extensor tendons are affected far more frequently than the flexor tendons. Extensor tendons that most often rupture, in order of frequency, are the common extensor tendons to the small and ring fingers and the extensor pollicis longus (EPL). The most common flexor tendon to rupture is the flexor pollicis longus (FPL).^{50,51,95,132}

The causes of rupture include infiltration of proliferative synovium in the tendon sheaths into tendons, which subsequently weakens the affected tendon; abrasion and fraying of a tendon as it moves over a bony prominence roughened or eroded by synovitis; periodic use of local steroid injections over time; or ischemic necrosis caused by direct pressure from hypertrophic synovium, particularly at the dorsal retinaculum, that compromises blood supply to a tendon. Common sites of abrasion that affect the extensors are the distal ulna and Lister's tubercle and the volar aspect of the scaphoid where it contacts the flexor tendons.^{5,9,50,51,132}

The indication for surgery is loss of function of the hand. Rupture of a single tendon, such as the extensor digiti minimi, may not impair a patient's function, whereas rupture of multiple tendons simultaneously or over a period of time may cause significant functional limitations and disability.

Procedures

The surgical procedures available for treatment of tendon ruptures in RA vary depending on which tendon(s) has ruptured, the number of ruptured tendons, the location of the rupture, the condition of the tendon at the site of rupture, and the quality of the remaining intact tendons of the hand. Options include^{9,50,51,95,132}:

- **Tendon transfer.** A tendon is removed from its normal distal attachment and attached at another site. For example, the extensor indicis proprius (EIP) can be transferred if the EPL has ruptured. A flexor tendon can also be transferred to the dorsal surface of the hand to act as an extensor if multiple extensor tendons have ruptured.
- **Tendon graft reconstruction.** A portion of another tendon that acts as a “bridge” is inserted between and sutured to the two ends of the ruptured tendon. The palmaris longus tendon is often selected as the donor tendon. A wrist extensor tendon may be selected if a wrist arthrodesis is performed at the time of the tendon reconstruction.
- **Tendon anastomosis (side-to-side tenorrhaphy).** The ruptured tendon is sutured to an adjacent intact tendon. This is a common option at the wrist for the finger extensor tendons.¹³²
- **Direct end-to-end repair.** The two ends of the ruptured tendon are re-opposed and sutured together. This option is used only occasionally because the ends of the ruptured tendons in patients with RA usually are frayed. Therefore, a considerable portion of the frayed tendon(s) must be resected, which shortens the tendon, making it difficult to suture end-to-end.

Concomitant procedures in the rheumatoid hand include tenosynovectomy, removal of osteophytes from

bony prominences, and ligament reconstruction or arthrodesis for instability. If late-stage MCP joint disease is also present and passive extension of the MCP joints is significantly limited, arthroplasty of the involved joints may also be indicated, either simultaneously with the tendon procedure or during two separate operations as determined by the surgeon. Without adequate joint mobility the transferred or reconstructed extensor tendons become adherent, resulting in a poor outcome.

Postoperative Management

The guidelines described in this section apply only to management of tendon transfer, reconstruction, or repair of *extensor* tendons in the rheumatoid hand. As mentioned previously, rupture of extensor tendons occurs far more frequently than flexor tendon rupture. As with postoperative management for other surgeries described in this chapter, pain and edema control and exercises for the nonoperated extremities are always essential components of rehabilitation.

Tendon transfers and reconstruction are delicate procedures requiring ongoing communication between the therapist and surgeon and active involvement of the patient in the postoperative program. Therefore, patient education is woven into every phase of rehabilitation.

Immobilization

A bulky compression dressing is applied to the hand and wrist at the close of extensor tendon surgery to control edema. The surgical compression dressing is removed after several days, and the wrist and hand are then immobilized in a volar splint. A forearm-based, static splint holds the wrist and digits in a position that minimizes stress to the transferred or reconstructed tendon(s).

For example, after side-to-side finger extensor transfer or extensor tendon reconstruction, the wrist and all fingers are immobilized in extension in the splint, but the thumb is free to move. After reconstruction of a ruptured EPL tendon or transfer of the EIP tendon to restore thumb extension, the wrist is immobilized in extension and the thumb in adduction, but the fingers are free to move.

Continuous immobilization of the wrist and digits is maintained for approximately 3 to 4 weeks to protect the healing tendons.^{71,132} Daytime splinting is discontinued at about 12 weeks, but night splinting typically continues for 6 months or longer.

NOTE: Use of dynamic splinting and early mobilization (a few days after surgery) typically is not recommended for tendon reconstruction or transfers in the rheumatoid hand. Tissue healing is slower and the risk of re-rupture higher postoperatively for patients with long-standing, systemic disease (who likely have been treated periodically with corticosteroids) than in otherwise healthy patients who have sustained an acute laceration or rupture of a tendon in the hand.⁴³

Exercise

During each phase of postoperative rehabilitation after extensor tendon transfer or reconstruction, exercises are

BOX 19.9 Precautions after Extensor Tendon Transfers or Reconstruction in the Rheumatoid Hand

- During the early phase of rehabilitation, do not initiate MCP extension from full, available MCP flexion to avoid excessive stretch on the operated tendon(s).
- Postpone stretching to increase MCP flexion if there is a deficit in active extension.
- Avoid activities or hand postures that combine finger flexion or thumb flexion and adduction with wrist flexion as this places extreme stress on the reconstructed or transferred extensor tendons. If a patient must use the hands for transfer activities, avoid weight bearing on the dorsum of the hand.
- Avoid vigorous grasping activities that could potentially overstretch or rupture the reconstructed or transferred extensor tendon(s).

progressed very gradually. Precautions during exercise and functional use of the hand are summarized in Box 19.9.

Exercise: Maximum Protection Phase

During the first 6 weeks after surgery, the priorities of rehabilitation are edema control and protection of the transferred or reconstructed tendon(s), followed by carefully controlled mobility of the operated areas to prevent adherence of healing tissues. It is usually permissible to remove the protective splint for exercise at around 3 to 4 weeks. If tendon quality is poor and the security of the sutured tissues is in question, exercise may be delayed until about 6 weeks postoperatively. The goals and intervention during the first phase include the following.^{51,71,132}

- **Maintain mobility of the elbow and forearm, unsplinted digits, and other involved joints.**
 - While the operated hand is immobilized, perform active ROM of all necessary joints.
- **Re-establish mobility and control of the repaired or transferred extensor muscle-tendon units.**
 - When the splint may be removed for exercise, initiate active wrist motions with the fingers relaxed.
 - Begin assisted MCP extension of each of the fingers or thumb with the wrist and IP joints of each digit stabilized in neutral.
 - Perform *place and hold* exercises by passively positioning the operated MCP joint first in a neutral and later in a slightly extended position. Have the patient briefly hold the position. This emphasizes end-range extension to prevent an extensor lag.
 - Progress to dynamic MCP extension with the wrist in neutral, initially from slight MCP flexion with the palm of the hand on a table and the fingers relaxed over the edge.

NOTE: To help a patient learn the new action of a transferred tendon, initially have the patient focus on the original action (function) of the muscle-tendon unit. For example, if

the EIP was transferred to replace the action of the EPL of the thumb, have the patient think about extending the index finger when trying to actively extend the thumb. Use biofeedback or functional electrical stimulation (FES) to assist with the motor learning.⁷¹

● Regain active flexion of the digits.

- Initiate MCP flexion of the fingers by having the patient relax the EDC after active extension rather than actively flexing the fingers.
- Progress to active MCP flexion within a protected range with the wrist and PIP joints stabilized in neutral. With the wrist and MCP joints stabilized in extension, actively flex (hook fist/intrinsic minus position) and extend (straight hand position) the PIP joints. PIP flexion while in wrist and MCP extension prevents stiffness of the IP joints without placing a stretch on the repaired EDC.⁴⁵

Exercise: Moderate and Minimum Protection Phases

By 6 to 8 weeks postoperatively, the transferred or reconstructed tendon can withstand greater imposed stresses. Use of the hand for light functional activities usually begins at this time. At about 8 weeks, daytime splinting is gradually decreased and is typically discontinued by 12 weeks postoperatively. Splint use during the day continues over a longer period of time if there is an extensor lag. Rehabilitation progresses as follows.

● Continue to increase active mobility of the operated digits.

- Add gentle passive stretching to increase MCP extension or flexion if one or both motions is restricted.
- Continue active MCP extension exercises to prevent an extensor lag or consider dynamic extension splinting if an extensor lag has developed and persists. If MCP extension to neutral is possible (no extensor lag), perform active MCP extension with the palm of the hand on a flat surface and extend each finger beyond neutral.
- With the wrist in neutral or slight extension, gradually increase MCP flexion by touching each fingertip to the palm of the hand (first straight and then full-fist positions) or the thumb to each fingertip and gradually to the base of the fifth finger. At 8 to 12 weeks institute dynamic flexion splinting intermittently during the day if grasp is significantly limited.

● Regain strength, control, and functional use of the hand.

- Incorporate active movements of the digits into manual dexterity and coordination activities that simulate functional activities. Remove the splint for functional activities that involve light grasp, such as picking up or holding light objects or folding clothing.
- Around 8 to 12 weeks add isometric and dynamic, *submaximal* resistance exercises to improve functional strength and endurance of the hand.
- Through ongoing patient education, reinforce principles of joint protection during functional use of the hand.

Outcomes

The results of surgical intervention and postoperative rehabilitation of ruptured tendons in the rheumatoid hand are highly dependent on the extent of involvement in the joints and soft tissues of the hand and wrist preoperatively. It is often difficult to differentiate postoperative functional improvement strictly as the result of a tendon transfer or reconstruction from procedures performed concurrently, such as joint arthroplasty or arthrodesis.

Barring complications, the most common of which is tendon re-rupture, a few generalizations can be made.^{50,51,132} Patients with a recent rupture of a single tendon and who have full passive ROM of the affected joint realize an optimum postoperative outcome, which is full functional grasp and no extensor lag in the involved digit. The greater the number of tendon ruptures or associated impairments, such as joint contractures, fixed deformities, or joint instabilities, the poorer are the results.

REPETITIVE TRAUMA SYNDROMES/ OVERUSE SYNDROMES

Disorders from cumulative or repetitive trauma in the wrist and hand lead to significant loss of hand function and lost work time.⁸ The causes are related to repeated movements over an extended period of time. The resulting inflammation can affect muscles, tendons, synovial sheaths, and nerves. Diagnoses include carpal tunnel syndrome, trigger finger, de Quervain's disease, and tendinitis. Management of impairments related to carpal tunnel syndrome and nerve compression in the tunnel of Guyon are described in Chapter 13.

Tenosynovitis, Tendinitis

Etiology of Symptoms

Inflammation results from continued or repetitive use of the involved muscle, from the effects of RA, from a stress overload to the contracting muscle (such as strongly gripping the steering wheel during a motor vehicle accident), or from roughening of the surface of the tendon or its sheath.

Common Impairments

- Pain whenever the related muscle contracts or whenever there is movement of another joint that causes gliding of the tendon through the sheath.
- Warmth and tenderness with palpation in the region of inflammation.
- In RA, synovial proliferation and swelling in affected tendon sheaths such as over the dorsum of the wrist or in the flexor tendons in the carpal tunnel.⁴⁴
- Frequently, an imbalance in muscle length and strength or poor endurance in the stabilizing muscles. The fault may be more proximal in the elbow or shoulder girdle, thus causing excessive load and substitute motions at the distal end of the chain.

Common Functional Limitations/Disabilities

Pain that worsens with the provoking activity of the fingers, thumb, or wrist, which may affect grip or repetitive hand motions.

Management: Protection Phase

Follow the guidelines for acute lesions described in Chapter 10, with special emphasis on relieving the stress in the involved musculotendinous unit and maintaining a healthy environment for healing with nondestructive forces.

- Splint the related joints to rest the involved tendon.
- If the tendon is in a sheath, apply cross-fiber massage while the tendon is in an elongated position so mobility develops between the tendon and sheath.
- Perform multiangle muscle-setting techniques in pain-free positions followed by pain-free ROM.
- Instruct the patient in tendon-gliding exercises to prevent adhesions. (These are described in the exercise section of this chapter.)

Management: Controlled Motion and Return to Function Phases

- Progress the intensity of massage, exercises, and stretching techniques.
- Assess the biomechanics of the functional activity provoking the symptoms and design a program to regain a balance in the length, strength, and endurance of the muscles. Frequently, problems arise because of poor stabilization or endurance in the shoulder or elbow.

Focus on Evidence

Backstrom⁶ reported a case study on a patient diagnosed with deQuervain's disease of 2 months' duration in which mobilization with movement (MWM) was used in addition to physical agents, exercise, and transverse friction massage. Pain was markedly reduced from 6/10 to 3/10 (50%) by the third intervention, and by completion of 12 sessions it was 0 to 1/10. The author proposed that the subtle malalignments in the wrist joints associated with the overuse syndrome perpetuated the symptoms and that the MWM helped restore normal arthrokinematics. The MWM techniques used included active movements of the thumb and wrist while a passive radial glide of the proximal row of carpal bones was applied (similar to Fig. 19.8). The principles of MWM are described in Chapter 5.

TRAUMATIC LESIONS IN THE WRIST AND HAND

Simple Sprain: Nonoperative Management

After trauma from a blow or a fall, an excessive stretch force may strain the supporting ligamentous tissue. There may be a related fracture, subluxation, or dislocation.

Common Impairments

- Pain at the involved site whenever a stretch force is placed on the ligament
- Possible hypermobility or instability in the related joint if supporting ligaments are torn

Common Functional Limitations/Disabilities

- With a simple sprain, pain may interfere with functional use of the hand for a couple of weeks whenever the joint is stressed. There is no limitation of function if a splint or tape can be worn to protect the ligament and the splint does not interfere with the task.
- With significant tears there is instability, and the joint may subluxate or dislocate with provoking activities, which requires surgical intervention.

Management

Follow the guidelines in Chapter 10 for treating acute lesions with emphasis on maintaining mobility while minimizing stress to the healing tissue. If immobilization is necessary to protect the part, only the involved joint should be immobilized. Joints above and below should be free to move. This maintains mobility of the long tendons in their sheaths that cross the involved joint. Avoid positions of stress and activities that provoke the symptoms while healing. Cross-fiber massage to the site of the lesion may help prevent the developing scar from adhering and restricting motion.

Lacerated Flexor Tendons of the Hand: Surgical and Postoperative Management

Background and Indications for Surgery

Lacerations of the flexor tendons of the hand, which can occur in various areas (zones) along the volar surface of the fingers, palm, wrist, and distal forearm, are common and cause an immediate loss of hand function consistent with the tendons severed. The musculotendinous structures damaged depend on the location and depth of the wound. Damage to one or more tendons may be accompanied by vascular, nerve, and skeletal injuries, which can cause additional loss of function and complicate management. An acute rupture of a flexor tendon may also occur as the result of a closed traumatic injury to the hand.^{35,116}

The volar surfaces of the forearm, wrist, palm, and fingers are divided into five zones; the thumb is divided into three zones. These zones are illustrated in Figure 19.12. The anatomical landmarks for each of the zones are described in Box 19.10.^{35,53,75,105,116,117} Use of this system of classifying lacerations improves consistency of communication and can provide a basis for predicting outcomes.⁷⁹

Knowledge of the complex anatomy and kinesiology of the hand is essential to understand the impairments and functional implications caused by damage to the flexor tendons in each of these zones. Box 19.11 identifies common impairments associated with damage in each of the zones.^{35,47,75,89}

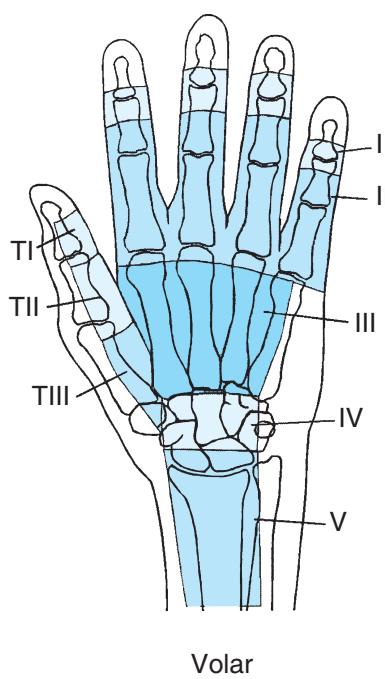

FIGURE 19.12 Flexor tendon zones; volar aspect of the hand and wrist.

Flexor tendons, when severed or ruptured, readily retract, thus requiring surgical intervention in most instances to restore function to the hand and prevent deformity. Repair and rehabilitation of lacerations in zone II, traditionally referred to as “no-man’s land,” pose a particu-

BOX 19.10 Flexor Tendon Zones: Anatomical Landmarks

Zones of the Fingers, Palm, Wrist, and Forearm

- I—from the insertion of the FDP on the distal phalanx to just distal of the FDS insertion on the middle phalanx
- II—from the distal insertion of the FDS tendon to the level of the distal palmar crease (just proximal to the neck of the metacarpals)
- III—from the neck of the metacarpals, proximally along the metacarpals to the distal border of the carpal tunnel
- IV—the carpal tunnel (area under the transverse carpal ligament)
- V—area just proximal to the wrist (proximal edge of the carpal ligament) to the musculotendinous junction of the extrinsic flexors in the distal forearm

Zones of the Thumb

- T-I—from the distal insertion of the FPL on the distal phalanx of the thumb to the neck of the proximal phalanx.
- T-II—from the proximal phalanx, across the MCP joint to the neck of the first metacarpal.
- T-III—from the first metacarpal to the proximal margin of the carpal ligament.

BOX 19.11 Consequences of Injury to the Volar Surface of the Hand, Wrist, and Forearm

- **Zone I.** Only one tendon, the FDP, can be severed as can the A-4 and A-5 retinacular pulleys, which are important for maintaining the mechanical advantage of the FDP for complete finger flexion (full fist).
- **Zone II.** FDS and FDP tendons, a double-layered synovial sheath and multiple annular pulleys (including A-1) of the flexor retinaculum (the fibrous sheath that approximates the tendons to the underlying bones and maintains them relatively close to the joints for full tendon excursion) can all be damaged. Inability to flex the PIP and DIP joints occurs if both tendons are severed. Potential damage to the vincula, the vascular structures that provide blood, and supplement nutrition derived from synovial diffusion can compromise tendon healing.
- **Zone III.** In addition to loss of the FDP and FDS, damage to lumbricales can disrupt MCP flexion.
- **Zone IV.** Damage in this zone (in the carpal tunnel) can affect all three extrinsic flexors of the digits—FDP, FDS, FPL—which disrupts finger and thumb flexion. Synovial sheath also sustains damage. Nerve injury frequently accompanies laceration in this zone.
- **Zone V.** Laceration in the forearm can cause major damage to flexor tendons of the digits and wrist, resulting in loss of wrist and digital flexion. The median and ulnar nerves and the radial and ulnar arteries also lie superficial in this zone.
- **Zones T-I and T-II.** Damage to the retinacular pulley system of the thumb, synovial sheath in addition to the FPL, and possibly the distal insertion of the FPB can occur; IP and MCP flexion are disrupted.
- **Zone T-III.** Potential damage to the thenar muscles.

lar challenge to hand surgeons and therapists. Because of the confined space in which the extrinsic flexors of the fingers lie and the limited vascular supply to the tendons in zone II, healing tissues in this area are prone to excursion-restricting adhesions. Scar tissue formation during the healing process can interrupt tendon-gliding in the synovial sheath and subsequently restrict ROM of the involved fingers. In zone IV (the carpal tunnel), the extrinsic flexor tendons of the digits (FDS, FDP, FPL) lie in close proximity to each other. An injury in this zone may lead to adherence of adjacent tendons to each other in the carpal tunnel and impairment of differential gliding between the tendons.

Procedures

Many factors influence the type of surgical repair selected to manage a tendon injury.^{35,53,75,105,115–117} Injury-related factors include the mechanism of injury; the type and location (zone) of the laceration; the extent of associated skin, vascular, nerve, and skeletal damage; and the time elapsed since the injury. Surgery-related factors include timing of

the repair, the need for staging surgeries, and the hand surgeon's background and experience. Patient-related influences are the patient's age, health, and lifestyle. These factors also have a significant impact on rehabilitation and outcomes of a tendon repair.

Types of repairs. Surgical options for repair of lacerations or a closed rupture of flexor tendons can be classified by the type of procedure.^{35,75,105,116}

- **Direct repair.** An end-to-end repair in which the tendon ends are re-opposed and sutured together.
- **Tendon graft.** An autogenous donor tendon (autograft), such as the palmaris longus, is sutured in place to replace the damaged tendon. This is necessary when the ends of the severed tendon(s) cannot be brought together without undue tension. Tendon grafts are performed in one or more stages depending on the severity, type, and location of injury.

A straight laceration usually lends itself well to a direct (end-to-end) repair, whereas a jagged laceration that frays the tendon may require a tendon graft.

Timing of a repair. Another method of classifying and describing tendon repairs is the *timing* of the repair, as related to the elapsed time since the injury. The timing of a repair after an acute tendon injury is critical because the severed ends of the tendon begin to soften and deteriorate quickly, and the proximal portion of the tendon retracts. These factors make it difficult to reattach the tendon with a strong repair at its normal length. However, only a tendon laceration associated with major damage to the vascular system is considered an emergency situation.^{35,75,116} Although better outcomes are thought to occur if the repair is done within the first few days, a delay of up to 10 days yields results equal to those of an immediate repair. Delays beyond 2 weeks are associated with poorer outcomes.^{35,116} If a repair must be delayed for more than 3 to 4 weeks, a direct repair is no longer possible, which necessitates a tendon graft.³⁵

Categories of surgeries based on elapsed time include^{17,35,55,75,105,116,117}:

- **Immediate primary repair.** A repair done within the first 24 hours after injury.
- **Delayed primary repair.** A repair performed up to 10 days after injury.
- **Secondary repair.** A repair done 10 days to 3 weeks after injury.
- **Late reconstruction.** Surgery performed well beyond 3 to 4 weeks, sometimes months after the injury.
- **Staged reconstruction.** Multiple separate surgeries performed over a period of weeks or months.⁵⁵ A staged reconstruction enables a surgeon to prepare an extensively damaged or scarred tendon bed months prior to a tendon graft so adhesions are less likely to develop.

A simple, clean, acute laceration of a tendon without associated injuries of the hand is most often managed with a *direct primary repair*, either immediate or delayed a few

days.^{35,116,117} However, if the wound is not clean, a *delayed primary repair* allows time for medical intervention to reduce the risk of infection. Lengthy delays that necessitate a *secondary repair* or *late reconstruction* are often associated with multiple injuries, such as extensive skin loss, fractures that cannot be stabilized immediately, or long-standing scarring and contractures. If there is damage to one or more of the tendon pulleys, these must be repaired before the lacerated tendon can be effectively repaired.

Of the multiple-stage reconstructions for extensive and complex flexor tendon injuries of the hand, the *Hunter two-stage reconstruction passive or active implant* is most widely known. During the first stage of this procedure, the scarred and adherent portions of the damaged flexor tendon are resected. A Hunter implant (rod) made of silicone is then secured in place to act as a tendon spacer around which a new sheath develops over a period of 3 months. In addition, a damaged retinacular pulley system is reconstructed, and any contractures are released during the first surgery. During the second phase, the implant is removed, and a donor tendon (graft) is drawn through the new sheath and sutured in place.⁵⁵

Overview of operative procedures. Some general aspects of the many variations of operative procedures for primary flexor tendon injuries are described in this section.^{35,75,79,115–117} However, careful review of a patient's operative report and close communication with the hand surgeon are necessary sources of specific details of each patient's surgery. For repair of lacerated finger tendons in zone II, for example, a volar, zigzag approach designed to avoid the lines of stress or a lateral incision may be elected by the surgeon, the former being the more common. When approaching the lacerated tendon, the incision is made between the annular pulleys to ensure optimal excursion. This approach preserves the function of these fibrous sheaths, which encircle the finger flexors and keep the tendons close to the joints (preventing bowstringing of the tendon).

For a direct repair after the tendon ends are located, prepared, and re-opposed, there are a number of delicate techniques for suturing the tendons.^{35,75,103,107,115–117} Core sutures and epitendinous sutures are used to hold the tendon ends together. Suturing technique and the number of suture strands influence the initial strength of the repair and consequently the type and timing of motion allowable postoperatively.^{35,75,105,115–117} A larger number of suture strands across the repair site (e.g., four or six strands instead of two) produces a proportionally stronger repair. Running, locked epitendinous sutures used in addition to core sutures appear to further increase the initial strength of the repair.^{103,107}

Suturing technique must also address the vascular supply to the repaired tendon. Nonreactive sutures are placed in the nonvascular volar aspect of the tendon so as not to disturb the vincula, which lies in the dorsal aspect of the tendon and provides a blood supply to the tendon.^{35,75,105,115–117} When present, as in zones II and IV, the synovial sheath is also repaired to re-establish cir-

culation of synovial fluid, an important source of nutrition to the healing tendons.¹¹⁵

After all repairs have been completed, the incision(s) are closed, and the hand and wrist are immobilized in a bulky compression dressing and elevated to control edema. The compression dressing remains in place for 1 to 3 days. When the bulky surgical dressing is removed, it is replaced with a light compressive dressing and splint.

Postoperative Management

General considerations. After surgical intervention for a flexor tendon injury, a strong, well-healed tendon that glides freely is the cornerstone for restoring functional mobility and strength in the hand.^{47,89,115–117} Every effort is made to prevent excursion-restricting adhesions from forming while simultaneously protecting the repaired tendon as it heals. Box 19.12 summarizes the factors that contribute to adhesion formation after tendon repair.^{35,47,55,54,79,89,105,116}

Many of the same patient-related and injury-related factors, already noted, that a surgeon weighs when determining the most appropriate approach to surgical management for a patient's hand injury also influence the complex components and progression of postoperative rehabilitation. In addition, surgery-related factors, including the type and timing of the repair, suturing technique, strength of the tendon repair, and the need for concomitant operative procedures affect rehabilitation and eventual outcomes. Furthermore, therapy-related factors—in particular the timing of when therapy is initiated, the use of early or delayed mobilization procedures, the quality of splinting, the expertise of the therapist, and ultimately the quality and consistency of the patient's involvement in the rehabilitation process—fluence outcomes.

Extensive research has been done on the process of tendon healing, the tensile strength of tendon repairs, adhesion formation, and tendon excursion and imposed stresses (loading) on a repaired tendon during digital motion. A number of sources provide an in-depth analysis and sum-

mary of basic and clinical studies, typically animal and cadaveric but some in vivo human studies, as they apply to rehabilitation.^{25,35,47,54,55,89,105,115–117}

The purpose of this section is to examine and summarize current concepts and approaches to immobilization and exercise used in rehabilitation after flexor tendon injury and repair, rather than to put forth or ascribe to any one particular approach or protocol. Therapists treating patients after tendon repair must be familiar with the various postoperative protocols or guidelines used by referring hand surgeons and those described in the literature.

A therapist's knowledge of the underlying concepts in any protocol is essential for effective communication with the surgeon. A therapist's skill in applying and teaching exercise procedures is equally necessary for effective patient education and helping a patient achieve optimal functional outcomes. This knowledge enables a therapist to make sound clinical judgments to determine when progression of activities in a protocol preferred by a referring surgeon is safe or when activities must be adjusted based on each patient's responses. Remember, a regimented protocol is only safe and effective when there are no postoperative variables, a situation that certainly does not occur in the clinical setting.

Approaches to postoperative management. There are two basic approaches to management after flexor tendon repair characterized by the timing and type of exercises in the program. They are categorized as *early controlled motion*, either passive or active, and *delayed motion*.

Numerous published protocols with considerable variability fall within these categories. Most current-day programs emphasize early controlled (protected) motion after surgery and include both passive and active exercises of the operated digit(s). Advances in surgical management (in particular, improved suturing technique) that establish a relatively strong initial tendon repair allow the use of early motion.

Focus on Evidence

Tottenham and colleagues¹²⁸ studied 22 patients who underwent primary zone II flexor tendon repairs. Half of the patients began passive motion exercises of the operated fingers by the first 7 days after surgery, whereas the other half began passive motion 7 to 21 days postoperatively. The results of the study, based on several assessment measures of motion and function, indicated that there was a significant difference between groups, with all of the early motion group but only 75% of the delayed motion group achieving “excellent or good” results (i.e., 25% of the delayed motion group had only “fair or poor” results). The investigators noted that nonrandomization and the small size of the groups were limitations of their study.

Box 19.13 summarizes the rationale for early, but carefully graded, motion as soon as a day or two after tendon repair based on three to four decades of evidence derived

BOX 19.12 Factors that Contribute to Adhesion Formation After Tendon Injury and Repair

- Location of the injury and repair: higher risk in zones II and IV; tendons glide in a closely confined area
- Extent of trauma: higher risk with extensive trauma and damage to associated structures
- Reduced blood supply, subsequent ischemia, and reduced nutrition to healing tendons
- Excessive handling of damaged tissues during surgery
- Ineffective suturing technique
- Damage or resection of components of the tendon sheath
- Prolonged immobilization after injury or repair, which prevents tendon-gliding
- Gapping of the repaired tendon ends associated with excessive stress to the healing tendon

BOX 19.13 Rationale for Early Controlled Motion After Tendon Repair

- Decreases postoperative edema.
- Maintains tendon-gliding and decreases the formation of adhesions that can limit tendon excursion and that consequently limit functional ROM. Gliding deteriorates by 10 days after repair when a tendon is immobilized.
- Increases synovial fluid diffusion for tissue nutrition, which increases the rate of tendon healing.
- Increases wound maturation and the tensile strength of the repaired tendon more rapidly than continuous immobilization by means of *appropriate-level* stresses achieved with early tendon motion. The repair site loses strength during the first 2 weeks after surgery.
- Decreases gap formation at the repair site, which in turn increases the tensile strength of the repair.

from scientific studies.^{25,27,35,47,54,89,103,107,115–117} However, there are instances when a traditional, delayed motion approach must be used. Indications for prolonged (3 to 4 weeks) immobilization after tendon repair (and therefore delayed motion) are noted in Box 19.14.^{17,33,86,89,105,115,116}

Key elements of early passive and active motion approaches and the delayed motion approach with regard to immobilization and selection and progression of exercises are presented in the following sections. More detailed descriptions of these approaches, as well as specific protocols, advocated by various practitioners and researchers, are available in many sources.*

With all approaches, the postoperative goals and interventions for pain reduction, edema control, and mainte-

BOX 19.14 Indications for Use of Prolonged Immobilization and Delayed Motion After Flexor Tendon Repair

- Patients who are unable to comprehend and actively participate in an early controlled motion exercise program. This includes:
 - Children less than 7 to 10 years of age
 - Patients with diminished cognitive capacity associated with head injury, developmental disability, or psychological impairment
- Patients who have the cognitive ability to understand and follow an early controlled motion program but who are unlikely to adhere to the program
 - The unmotivated patient
 - The overzealous, impatient individual with a history of a previously failed repair
- Patients in whom repair of other hand injuries or surgeries necessitates extended immobilization of the hand

nance of function in uninvolved regions (e.g., the elbow and shoulder) are consistent with management employing other operative procedures previously discussed in this chapter. Patient education is of the utmost importance for effective outcomes after hand surgery.

NOTE: Unless otherwise noted, the guidelines described in this section for immobilization and exercise are for injury and primary repair or one-stage tendon grafts of the FDS and/or FDP muscle-tendon units in zones I, II, and III. The guidelines are similar but not addressed for zones T-I and T-II of the thumb. Postoperative guidelines for multistage or late reconstructions are progressed in a similar but more cautious manner. Refer to other resources for this information.^{55,89,105}

Immobilization

The duration, type, and position of immobilization must be considered.

Duration of immobilization. With some exceptions previously noted (see Box 19.14) when prolonged immobilization (3 to 4 weeks) is necessary, the repaired tendon is continuously immobilized after surgery for up to 5 days while the bulky compression dressing is kept in place. This allows some time for postoperative edema to decrease.

Type or method of immobilization. This usually depends on the preference of the hand surgeon and therapist, the approach to postoperative exercise, and the stage of tissue healing. If motion of the operated digit is to be delayed for 3 to 4 weeks, a cast or static splint provides the immobilization. Early controlled motion approaches require the fabrication of different types of customized splint.

There are three general types of splint used after flexor tendon repair: a static dorsal blocking splint^{27,42,47,89,112,116}; a dorsal blocking splint with dynamic traction, originally proposed by Kleinert and colleagues^{63,67} and subsequently modified and improved by clinicians and researchers^{47,89,107,112}; and a dorsal tenodesis splint with a wrist hinge.^{24,25,115–117} Descriptions of these static and dynamic splinting techniques for immobilization and/or exercise are noted in Box 19.15. Figure 19.13 shows an example of a dorsal blocking splint with dynamic traction. The splint allows active extension of the involved finger, and the elastic band passively returns the finger to a flexed position. (See Figure 19.14A for a depiction of a dorsal tenodesis splint.)

Position of immobilization. The typical position of immobilization for repairs in zones I, II, and III is wrist and MCP flexion coupled with PIP and DIP extension. This position prevents full lengthening and undue stress on the repaired FDS and/or FDP tendons while minimizing the risk of IP flexion contractures. The recommended degrees of wrist and MCP flexion differ somewhat from one source to another. Recommended positions range from 10° to 45° of wrist flexion and from 40° to 70° of MCP flexion with the IP joints in full but comfortable extension.^{24,25,27,35,42,47,89,112,115–117} The wrist typically is positioned in less flexion than the MCP joints. The trend over the years has been

BOX 19.15 Static and Dynamic Dorsal Blocking Splints: Position and Use
Static dorsal blocking splint

- Covers the dorsal surface of the entire hand and the distal forearm (the thumb is free).
- Positioned in wrist and MCP flexion and IP extension to avoid excessive tension on the repaired flexor tendon. The degrees of flexion vary with the philosophy of the surgeon or therapist and the approach (protocol) used.
- Straps across the volar aspect of the hand and forearm hold wrist and fingers in this position.
- Restricts wrist and MCP extension.
- Is worn during early phases of rehabilitation. Splint is loosened or removed for early exercises.
- Also worn as a protective night splint.

Dorsal blocking splint with dynamic traction

- Allows early motion of the operated joint while the hand is in the splint.
- Elastic band (or nylon line with a rubber band) is attached to the nail of the operated finger (or all four fingers), pass-

es under a palmar bar that acts as a pulley, and then attaches proximally at the wrist.

- At rest, the elastic band provides dynamic traction that holds the operated finger in flexion.
- Allows *active extension* of the IP joints to the surface of the dorsal splint.
- When PIP and DIP extensors relax, the tension from the elastic band pulls on the finger, causing *passive flexion*.

Dorsal tenodesis splint with wrist hinge

- Worn exclusively for exercise sessions
- No dynamic traction with elastic bands.
- Allows full wrist flexion and limited (approximately 30°) wrist extension but maintains the MCP joints in at least 60° of flexion and the IP joints in full extension when the straps are secured.
- When the straps across the fingers are loosened during exercise, allows active wrist extension initially during passive IP flexion and later when finger flexion is maintained for several seconds by a static contraction of the IP flexors.

to fabricate splints in less wrist and MCP flexion than early protocols recommended to increase patient comfort and reduce the risk of carpal tunnel syndrome.^{47,89}

Positioning after a zone IV repair typically is 70° MCP flexion and a neutral position of the wrist.⁸⁹

Exercise—Early Controlled Motion Approaches

There are two basic approaches to the application of early, controlled motion to maintain tendon-gliding and prevent tendon adhesions after flexor tendon repair: early passive motion and early active motion. The way in which passive or active motion of the repaired tendon is achieved, however, varies among protocols.

Early controlled passive motion. Historically, the use of early passive motion is based on the work of Duran and Houser⁴² and that of Kleinert et al.^{63,67} Both proposed early passive flexion of the IP joints within a protected range

postoperatively but used different approaches to splinting and exercise. Duran advocated use of a static dorsal blocking splint and early removal of the splint or loosening of the stabilization straps for passive ROM exercise of the IP joints of the operated finger(s). Kleinert and colleagues^{63,67} advanced use of a dorsal splint with dynamic traction, for early exercise (see Fig. 19.13). Within the confines of the splint, the patient performs *active extension* of the operated finger. The elastic band returns the finger to a flexed position with each repetition after the finger extensors relax, thus causing excursion of the repaired tendon without active tension in the finger flexors. A manual push into maximum DIP flexion may be added to increase passive flexion.

NOTE: When a dynamic traction splint is used during the day, a static splint is worn at night that holds the IP joints in neutral and the wrist and MCP joints in flexion to prevent IP flexion contractures.

These original passive motion protocols have been modified over the past three decades. Today, some surgeons and therapists use selected elements (splinting and/or exercise) of these passive motion approaches.^{25,27,47,89,129} However, use of early *active* motion that imposes controlled stresses on the repaired tendon is gradually replacing passive motion approaches.¹¹⁵

Early controlled active motion. The primary feature that distinguishes an early active motion from an early passive motion approach is the use of *minimum-tension, active contractions* of the repaired muscle-tendon units initiated during the acute stage of tissue healing, often by the first 24 to 48 hours but no later than 5 days postoperatively.^{25,46,47,103,106,107,115-117} Some passive exercises also are incorporated into active regimens.

Based primarily on experimental studies using animal models, it is hypothesized that gentle stresses placed on a

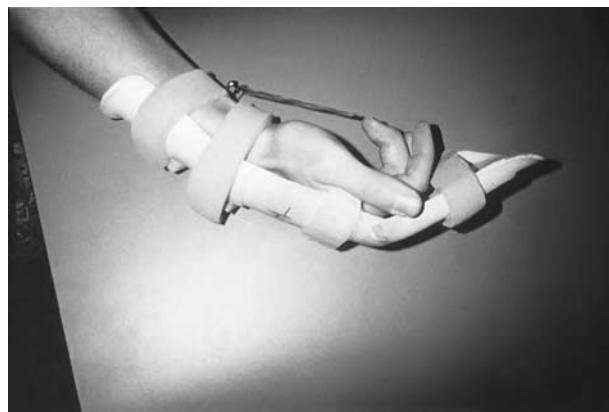

FIGURE 19.13 A dorsal blocking splint with dynamic traction for early controlled motion after flexor tendon repair.

repaired tendon by means of a very low-intensity static or dynamic muscle contraction, which “pulls” the repaired tendon through its sheath, is a more effective method of creating tendon excursion (gliding) than “pushing” the tendon with passive motion.^{46,47,54,105,107,115,116} Early active motion has become more widely accepted because stronger suturing techniques produce a repair that can withstand early, controlled stresses.

PRECAUTION: Proponents of early, active tendon mobilization caution that this approach is recommended only for primary tendon repairs, using the stronger four- and six-strand core and epitendinous suture techniques (in contrast to conventional, two-strand suturing) in carefully selected patients who have access to rehabilitation with an experienced hand therapist and who are most likely to adhere to the prescribed exercise and splinting regimen.^{24,25,46,47,54,89,116,117}

There are two ways in which early active motion can be implemented. Both methods are founded on an analysis and application of evidence in the scientific literature on tendon repair and healing, tendon excursion, and imposed loading on repaired tendons.^{103,106,107,115–117} One approach uses “place-and-hold” exercises by means of *static* muscle contractions to generate active tension of the finger flexors and impose controlled stress on the repaired tendon. (Place-and-hold exercises are described in the phase-specific exercises that follow.) This approach to early active motion is used in the Indiana protocol.^{24,25,79,115–117} The other approach to early active motion, developed by Evans,^{46,47} and others^{103,106,107} uses *dynamic*, short-arc, minimum muscle tension exercises to impose initially low-intensity stresses on the healing tendon.

A recently developed conceptual model for the use of early active motion and application of progressive forces to the healing tendon after flexor tendon repair, proposed by Groth,⁵⁴ combines elements of both of the aforementioned approaches. In addition, in the rationale for this model Groth discusses the effects of each level of exercise on internal tendon loads and tendon excursion supported by key evidence from the literature when available. A unique feature of this model is that it is criterion-based, rather than time-based. By providing criteria for progressing exercises based on optimal tendon loading, this program provides a mechanism for an individualized sequence of exercises adjusted for each patient rather than using predetermined timelines for progression.

The model contains eight progressive levels of active exercises, from the least to the greatest levels of loading on the tendon. The sequence is preceded by warm-up exercises (slow, repetitive passive finger motions in protected ranges). As with other early active motion approaches, exercises are begun during the first few days after surgery and are progressed until conclusion of postoperative rehabilitation. Box 19.16 describes the eight-level sequence of exercises in Groth’s conceptual model.⁵⁴

Descriptions and a progression of early active exercises during maximum, moderate, and minimum protection

BOX 19.16

A Sequence of Exercises for Early Active Motion with Progressive Tendon Loading after Flexor Tendon Repair⁵⁴

Warm-up

Warm-up exercises (passive finger motions within protected ranges precedes each exercise session.

Progressive Levels of Exercise*

- Level 1—place-and-hold finger flexion
- Level 2—active composite finger flexion
- Level 3—hook and straight fist finger flexion
- Level 4—isolated finger joint motion
- Level 5—continuation of levels 1–4 of exercise and discontinuation of protective splinting with introduction of gradually increasing use of the hand for functional activities
- Level 6—resisted composite finger flexion
- Level 7—resisted hook and straight fist exercises
- Level 8—resisted isolated joint motion.

*Note: Exercise sequence is from least to greatest tendon loading. Repetitions are highest at the lowest level of loading and least at the highest level of loading. Progression to next level occurs when specific criteria are met.

phases of rehabilitation after *zone I, II, or III flexor tendon repairs*, drawn from several resources, are presented in the following sections. Then, key features of a delayed motion approach to management are summarized.

Exercise: Maximum Protection Phase

The maximum protection phase begins 1 to 3 days postoperatively and continues for the first 3 to 5 weeks, the period of time when the tendon repair is weakest. The goals of this phase of rehabilitation are control of pain and edema and protection of the newly repaired tendon while imposing very low-level, controlled stresses on the tendon to maintain adequate tendon gliding and prevent adhesions that can restrict tendon excursion. Interventions in this phase include elevating the hand, splint use and care, wound management and skin care, and passive and active exercises.

During the first phase of rehabilitation, most exercises are performed in a static dorsal blocking splint or in a wrist tenodesis splint (Fig. 19.14A) specifically designed for exercise. With both types of splint, the stabilization straps are loosened to allow finger flexion. The following exercises are performed frequently during the day and continue for about the first 4 weeks.

- **Passive ROM exercises.** On an hourly basis perform passive MCP, PIP, and DIP flexion and extension of each individual joint to the extent the dorsal splint allows, followed by composite passive flexion in the confines of the splint. Composite flexion can include passive movements into full fist and straight fist positions.
- Independent motions of the PIP and DIP joints achieve *differential gliding* of the FDP and FDS tendons. For

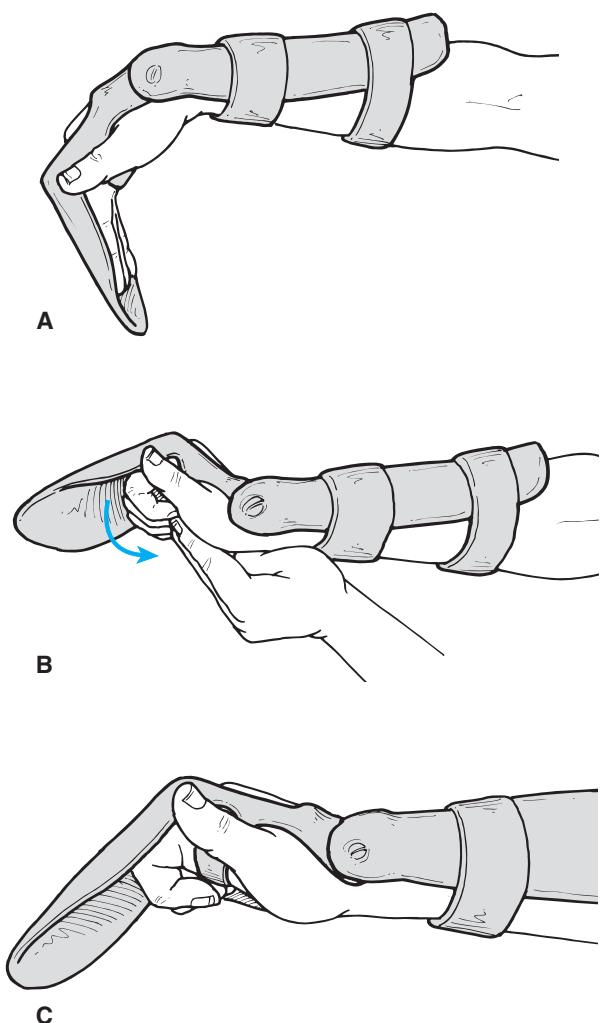

FIGURE 19.14 Splinting and exercise for early active motion post-finger tendon repair. (A) Following removal of the surgical compression dressing and fabrication of a static dorsal blocking splint, a tenodesis splint with a wrist hinge is fabricated. (B) The tenodesis splint allows full wrist flexion but limits wrist extension to 30°. During early movement of the fingers, the MCP joints are maintained in at least 60° of flexion as the IP joints are passively moved and placed in composite flexion. (C) Then the patient actively extends the wrist while maintaining the flexed finger position with a static muscle contraction and the least amount of tension possible in the finger flexors. (From Strickland JW: Flexor tendon injuries. In Strickland JW, Graham TJ [eds] Master Techniques in Orthopedic Surgery—The Hand, ed 2. Lippincott Williams & Wilkins, Philadelphia, 2005, p 262, with permission.)

example, the DIP joint must be flexed and extended separately while each PIP joint is stabilized in flexion. In this way, as the DIP joint is passively extended, the FDP repair site glides distally, away from the FDS repair.^{89,114}

PRECAUTION: It is essential to maintain the MCP joints in flexion during passive ROM of the IP joints to avoid excessive stretch of the repair site, which could cause gapping of the re-opposed tendon ends during IP extension.

● **Place-and-hold exercises.** Many programs initiate place-and-hold exercises of the repaired digit with the patient

wearing either a dorsal blocking splint^{46,47,107} or a tenodesis splint.^{24,25,54,115–117} With the MCP joints in flexion, passively place the IP joints in a partially flexed position and have the patient hold the position independently for 5 seconds with a minimum static contraction of the finger flexors. If the patient is wearing a tenodesis splint, combine place-and-hold finger flexion with active wrist extension (Fig. 19.14 B&C). Have the patient relax and allow the wrist to passively flex and the digits to passively extend. Initially, have the patient practice this with the uninjured hand or use biofeedback to learn how to hold the position with a minimum of force production in the FDP and FDS.

Focus on Evidence

Research has shown that it is preferable to perform place-and-hold exercises with the wrist extended and the MCP joints placed in flexion because wrist extension is the position in which the IP joints can be moved by contraction of the FDS and FDP with the *least* amount of contraction force and, therefore, a very low-level load on the repaired tendon.¹⁰²

● **Minimum-tension, short-arc motion.** Some programs begin active, dynamic finger flexion during the first few days after surgery if the suturing technique and strength of the repair allow.^{44,46,47} Active contractions that generate minimum tension, just enough tension to overcome the resistance of the extensors and cause flexor tendon excursion, are performed with the wrist in slight extension and the MCP joints flexed.

Exercise: Moderate Protection Phase

The moderate protection phase begins at about 4 weeks and continues until 8 weeks postoperatively. The focus during this phase is on safely increasing stresses on the repaired tendon, achieving full active flexion and extension of the wrist and digits, and differential gliding of the tendons. If a tenodesis splint was worn for early active exercises, it is discontinued at the beginning of this phase. However, use of the static dorsal blocking splint continues during the day except for exercise until at least 6 to 8 weeks. Use of a night splint continues for protection or to decrease or prevent a flexion contracture. Exercises include:

- **Place-and-hold exercises.** Continuation of place-and-hold exercises but with gradually increasing tension.
- **Active ROM.** Continuation or initiation of active composite flexion and extension of the IP joints with the MCP joints flexed, MCP flexion/extension with the IP joints relaxed, and active wrist flexion and extension with the fingers relaxed.
- **Tendon-gliding and blocking exercises.** These exercises are initiated at about 5 to 6 weeks (see Fig. 19.17A–E, Fig. 19.18 A–C, and descriptions in the final section of this chapter).

PRECAUTION: Avoid finger extension combined with wrist extension for about 6 to 8 weeks, as this position places extreme tension on the repaired flexor tendon.

Exercise: Minimum Protection/Return to Function Phase

The minimum protection/return to function phase begins at approximately 8 weeks postoperatively and is characterized by gradual but progressive use of resistance exercises to improve strength and endurance, dexterity exercises, and use of the hand for light (1 to 2 lb) functional activities. (Refer to the final section of this chapter for suggested exercises and activities.)

Protective splinting is discontinued, but intermittent splinting may be necessary if the patient has a persistent extensor lag or flexion contracture. After primary flexor tendon repairs, most patients return to full activity by 12 weeks after surgery.

Exercise: Delayed Motion Approach

In instances where continuous immobilization of a repaired flexor tendon extends for 3 to 4 weeks (indications already noted in Box 19.14), some degree of tendon healing and adhesion formation already has occurred by the time exercises can be initiated.

PRECAUTION: Despite the extended period of immobilization, at 3 to 4 weeks the tendon repair must still be protected in a dorsal blocking splint, and exercises must be performed in protected positions and progressed gradually.

Exercises such as passive ROM, tendon-blocking and tendon-gliding, and active ROM can be initiated when the cast is removed. Exercises used in early motion approaches are appropriate. The reader also is referred to additional resources that provide detailed exercise programs when delayed mobilization is necessary.^{17,89,112}

Outcomes

Functional outcomes. There is a substantial body of evidence on flexor tendon repairs, some of which is based on longitudinal clinical outcome studies.^{35,55,105,115,116} One review of the literature¹¹⁵ indicated that with the advances made in flexor tendon surgery and rehabilitation techniques over the past few decades, recovery of good or excellent function can be expected in 80% or more of patients after flexor tendon injury and repair. Two factors that have contributed considerably to a high rate of favorable outcomes are the use of improved suturing techniques that produce a strong repair site and implementation of early motion in rehabilitation programs.

There are several quantitative assessment tools used in outcome studies of tendon repair.⁸⁹ It is helpful to become familiar with the more frequently used assessments in order to understand the findings of studies. With some of these tools, results are reported as excellent, good, fair, and poor. For the most part, these terms are not simply subjective descriptors but, rather, are associated with objective measurement tools. For example, in the Strickland system^{43,89} the terms refer to a percentage of “normal” total active motion (total active flexion minus

deficits in active extension) of the PIP and DIP joints achieved after zone I, II, or III repairs and rehabilitation.

Some generalizations can be made about outcomes after flexor tendon repair. Findings in the literature indicate that immediate primary and delayed primary repairs (up to 10 days after injury) yield equally positive outcomes.¹⁰⁵ However, late reconstructions and multistage reconstructions, not surprisingly, result in poorer outcomes (less active and passive ROM, greater functional limitations) than primary repairs.¹⁰⁵ This is consistent with the findings that the greater the severity and number of associated injuries, the less favorable are the outcomes.¹¹⁶

Studies dating back to the 1980s have documented that the use of 4 weeks of uninterrupted immobilization leads to a slower return of tensile strength in the repaired tendon and greater adhesion formation than the use of early mobilization.³⁵ Although extended immobilization continues to be the treatment of choice for children under 7 to 10 years of age, a recent study indicated that the incidence of chronic contractures or diminished hand function is minimal in this age group.⁸⁶

Studies of various approaches to early motion, passive or active, after flexor tendon repair demonstrate superior outcomes when compared with outcomes after extended immobilization.^{27,104,128} Although the use of early motion in rehabilitation after flexor tendon repair has been well documented for more than two to three decades, the results of early active motion compared with early passive motion continue to be investigated. In one such study, carried out retrospectively, a “passive flexion–active extension” program of exercises in a dynamic traction splint was compared with a “controlled active motion” program that included therapist-supervised, active contractions of the repaired FDS and FDP muscle-tendon units.⁷ The investigators reported that although there were no significant differences in outcomes (total active flexion and active extension deficit) 16 weeks after surgery between groups in patients who had zone I repairs there were substantial differences between groups in patients with zone II repairs. In the “passive flexion–active extension” group, 50% of patients had good or excellent results, whereas 94% of patients in the “controlled active motion” group had good or excellent results. In addition, 39.7% of the passive flexion group had an active extension deficit $>15^\circ$, but only 10.5% of the active flexion group had an extensor lag 4 months after repair.

A comparable percentage of excellent and good outcomes for total active motion was reported in a 9-year, prospective follow-up study of 130 patients with zone I and II repairs who began supervised active exercises, including minimal-tension IP flexion and extension (detailed in the study), the day after surgery. Patients also performed active extension exercises in a dynamic traction splint regularly during the day. At the conclusion of the study, 92% of the patients had excellent and good results.⁶²

Complications. The most frequent early complication after surgery is rupture of the repaired tendon, and the

most frequent late complication is flexion contracture or a deficit in active extension of the repaired DIP and/or PIP joints, typically associated with tendon adhesions.^{35,117} Rupture may occur because of strong gripping activities, but it also may occur while the patient is asleep if the hand is unprotected during the first few months after surgery.

Although there is general agreement that early motion after tendon repair reduces adhesion formation, there are concerns that implementing early active flexion, which places active tension on the newly repaired tendon, may increase the risk of tendon rupture. Overall, however, rupture rates are low and appear to be relatively equal to those seen with early passive flexion/active extension and early active flexion/extension programs.¹¹⁵ In studies that have used passive flexion/active extension exercise in a dynamic traction splint, rupture rates have ranged from 3.0%^{7,67} to 6.8%.²⁷ In patients using dynamic traction splinting, who also have participated in a variety of early active exercises, including active flexion, rupture rates have been reported at 3.6%,¹⁰⁷ 5.0%,⁷ and 5.7%.⁶²

Lacerated Extensor Tendons of the Hand: Surgical and Postoperative Management

Background and Indications for Surgery

Laceration and traumatic rupture of the extensor tendons of the fingers, thumb, or wrist are more common than in the flexor tendons.⁴¹ Their superficial location makes the extensor tendons vulnerable to damage when trauma occurs to the dorsum of the hand. Furthermore, extensor tendons in the digits are substantially thinner than flexor tendons, making them more prone to traumatic rupture.^{41,84,97}

As with the flexor surface, the extensor surface of the hand, wrist, and forearm is divided into zones (Fig. 19.15). The dorsal surface of the fingers and wrist are divided into seven zones, and the thumb is divided into four zones. Each of these zones is identified by specific anatomical landmarks, as noted in Box 19.17.^{41,43,53,84,97} The odd-number zones correspond to the location of the DIP, PIP, MCP, and wrist joint regions. Although not depicted in Figure 19.15, the dorsal surface of the distal and middle forearm are often identified as zones VIII and IX, respectively. The area at the CMC joint of the thumb is often identified as zone T-V.⁸⁴

The extensor mechanism of the hand and wrist is complex. The structural characteristics of these mechanisms vary in each zone. Damage in one zone produces compensatory imbalances in adjacent zones. Knowledge of the anatomy and kinesiology of the extensor mechanism is basic to an understanding of how a patient's physical impairments and functional limitations occur according to the structures damaged in each zone. Box 19.18 identifies key structures and characteristic impairments associated with tendon rupture or laceration by zone.^{41,43,84,97,114} Of all the extensor zones, injuries in zones III and VII pose the greatest surgical and rehabilitation problems and challenges.

Depending on the type and location of injury to the extensor mechanism and the extent of associated skeletal,

BOX 19.17 Extensor Tendon Zones: Anatomic Landmarks

Zones of the Dorsal Surfaces of the Fingers, Hand, Wrist and Forearm

- I—DIP joint region
- II—middle phalanx
- III—PIP joint region
- IV—proximal phalanx
- V—apex of the MCP joint region
- VI—dorsum of the hand
- VII—wrist region/dorsal retinaculum
- VIII and IX—distal and middle forearm

Zones of the Thumb

- T-I—IP joint region
- T-II—proximal phalanx
- T-III—MCP joint region
- T-IV—metacarpal
- T-V—carpometacarpal joint region

joint, vascular, or nerve damage, surgery may or may not be indicated. The tendons of the extensor system distal to the dorsum of the hand have many soft tissue attachments along various structures, making extensor tendons far less likely to retract when lacerated or ruptured than flexor tendons.^{41,84,97} Consequently, with a rupture (closed injury) or a simple laceration in a peripheral zone, the tendon is reopposed and managed by uninterrupted immobilization in a splint or cast for 6 weeks as it heals.^{41,97} For example, this is a common course of treatment for a *mallet finger* (or thumb) deformity, which is a closed rupture of the terminal extensor tendon in zone I usually from forceful hyperflexion.⁸⁴

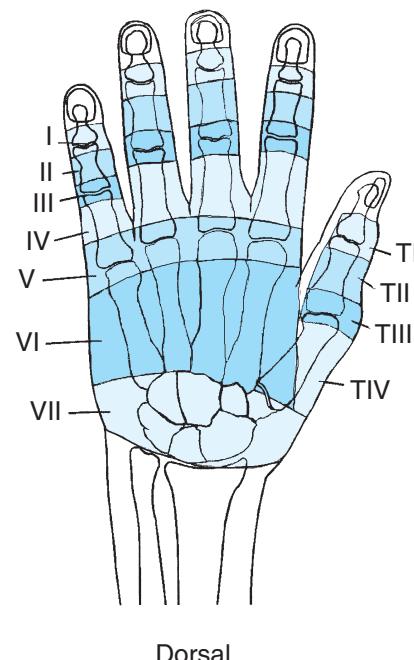

FIGURE 19.15 Extensor tendon zones; dorsal aspect of the hand and wrist.

BOX 19.18 Consequences of Injury to the Dorsal Structures of the Hand and Wrist

- **Zones I and II.** Damage to the terminal extensor leads to inability to actively extend the DIP joint (extensor lag) and eventual DIP flexion contracture and deformity (mallet finger). A swan-neck deformity secondary to an unopposed central slip and migration of the extensor mechanisms proximally may also develop. Damage in those zones is usually the result of a closed rupture rather than a laceration.
- **Zones III and IV.** Damage to the central slip tendon and possibly the lateral bands results in an inability to actively extend the PIP joint from a 90° flexed position. Flexion contracture of the PIP joint and eventually a boutonnière deformity develops as the lateral bands slip volarward and cause hyperextension of the DIP joint.
- **Zone V.** Damage to the common extensor tendons (EDC), extensor indicis proprius (EIP), and extensor digiti minimi (EDM), and sagittal bands that surround the MCP joints cause inability to actively extend the MCP joints, eventually resulting in MCP flexion contractures.
- **Zones VI and VII.** The juncturae tendium along the dorsum of the hand (VI) and the dorsal retinaculum (VII) under which multiple extensor tendons of the wrist and digits pass in close proximity can be damaged. A bow-string effect occurs in the extensor tendons if the retinaculum, which acts as a pulley, is lacerated. The synovial sheath through which the tendons glide in zone VII can also be damaged, subsequently compromising synovial diffusion and nutrition to the tendons. Injuries in zones VI and VII can result in loss of extension of the digits and wrist.
- **T-I and T-II.** Damage to the EPL and possibly the EPB (if laceration is in the proximal region of the proximal phalanx) leads to loss of hyperextension of the IP joint (mallet thumb deformity) and weakened MCP extension.
- **T-III and T-IV.** Damage to EPB leads to weakened MCP extension and transfers extension forces to IP joint, leading to a flexion deformity of the MCP joint and a hyperextension deformity of the IP joint if the EPL is intact.

Nevertheless, surgical intervention, even for a simple distal tendon injury, usually is necessary to restore active ROM, muscular balance, strength, and function to the hand and prevent contractures and deformity. Although the extensor muscles of the digits are substantially weaker than the flexors, an intact extensor mechanism is essential for functional grasp.

Procedures

Types of repairs. Surgical options for extensor tendon repair include a direct (end-to-end) repair or a reconstruction. As with flexor tendon repair, surgeries are classified as *primary* (immediate or delayed up to 10 days), *secondary*, *late*, or *staged*.^{22,41,84,97} These terms already have been defined in the previous section of this chapter on flexor tendon repair and rehabilitation. Operative procedures, such as tendon transfers, for ruptured, diseased extensor tendons associated with RA also were described earlier in the chapter.

Overview of operative procedures. Although similarities of definition exist for extensor and flexor tendon procedures, there are substantial differences in operative techniques used to repair extensor versus flexor tendons. These differences are based largely on the fact that extensor tendons are morphologically thinner than flexor tendons. This fact led to the belief that extensor tendon repairs are more prone to gapping, have less tensile strength, and are more likely to rupture than flexor tendons after repairs. However, stronger suturing techniques, specifically designed for extensor tendon repair and reconstruction, are used more frequently today, allowing early postoperative mobilization of the repaired tendon while lessening concerns of gapping and rupture.^{41,43,111}

Operative procedures for repair of lacerated or ruptured extensor tendons vary significantly in the distal versus the proximal zones. In this overview only repair of a

zone III/IV laceration (the most common cause of injury in these zones) is described, simply as an example. Detailed descriptions of operative techniques for primary repair and late reconstruction of extensor tendons in all zones of the hand, wrist, and forearm can be found in several sources.^{9,22,41,53,84,97}

With an acute laceration of the PIP joint and middle phalanx, the wound often enters the joint space. Therefore, the area must be débrided, cleansed, and treated with antibiotics. The central slip, which refers to the extensor mechanism in zones III and IV, then can be managed with a direct repair.^{41,53,84} The severed tendon is repaired and then sutured into the fibrocartilaginous dorsal plate of the middle phalanx, which is thicker and holds sutures better than the central slip, thereby producing a stronger repair.⁴¹

NOTE: The suturing and repair technique in zones III/IV may decrease the overall length of the tendon by 2 to 3 mm, causing a loss of 2° to 5° of PIP flexion.⁸⁴

If damaged, the lateral bands are repaired. If a boutonnière deformity is evident or likely to develop, a K-wire may be inserted to immobilize the PIP joint in extension for about 3 weeks and then be removed. After closure of the area, a bulky compression dressing immobilizes the repaired tissues and controls edema.

Postoperative Management

General considerations. The overall goal of postoperative rehabilitation after extensor tendon injury and repair is the same as after flexor tendon repair—that is, to restore mobility and strength to the hand and wrist for functional activities. Adhesion formation is a concern in the extensor tendons after repair, just as it is after repair of the flexor tendons. As noted previously, extensor tendons of the fingers are less likely to retract after laceration or rupture because of the extensor mechanism's multiple soft tissue

linkages to surrounding structures. However, these attachments make extensor tendons prone to adhesion formation and loss of excursion during the healing process. At the level of the dorsum of the hand, although the extensor tendons are relatively mobile, they also are surrounded by synovial sheaths to which they may adhere if immobilized over a period of time.^{41,84,97} As with management after flexor tendon repair, emphasis after extensor tendon repair is placed on preventing adhesions that restrict tendon gliding and limit joint ROM and functional use of the hand. (Refer to Box 19.12 to review factors that contribute to adhesion formation.)

The components and progression of postoperative rehabilitation and eventual outcomes after extensor tendon repair are influenced by many of the same factors that influence rehabilitation and outcomes of flexor tendon repair, including the location (level) and severity of the injury, the specifics of the surgical procedure(s), particularly the type of suturing technique and strength of the repair, and the timing of and the patient's access and commitment to a supervised rehabilitation program with an experienced hand therapist.^{26,43,111,114,129}

Approaches to postoperative management. Two general approaches to rehabilitation after surgical repair of extensor tendon injuries are described in the literature: prolonged, uninterrupted immobilization with motion of the injured region(s) delayed for 3 to 6 weeks or, in carefully selected patients, early controlled passive or active motion initiated during the first few postoperative days. The latter is based on the same rationale for early mobilization of flexor tendon repairs (see Box 19.13).

Historically, prolonged immobilization has been used more widely than early motion after extensor tendon repair, perhaps because of concerns that inadvertent but forceful or rapid movements could cause gapping or rupture of the repair if the splint or cast is removed early in the healing process⁹ or simply that alternative forms of immobilization, such as dynamic splinting, are cumbersome and more costly for the patient.⁹² Given these issues, the use of early motion after extensor tendon repair has evolved more slowly than it has for use after flexor tendon repair.

There are situations when an extended immobilization/delayed motion approach is the only appropriate method of management (see Box 19.14), and current studies continue to show that in many instances this traditional approach yields acceptable results.⁹² However, during the past two decades, some studies have shown that extensor tendon repairs, managed with prolonged immobilization, are more likely to develop adhesions, resulting in only marginal outcomes (increased incidence of extensor lag, joint contracture, boutonnière deformity).^{28,85} In addition, these and other studies have demonstrated that early motion programs after *primary* repair of acute extensor tendon injuries in zones III and VII are effective and safe^{18,19,34,44,45,56,60,99,124} and produce superior outcomes compared with prolonged immobilization/delayed motion programs.^{28,34,44,85,99} Consequently, early motion approaches have become more widely used in recent years.

It should be noted, however, that prolonged immobilization continues to be the most frequently selected method of treating zone I and II extensor tendon injuries.^{41,84,97} Late reconstruction, which is more complex and usually involves tendon grafts, also is managed in most cases with continuous, extended immobilization and delayed motion.²²

The first early motion programs for extensor tendons involved passive mobilization, with dynamic extension splinting, which allows active flexion followed by passive extension (see Fig. 19.11).^{28,45,85,99} In these programs, although active flexion is initiated just a few days after surgery, active digital extension at least at the level of the repair typically is delayed for 4 to 5 weeks.^{18,19,28,34,56,99} For an explanation of dynamic extension splinting after extensor tendon repair, refer to the earlier section of this chapter on repair of tendon ruptures associated with RA.

Although dynamic extension splinting for early mobility of the extensor tendons continues to be used, there is a growing trend to incorporate controlled active extension into early mobilization programs.^{26,43,44,60,124} Following a brief overview of immobilization procedures, key elements of early active motion and delayed motion approaches to rehabilitation after extensor tendon repair are presented.

Immobilization

Immobilization typically is maintained with a volar (palmar) splint after the bulky surgical dressing is removed a few days postoperatively. The duration of immobilization, the type(s) of immobilization selected, the joints immobilized, and the position of immobilization are based on the location (zone) of the injury and repair and the structures involved.

Duration of immobilization. If a patient is a good candidate for an early motion program, the duration of uninterrupted immobilization often is just a few days. If delayed motion is a more appropriate course of action, uninterrupted immobilization ranges from 3 to 6 weeks. In early motion programs, some type of protective splinting is used during exercise for about 6 weeks after surgery.

Types of immobilization. Either static or dynamic splinting or a combination of both is used. Depending on the joints immobilized, a forearm and wrist-based or a hand-base splint is indicated to block excessive flexion at the region of the repair and prevent stretching of the repaired tendon(s). A static splint is considered a low-profile splint, whereas a dynamic splint (see Fig. 19.11) with its outrigger secured to the dorsal surface of the splint for the elastic band and sling attachments is a high-profile splint. The slings and elastic band attachments hold the digits in extension at rest but allow active flexion.

For a delayed motion program, a static volar or bivalved circumferential splint is fabricated and worn on a continuous basis (other than daily skin care). A dynamic splint, worn during the day for frequent exercise sessions, is an integral aspect of many early motion programs. At night a static splint is worn to protect the repair. However, some early active motion programs use only static splints

that allow active motion when the straps are loosened but prevent excessive motion of joints. In some early active motion programs, special static template splints for the digits are fabricated and used only during exercises to limit the range of allowable motion (see Fig. 19.16).

The joints are immobilized in an extended position or a position that places only minimal tension on the tendon to protect the repair from excessive stretch and potential gapping. As examples, for a zone III/IV repair, the PIP and sometimes the DIP joints are placed in extension, but for a zone V/VI repair, the wrist is held in 30° of extension and the MCP joints in 30° to 45° of flexion. Recommended positions of the joints proximal or distal to the injured zone vary considerably. Several resources provide detailed information on immobilization and splinting procedures after extensor tendon repairs.^{26,43,111}

Exercise: Early Controlled Active Motion Approach

As interest in the application of early active motion after tendon repair has grown, so have the number of studies describing details of exercise programs and outcomes. In addition to one example of an early active motion program for zone III/IV repairs presented in this section, guidelines for early mobilization of zones V, VI, and VII also have been proposed and detailed in the literature.^{26,43,60,111,124} The distinguishing feature common to all early active motion programs following extensor tendon repair is that low-intensity and controlled active contractions of the repaired muscle-tendon units are initiated during the first few postoperative days, albeit in the confines of some type of static volar splint.

As noted previously, extensor tendon repairs in zones III and IV are especially prone to adhesion formation because of multiple soft tissue attachments of the extensor mechanism to surrounding structures and the broad bone–tendon interface of the proximal phalanx along which the extensor mechanism must glide.^{41,43,53,84,97} Evans^{43,44} proposed an early motion program of splinting and exercise for repairs of the central slip that involves minimal active tension of the repaired extensors for controlled, short-arc motion of the PIP and DIP joints.

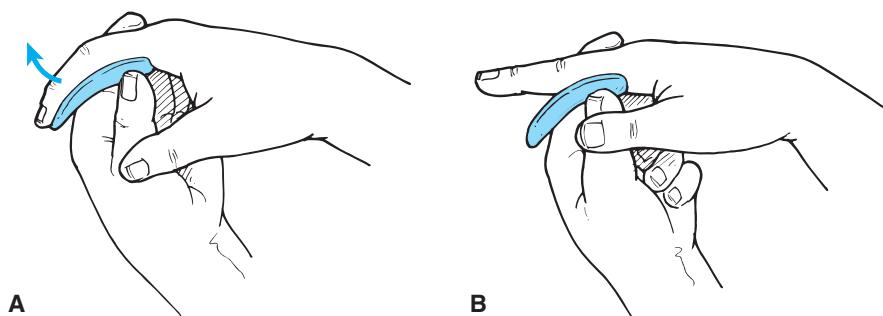

FIGURE 19.16 One of two static volar template splints used during early short-arc exercises of the PIP and DIP joints after repair of the extensor mechanism in zones III/IV. During exercise the patient actively holds the wrist in approximately 30° of flexion and manually holds the MCP joint in neutral to slight flexion. (A) Using minimal active tension during combined active PIP and DIP flexion, the splint initially limits PIP and DIP flexion to 30° and 20° to 25°, respectively, to prevent excessive stretch of the repair site. (B) The patient actively and slowly extends the PIP and DIP joints to full extension and briefly holds the extended position.

Focus on Evidence

Evans⁴⁴ compared the results of a prolonged immobilization/delayed motion program and an early short-arc motion (SAM) program in 55 patients who had undergone primary repair of 64 fingers for injury of the central slip. Patients in one group (36 digits) were managed with 3 to 6 weeks (mean 32.9 days) of continuous immobilization, whereas patients in the early motion group (28 digits) began active motion in a protected range at 2 to 11 days (mean 4.59 days) after surgery. After 6 weeks of treatment, patients in the delayed motion group had significantly less PIP flexion (44°) than the early motion group (88°). At discharge, the delayed motion group continued to have significantly less PIP flexion (72° after 76 days) than the early motion group (88° at 51 days). In addition, at discharge the delayed motion group had significantly less DIP flexion than the early motion group (37.6° and 45.0°, respectively). It also is interesting to note that at discharge the delayed motion group compared to the early motion group had significantly greater PIP extensor lag (8.1° and 2.9° respectively). However, at the initiation of treatment, the delayed motion group had a 13° PIP extensor lag, whereas the early motion group had only a 3° lag.

Key elements of the early short-arc, active motion program for central slip repairs include the following splinting and exercise procedures.^{26,43,44}

Use of customized static volar splints. A static, hand-based volar splint is fabricated and applied as soon as the surgical dressing is removed. It holds only the PIP and DIP joints in 0° extension; the wrist and MCP joints are free. This splint is removed for exercise on an hourly basis during the day but replaced between exercise sessions. A forearm-based resting splint is worn at night for protection for at least 6 weeks postoperatively.

Two static, volar, finger-based, template splints are fabricated and worn only during exercise to limit joint motion extensor tendon excursion, and the level of stress on the repaired central slip. One splint (Fig. 19.16) is

molded to limit PIP flexion to 30° and DIP flexion to 20° or 25° during exercise. A second template splint is fabricated to hold the PIP joint in full extension during isolated DIP flexion limited to 30° to 35°.

The PIP exercise splint is revised during the second week of exercise to allow 40° of flexion if no extensor lag is present. The PIP flexion allowed by the splint is increased incrementally by 10° each week thereafter.

Exercise progression. The patient is taught the concept of minimum active tension (MAT) to protect healing tissues during tendon excursion. MAT is just enough tension generated during an active muscle contraction to overcome the elastic resistance of an antagonist.⁴⁴ Exercises are initiated within the first few postoperative days and performed hourly during the day. While actively holding the wrist in 30° of flexion and manually stabilizing the MCP joint in neutral to slight flexion, the patient performs active PIP and DIP flexion within the limits allowed by the PIP exercise splint (see Fig. 19.16A), followed by full active extension held for several seconds (see Fig. 19.16B). The patient also performs active, isolated DIP flexion/extension in the second volar template splint that stabilizes the PIP joint in full extension.

Exercises continue regularly during the day for several weeks using revised exercise splints. Ideally, by the end of 4 weeks the patient achieves 70° to 80° of active flexion and full extension of the PIP joint. Composite MCP, PIP, and DIP flexion (full fist) is postponed for at least 4 weeks or when the exercise splints have been discontinued. By 6 to 8 weeks, low-intensity resisted exercises are initiated along with gradual use of the hand for functional activities.

Exercise: Delayed Mobilization Approach

If a traditional approach to postoperative management of extensor tendon repairs is used, exercises are delayed for at least several weeks after surgery. Special considerations and precautions for exercise using a delayed motion approach are summarized by zones in Box 19.19.^{17,26,43,48,92,111,129}

Guidelines for resistance exercises to strengthen the hand and continuation or modification of splinting for protection are not addressed in this summary. In general, splinting is continued during the day if an extensor lag persists and at night for protection for about 12 weeks. If grasp is limited because of insufficient finger flexion, passive stretching is initiated, or dynamic flexor splinting may be incorporated into the program by alternating flexion and extension splints.

Resistance to the repaired muscle-tendon unit is not initiated until 8 to 12 weeks postoperatively regardless of the site of the repair. First, emphasis is placed on gradually strengthening the extensors to prevent or minimize an extensor lag. After 10 to 12 weeks *low-intensity* resisted grasp and pinch activities are initiated to gradually strengthen the flexors if no extensor lag is present.

Outcomes

Outcomes, including complications, after extensor tendon repair and postoperative rehabilitation are well documented in the literature. Early and late complications are similar to those occurring after flexor tendon repair, including rupture, adhesion formation, and limited motion. Outcomes typically measured and reported after extensor tendon repair are ROM of the wrist and/or digits and grip strength with only limited information reported on use of the hand for functional activities.

Digital motion often is expressed in terms of “pad-to-palm” distances or total active motion (active flexion minus extensor lag). These figures are then compared to the contralateral hand or to the “normal” population and are typically expressed as excellent, good, fair, or poor. For example, if ROM is only 75% of that found in normal individuals or if there is < 15° of extensor lag in a digit and sufficient digital flexion to touch the pad of the distal phalanx to the mid-palm, the result is described as “good.” To understand the results of studies on tendon repair, it is necessary to have some understanding of the various assessment tools.

Some generalizations about outcomes can be drawn from the literature regarding the severity and location of the injury. As with flexor tendon injuries, the greater the extent of associated skeletal, joint, vascular, or nerve injuries, the poorer are the results of the repair with respect to extensor lag and digital flexion for grasp. For example, in a study of outcomes after extended immobilization following extensor tendon repair, 64% of patients with simple tendon injuries had good results, whereas only 47% of patients with associated skeletal or joint injuries had a good result.⁸⁵ In the same study, investigators found that repairs of distal injuries (zones I to IV) have less favorable results than repairs of more proximal injuries (zones V to VIII).

Outcomes of the various approaches to postoperative management of extensor tendon injuries are reported in the literature on an ongoing basis. With regard to the timing of the surgical intervention, for example, primary repairs of acute injuries (rupture or laceration), whether repaired immediately or delayed for up to 10 days, yield equally good results.^{41,84} As noted throughout this section on extensor tendon injury and repair, numerous studies have been published describing outcomes of the various approaches to postoperative management. Although some current studies support the use and effectiveness of prolonged immobilization of extensor tendon repairs,⁹² there is growing use and ongoing modification and refinement of early controlled motion approaches to help patients achieve the best possible outcomes.

For example, dynamic extension splinting, a mainstay of early passive mobilization protocols for more than 20 years, now is being re-evaluated. Although some recent studies^{19,34} have demonstrated that high-profile, dynamic splinting continues to be used and is effective,

BOX 19.19 Special Considerations for Exercise After Extensor Tendon Repair and Extended Immobilization
Zones I and II

- Tendon injuries in these zones are typically managed non-operatively.
- PIP and MCP AROM while the DIP is continuously immobilized in extension for at least 4 weeks but more often 6 to 8 weeks.
- When splint can be removed for exercise, perform active DIP extension and very gentle active flexion with the MCP and PIP joints stabilized in neutral. Briefly hold the extended position with each repetition.
- Emphasize active extension more than flexion to avoid an extensor lag.
- After initiating exercises, splint between exercise sessions an additional 2 weeks or longer if an extensor lag develops.

PRECAUTION: Increase active flexion of the DIP joint *very gradually*, initially limiting flexion to 20° to 25° during the first week of exercise. The strong FDP can easily place excessive stress on the terminal extensor tendon and cause gapping or rupture of the repair. Progress active flexion by about 10° per week. Do not attempt full DIP flexion for about 3 months.

Zones III and IV

- If the lateral bands were intact, begin DIP AROM 1 week postoperatively while the PIP joint is immobilized in extension in a volar splint or cylinder cast. Early DIP motion prevents adherence and loss of extensibility of the lateral bands and oblique retinacular ligaments and loss of mobility of the DIP joint.
- If the lateral bands were damaged and repaired, postpone DIP ROM until 4 to 6 weeks postoperatively.
- At a minimum of 3 to 4 weeks but more often at 6 weeks, the volar splint is removed for active ROM of the PIP joints with the MCP joints stabilized. Emphasize active extension more than flexion.

PRECAUTIONS: Progress PIP flexion in *very gradual* increments; limit PIP flexion to 30° the first week of PIP ROM exercises. Increase an additional 10° per week if no extensor lag.

other studies reflect a return to the use of low-profile, static splinting if coupled with early active motion.^{44,60,124}

In a prospective, randomized study, Khandawala et al.⁶⁰ compared the effectiveness of two early mobilization programs for patients with zone V/VI extensor tendon repairs—a dynamic splinting program and a static splinting program combined with early active exercise. One group of 50 patients performed exercises in a volar, wrist-based dynamic extension splint that allowed free movement of IP joints and active MCP flexion to the level of the splint. The elastic bands and slings passively extended the MCP joints to a neutral position as the flexors relaxed. A second group of 50 patients wore a static volar blocking splint that positioned the wrist in 30° of extension and the MCP joints in 45° of flexion. The IP

- If the wrist and MCP joints have been immobilized postoperatively, include active ROM of the wrist with the MCP and PIP joints stabilized and active MCP ROM with the wrist and PIP joints stabilized in extension.

Zones V and VI

- When the volar splint can be removed for exercise (between 3 and 4 weeks or as late as 6 weeks postoperatively), begin active or assisted MCP extension and passive flexion with the wrist and IP joints stabilized in neutral and the forearm *pronated*. Actively hold the extended position for a few seconds with each repetition. Let the extensors relax to flex the MCP joints.
- Add carefully controlled active MCP flexion within a protected range with the wrist stabilized in extension.
- Emphasize active MCP extension more than flexion to prevent an extensor lag.

PRECAUTION: Initially limit active MCP flexion to 30° in the index and middle fingers and 35° to 40° in the ring and small fingers.

- During active IP flexion and extension exercises, stabilize the MCP joints in neutral and the wrist in slight extension. Encourage full-range DIP motion.
- Combine active MCP extension with active PIP flexion (hook fist position) and PIP extension (straight hand position).
- Incrementally progress to full fist position over several weeks if no extensor lag develops.

Zone VII

- If the wrist extensors are intact and only extrinsic finger extensors have been repaired, follow the guidelines for zone V/VI repairs.
- If the wrist extensors were repaired, begin active wrist extension from neutral to full extension in a gravity-eliminated position (forearm in mid-position) at 3 to 4 weeks.
- Incrementally increase wrist flexion beyond neutral between 5 and 8 weeks postoperatively.
- Perform radial and ulnar deviation with the wrist in neutral.

joints were free. With the stabilization straps loosened, this group performed active MCP flexion to 45° (further motion was blocked by the splint) and MCP extension to neutral. In both groups IP motion was unrestricted. After 6 weeks of exercise, splinting was discontinued and outcomes were measured by two assessment tools. As reflected by scores on the two assessment instruments, a high percentage of patients in both groups had good and excellent results, specifically 95% and 98% of the dynamic splinting group and 93% and 95% of the static splinting/active exercise group. These results, when analyzed, demonstrated that there were no significant differences in outcomes between the groups. With two splinting and early motion approaches yielding equally favorable results, the investigators concluded that static

splinting could be considered a less cumbersome and expensive alternative to dynamic splinting for early motion programs. Additional research is needed to determine if modification of early active motion programs could provide significantly better outcomes over early passive motion programs.

EXERCISE INTERVENTIONS FOR THE WRIST AND HAND

TECHNIQUES FOR MUSCULOTENDINOUS MOBILITY

Active muscle contraction and specific motions of the digits and wrist are used to maintain or develop mobility between the multijoint musculotendinous units and other connective tissue structures in the wrist and hand. Because adhesions between the various structures can become restrictive or incapacitating, *tendon-gliding exercises* and *tendon-blocking exercises* are used, whenever possible, to develop or maintain mobility. This is particularly important when there has been immobilization after trauma, surgery, or a fracture, and scar tissue adhesions have developed. If restrictions occur as a result of scar tissue adherence between tendons or between tendons and surrounding tissues, mobilization techniques described in this section may be necessary. General stretching techniques may also be necessary; they are described in the next section. The tendon-gliding and tendon-blocking exercises described here may also be used to develop neuromuscular control and coordinated movement.

Tendon-Gliding and Tendon-Blocking Exercises

Place-and-Hold Exercises

Place-and-hold exercises are a form of gentle muscle setting (static/isometric) exercises that are used during the early postoperative period following tendon repair before active ROM is initiated but when a minimal level of stress on the repaired tendon and passive joint movement are beneficial for maintaining joint mobility and tendon excursion.

- Following flexor tendon repair, the patient usually wears a dorsal blocking splint^{46,47,107} or a tenodesis splint.^{24,25,115–117} With the MCP joints in flexion, passively place the IP joints in a partially flexed position and have the patient hold the position independently for 5 seconds with a minimum static contraction of the finger flexors.
- If the patient is wearing a tenodesis splint, combine place-and-hold finger flexion with active wrist extension (see Fig 19.14 B&C). Have the patient relax and allow the wrist to passively flex and the digits to passively extend.

- Following extensor tendon repair, when the volar blocking splint may be removed for exercise, passively position the joint in the zone of the repair first in a neutral and later in a slightly extended position. Then, have the patient hold the position. This emphasizes end-range extension to prevent an extensor lag.
- Have the patient practice the exercise with the uninjured hand or use biofeedback to learn how to hold the position with a minimum of force production.

Flexor Tendon-Gliding Exercises

Flexor tendon-gliding exercises are designed to maintain or develop free gliding between the flexor digitorum profundus and superficialis tendons and between the tendons and bones in the wrist, hand, and fingers.^{101,109,130} There are five positions in which the fingers move during tendon-gliding exercises: straight hand (all the joints are extended), hook (claw) fist (MCP joints are extended, IP joints are flexed), full fist (all the joints are flexed), table-top position, also known as the intrinsic plus hand (MCP joints are flexed, IP joints are extended), and straight fist (MCP and PIP joints are flexed, IP joints are extended) (Fig. 19.17). The following progression is suggested.

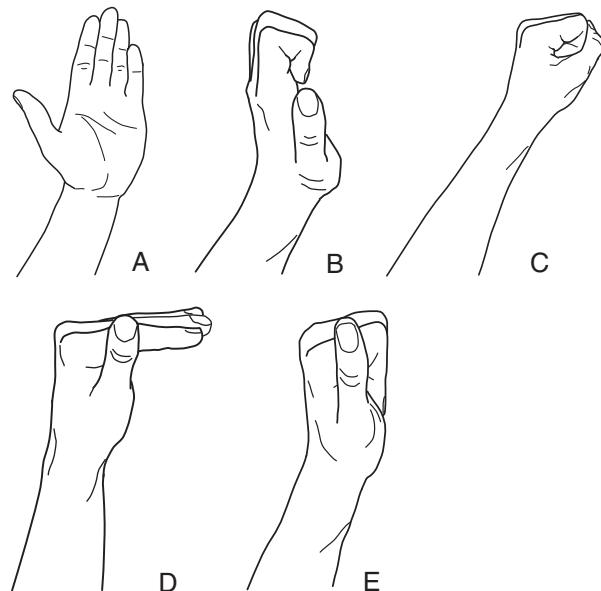

FIGURE 19.17 The five finger positions used for flexor tendon gliding exercises: (A) straight hand, (B) hook fist (claw fist), (C) full fist, (D) table top (intrinsic plus), and (E) straight fist.

- Initiate the exercises with the wrist in neutral position.
- Once full range of the finger motions is achieved, progress to doing the gliding exercises with the wrist in flexion and in extension to establish combined finger and wrist mobility.
- Full excursion and tendon-gliding of all the extrinsic muscles are accomplished by starting with the wrist and fingers in full extension and moving to full wrist and finger flexion and then reversing the motion.

Hook (Claw) Fist Position

Have the patient move from the straight hand to the hook fist position by flexing the DIP and PIP joints while maintaining MCP extension (Fig. 19.17 A&B). Maximum gliding occurs between the profundus and superficialis tendons and between the profundus tendon and the bone. (There is also gliding of the extensor digitorum communis tendons; this motion is used with the extensor gliding exercises.)

Full Fist

Have the patient move to the full fist position by flexing all the MCP and IP joints simultaneously (Fig. 19.17C). Maximum gliding of the profundus tendon with respect to the sheath and bone as well as over the superficialis tendon occurs.

Straight Fist (Sublimis Fist)

Have the patient move from the table-top position (Fig. 19.17D) to the straight fist position by flexing the PIP joints while maintaining the DIP joints in extension (Fig. 19.17E). Maximum gliding of the superficialis tendon occurs with respect to the flexor sheath and bone.

Thumb Flexion

Have the patient flex the MCP and IP joints of the thumb full range. This promotes maximum gliding of the flexor pollicis longus.

Flexor Tendon-Blocking Exercises

Blocking exercises for the flexor tendons (Fig. 19.18) not only develop gliding of the tendons with respect to the sheaths and related bones, they also require neuromuscular control of individual joint motions. Therefore, they use the mobility gained by the flexor tendon-gliding exercises and are a progression of the flexor tendon-gliding exercises. Progress to manual resistance as the tissues heal and can tolerate resistance.

PRECAUTION: These exercises should not be used in the early stages after flexor tendon repair because of the stress placed on the tendons.

Patient position and stabilization: Sitting with the forearm supinated and the back of the hand resting on a table. The opposite hand provides stabilization and “blocking” against unwanted movement. Each finger performs the exercise separately.

Isolated MCP Flexion (Lumbricales and Palmar Interossei)

- Have the patient flex only the MCP joint of one digit (Fig. 19.18A).
- If necessary, the rest of the fingers are stabilized in extension against the table with the other hand.
- With improved control, the hand does not have to be stabilized against the table.

PIP Flexion (Flexor Digitorum Superficialis)

- Have the patient stabilize the proximal phalanx of one digit with the other hand, and if possible, flex just the PIP joint of the one digit while keeping the DIP joint extended and the rest of fingers on the table (Fig. 19.18B).

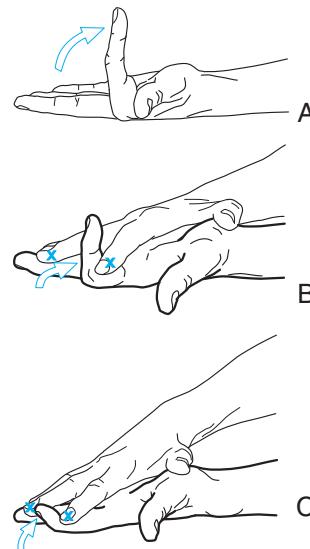

FIGURE 19.18 Flexor tendon blocking exercises: (A) isolated MCP flexion of one digit, (B) isolated PIP flexion (flexor digitorum superficialis) of one digit, and (C) isolated DIP flexion (flexor digitorum profundus) of one digit.

- If the patient has difficulty doing this, the other digits are stabilized in extension with the other hand.

DIP Flexion (Flexor Digitorum Profundus)

- The middle phalanx of one digit is stabilized with the other hand.
- Have the patient attempt to flex just the distal phalanx (Fig. 19.18C).
- Vary this exercise by increasing the range of MCP and PIP flexion to where the patient just begins to lose DIP motion; stabilize in this position and have the patient attempt DIP flexion.

Full Fist

When full independent tendon-gliding is available, the patient should be able to make a full fist. Progress the exercises described by adding resistance.

Exercises to Reduce Extensor Lag

The extrinsic finger extensors (extensor digitorum communis, extensor digitorum indicis, and extensor digiti minimi) are more superficial than the flexor tendons and therefore more easily damaged. Their prime function is to extend the MCP joints. Extension of the IP joints requires active interaction with the intrinsic muscles of the hand via the extensor mechanism. Adhesions within their sheaths at the wrist or between tendon and bone restrict tendon-gliding both proximally (restricting active finger extension) and distally (restricting active and passive finger flexion). When full passive range of extension is available, but the person cannot actively move the joint through the full range of extension, it is called an *extensor lag*. It can occur as the result of weakness but is frequently caused by adhesions that prevent gliding of the tendons when the muscles contract.

One of the purposes of the following exercises is to maintain mobility and thus prevent adhesions. The exercises are also used to regain control of finger extension. Mobi-

lization of adhesions is described immediately following the differential gliding of extensor tendon exercises. Stretching techniques are described in the next section.

Isolated MCP Extension

- Have the patient move from the full fist position (see Fig. 19.17C) to the hook fist position (see Fig. 19.17B).
- If the patient has difficulty maintaining the IP joints in flexion, have him or her hook the fingers around a pencil while extending the MCP joints.
- Begin with the wrist in neutral and progress to positioning the wrist in flexion and extension while performing MCP extension.

Isolated PIP and DIP Extension

Extension of the interphalangeal joints requires intrinsic and extrinsic muscle (extensor digitorum communis) control.

- For strongest participation of the lumbricales, stabilize the MCP joint in flexion while the patient attempts IP extension, moving from the full fist position (see Fig. 19.17C) to the table-top position (see Fig. 19.17D).
- Progress to stabilizing the palm of the hand on the edge of a table (or block) with the PIP or DIP joint partially flexed over the edge.
- Have the patient extend the involved phalanx through the ROM.

Terminal-Range Extension of IP Joints

- Progress to the terminal range by stabilizing the entire hand, palm side down on a flat surface, and have the patient extend the involved phalanx into hyperextension.
- If there is not enough range available, place a pencil or block under the proximal phalanx or middle phalanx so the PIP or DIP joint can go through a greater range (Fig. 19.19).

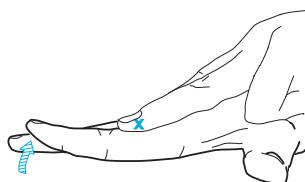

FIGURE 19.19 Terminal extension of the PIP joint. The MCP joint is stabilized in extension, and the patient lifts the middle and distal phalanges off the table.

Extensor Tendon-Gliding Exercises

Differential gliding of the extensor digitorum communis tendons to each of the fingers can be achieved by the following progression.

- Teach the patient to passively flex the MCP and IP joints of one finger with the opposite hand while actively maintaining the other fingers in extension.
- If the patient has difficulty doing this, begin with the involved hand resting on a table with the palm up. Stabilize three of the four fingers against the table while pas-

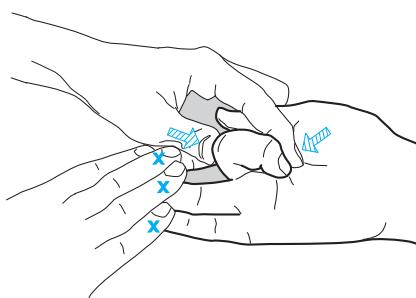

FIGURE 19.20 Differential gliding of the extensor digitorum tendons. Move each digit into flexion while stabilizing the other digits in extension.

sively flexing one of the digits (Fig. 19.20). Then instruct the patient to attempt to actively keep the fingers against the table while one of the digits is passively flexed.

- Progress by having the patient actively maintain the fingers in extension with the fingers spread out and then actively flex each finger in turn while the other fingers remain extended.
- Have the patient flex the middle and ring fingers while maintaining extension of the index and little fingers (long horn sign). This promotes isolated control of the extensor indicis and extensor digiti minimi tendons and promotes their gliding on the extensor digitorum communis tendons.

Scar Tissue Mobilization for Tendon Adhesions

Ideally, the tendon-gliding exercises described previously in this section maintain or develop mobility between the long tendons and surrounding connective tissues or within their sheaths. However, when there has been inflammation and immobilization during the healing process following trauma or surgery, scar tissue adhesions may form and prevent gliding of the tendons. Contraction of the muscle does not result in movement of the joint or joints distal to the site of the immobile scar.

Techniques to mobilize the adhesive scar tissue include the application of friction massage directly to the adhesion. This is superimposed on active and passive stretching techniques (described in the next section), and the tendon-gliding techniques already described. To apply friction massage, hold the tendon in its lengthened position; apply pressure with your thumb, index, or middle finger and massage perpendicular to the tendon and longitudinally in proximal and distal directions. A sustained force against the adhesion allows for creep and eventual movement of the scar. Techniques to mobilize the flexor and extensor tendons follow.

To Mobilize the Long Finger Flexor Tendons

Adhesions between the flexor tendons and their sheaths or between tendons and underlying bones restrict tendon-gliding in both a proximal and distal direction so the joints distal to the scar do not flex when the muscle contracts. Passive movement into flexion of the joints distal to the

adhered scar is possible if there are no capsular restrictions. Full range of extension of the joints distal to the scar is not possible actively or passively owing to the inability of the tendon to glide distally.

The following is a suggested progression in intensity of scar tissue mobilization.

- Begin the stretching routine by passively moving the tendon in a distal direction by extending the finger joints as far as possible and apply a sustained hold to allow for creep. Follow this with active contraction of the flexor muscle to create a stretch force against the adhesion in a proximal direction¹⁰⁹ using the patterns of movement described for tendon-gliding exercises (see Fig. 19.17).
- If active and passive stretching, described in the above technique, does not release the adhesion, extend the MCP and IP joints as far as allowed, stabilize them, then apply friction massage with your thumb or finger at the site of the adhesion while the tendon is held in its stretched position.³⁶ As indicated above, apply the massaging stretch force across the tendon and in a longitudinal direction, both proximally and distally. When applying friction massage in a proximal direction, ask the patient to simultaneously contract the flexor muscle in order to superimpose an active stretch force.
- After friction massage, have the patient repeat the flexor tendon-gliding exercises to utilize any gained mobility.

To Mobilize the Extensor Tendons and the Extensor Mechanism

As with the flexor tendons, if the extensor tendons or extensor mechanism has restricted mobility because of adhesions, muscle action is not transmitted through the mechanism to extend the joint or joints distal to the restriction. Without free gliding, an extensor lag may result. As defined earlier, an extensor lag is the loss of active extension when there is full passive extension. The following is a progression in intensity of scar tissue mobilization.

- Stretch the adhesion in a distal direction by passively flexing the joint distal to the site. Follow this by having the patient attempt to actively extend the joint and put tension on the scar in a proximal direction.

PRECAUTION: If the extensor lag increases (i.e., flexion increases, but there is no active extension through the increased range), the tendon distal to the adhesion may be stretching, not the adhesion. Do not continue with passive stretching into flexion but, rather, emphasize friction massage applied to the scar tissue.

- Apply friction massage at the site of the adhesion with the tendon kept taut by holding the joint at the end of its range of flexion. Apply friction massage across the fibers and in a distal and proximal direction. When applying friction massage in a proximal direction, have the patient actively contract the extensors to assist with the mobilization effort.
- Follow these mobilization techniques with extensor tendon-gliding exercises, as described in the previous section.

EXERCISE TECHNIQUES TO INCREASE FLEXIBILITY AND RANGE OF MOTION

Stretching the muscles and connective tissue structures of the wrist and hand requires knowledge of the unique anatomical relationships of the multijoint musculotendinous units and the extensor mechanism of the digits. These are described in the first section of this chapter. The principles and techniques of stretching are presented in Chapter 4, and special note is made of the importance of stabilization when stretching the multijoint muscles of the hand and fingers. This is re-emphasized here. In addition, because scarring and adhesions can restrict tendon-gliding and therefore motion of the digits, it is important to recognize these restrictions and utilize specific techniques that address the adhesions as presented in the previous section (see Scar Tissue Mobilization for Tendon Adhesions). Before stretching muscle or connective tissue, there also should be normal gliding of the joint surfaces to avoid joint damage. Use joint mobilization techniques to stretch the joint capsule and restore gliding (see Chapter 5).

NOTE: Patient position for most wrist and hand exercises is sitting with the forearm supported on a treatment table unless otherwise noted.

General Stretching Techniques

When stretching to increase wrist flexion or extension, it is important that the fingers are free to move so the extrinsic finger flexor and extensor musculotendinous units do not restrict motion at the wrist. Similarly, when stretching ligaments and other periarticular connective tissues across individual finger joints, it is important that there is no tension on the multijoint tendons. The following techniques are initially applied by the therapist and then are taught to the patient as self-stretching techniques for a home exercise program when he or she understands how to safely apply the stretch force and stabilization.

To Increase Wrist Extension

- Have the patient place the palm of the hand on a table with the fingers flexed over the edge. The other hand stabilizes the dorsal surface of the hand to maintain the palm against the table. Then have the patient move the forearm up over the stabilized hand (similar to Fig. 19.22 except the fingers are over the edge of the table so they are free to flex and the stretch occurs only at the wrist).
- Have the patient place the palms of the hands together at right angles to each other and allow the fingers to intertwine and flex. Instruct the patient to press the restricted hand in a dorsal direction with the palm of the other hand and sustain the stretch.

To Increase Wrist Flexion

- Have the patient place the dorsal surface of the hand on a table. The other hand provides stabilization against the

palm of the hand. Have the patient move the forearm up over the stabilized hand.

- Have the patient sit with the forearm pronated and resting on a table and the wrist at the edge of the table. The patient then presses the hand toward flexion with the opposite hand.
- Have the patient place the dorsum of both hands together. Then, with the fingers relaxed, move the forearms so the wrists flex toward 90°.

To Increase Flexion or Extension of Individual Joints of the Fingers or Thumb

To increase extension at any one joint, the patient's forearm is supinated; to increase flexion, the forearm is pronated, and the phalanx to be stretched is at the edge of the table. Show the patient how to apply the force against the distal bone while stabilizing the proximal bone against the table.

Stretching Techniques for the Intrinsic and Multijoint Muscles

Self-Stretching the Lumbricales and Interossei Muscles

Have the patient actively extend the MCP joints and flex the IP joints and apply a passive stretch force at the end of the range with the opposite hand (Fig. 19.21A).

Self-Stretching the Interossei Muscles

Have the patient place the hand flat on a table with the palm down and the MCP joints extended. Instruct the patient to abduct or adduct the appropriate digit and apply the stretch force to the distal end of the proximal phalanx. Stabilization is provided by holding the adjacent digit.

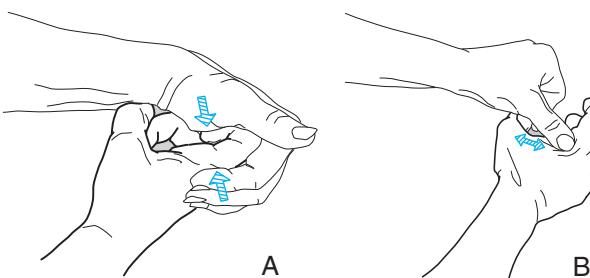

FIGURE 19.21 Self-stretching (A) the lumbricales with MCP extension and IP flexion; and (B) the adductor pollicis with CMC abduction of the thumb. To increase thumb abduction, it is critical that the stretch force is applied against the metacarpal head not the proximal or distal phalanges.

Self-Stretching the Adductor Pollicis

Have the patient rest the ulnar border of the hand on the table and abduct the thumb perpendicular to the palm of the hand. Instruct the patient to apply the stretch force with the crossed thumb and index or long finger of the other hand against the metacarpal head of the thumb and index finger and attempt to increase the web space (Fig. 19.21B).

PRECAUTION: It is critical that the patient does not apply the stretch force against the proximal or distal pha-

lanx. This places stress on the ulnar collateral ligament of the MCP joint of the thumb and leads to instability at that joint with poor functional usage of the thumb. Abduction occurs at the CMC joint at the articulation between the metacarpal and the trapezium.

Manual Stretching of the Extrinsic Muscles

Because they are multijoint muscles, the final step is to elongate each tendon of the extrinsic muscles over all the joints simultaneously but *do not* initiate stretching procedures in this manner because joint compression and damage can occur to the smaller or less stable joints. Begin by allowing the wrist and more proximal finger joints to relax; stretch the tendon unit over the most distal joint first. Stabilize the distal joint at the end of the range and then stretch the tendon unit over the next joint. Next, stabilize the two joints, and stretch the tendon over the next joint. Progress in this manner until the desired length is reached.

PRECAUTION: Do not let the PIP and MCP joints hyperextend as the tendons are stretched over the wrist.

Self-Stretching the Flexor Digitorum Profundus and Superficialis

Have the patient begin by resting the palm of the involved hand on a table and first extend the DIP joint, using the other hand to straighten the joint; keeping it extended, then have the patient straighten the PIP and MCP joints in succession. If the patient can actively extend the finger joints to this point, the motion should be performed unassisted. With the hand stabilized on the table, have the patient then begin to extend the wrist by bringing the arm up over the hand. The patient goes just to the point of feeling discomfort, holds the position, then progresses as the length improves (Fig. 19.22).

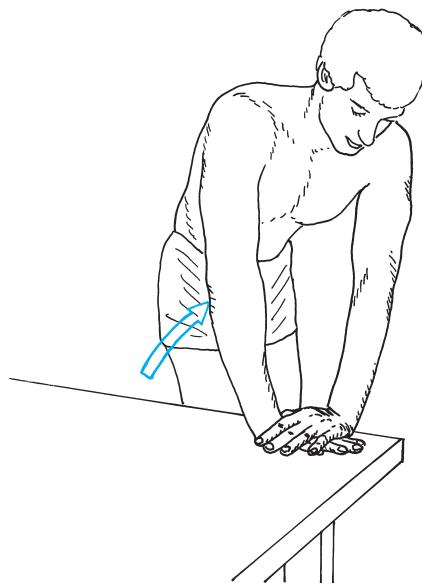

FIGURE 19.22 Self-stretching of the extrinsic finger flexor muscles, showing stabilization of the small distal joints. To isolate stretch to the wrist flexors, allow the fingers to flex over the edge of the table.

Self-Stretching the Extensor Digitorum Communis

The fingers are flexed to the maximum range, beginning with the distalmost joint first and progressing until the wrist is simultaneously flexed. The opposite hand applies the stretch force.

EXERCISES TO DEVELOP AND IMPROVE MUSCLE PERFORMANCE, NEUROMUSCULAR CONTROL, AND COORDINATED MOVEMENT

Exercises described in this section are for use during the controlled motion and return to function phases of rehabilitation when the tissues are in the subacute and chronic stages of healing and require only moderate or minimum protection. In addition to the conditions already described in this chapter, imbalances in the length and strength of the wrist and hand muscles can occur as the result of a variety of causes, such as nerve injury, trauma, disuse, or immobilization. Appropriate exercises to develop fine finger dexterity or strength and muscular endurance for strong or repetitive gripping can be selected from the following exercises or their adaptations. The flexor tendon blocking exercises and extensor tendon-gliding exercises described previously in this section may also be used to strengthen the musculature by adding resistance manually or mechanically. Exercises for shoulder, elbow, and forearm strength and muscular endurance should also be included to restore proper function in the upper extremity.

Techniques to Strengthen Muscles of the Wrist and Hand

If the musculature is weak, use progressive strengthening exercises, beginning at the level of the patient's ability. Use active-assistive, active, or manual resistance exercises as described in Chapters 3 and 6 of this text. Progress to mechanical resistance.

To Strengthen Wrist Musculature

Allow the fingers to relax. Exercise the wrist muscles in groups if their strength is similar. If one muscle is weaker, the wrist should be guided through the range desired to minimize the action of the stronger muscles. For example, with wrist flexion, if the flexor carpi radialis is stronger than the flexor carpi ulnaris, have the patient attempt to flex the wrist toward the ulnar side as you guide the wrist into flexion and ulnar deviation. If the muscle is strong enough to tolerate resistance, apply manual resistance over the fourth and fifth metacarpals.

Wrist Flexion (Flexor Carpi Ulnaris and Radialis) and Extension (Extensor Carpi Radialis Longus and Brevis and Extensor Carpi Ulnaris)

The patient sits with the forearm supported on a table, grasping a weight or elastic resistance that is secured on

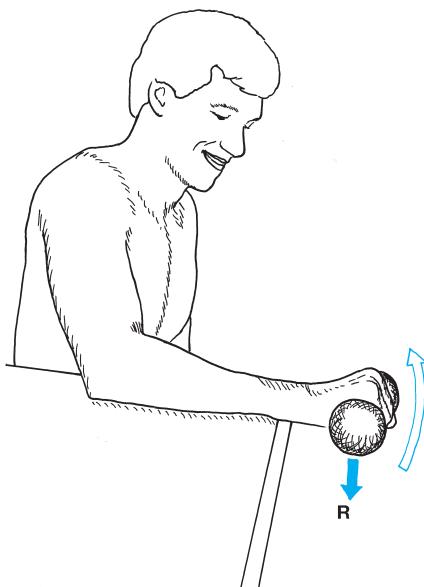

FIGURE 19.23 Mechanical resistance to strengthen wrist extension. Note that the forearm is pronated. To resist wrist flexion, the forearm is supinated.

the floor. The forearm is supinated to resist flexion or pronated to resist extension (Fig. 19.23).

Wrist Radial Deviation (Flexor and Extensor Carpi Radialis Muscles and Abductor Pollicis Longus) and Ulnar Deviation (Flexor and Extensor Carpi Ulnaris Muscles)

The patient stands and holds a bar with a weight on one end. To resist radial deviation the weight is on the radial side of the wrist (Fig. 19.24A); to resist ulnar deviation the weight is on ulnar side of the wrist (Fig. 19.24B).

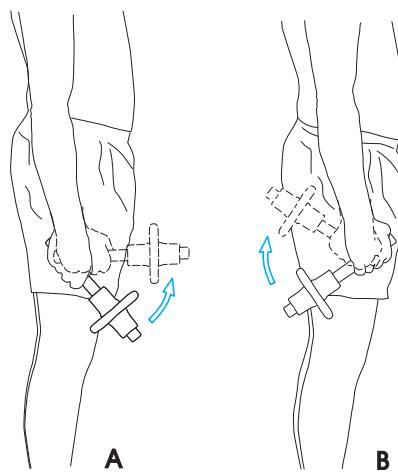

FIGURE 19.24 Mechanical resistance to strengthen (A) radial deviation and (B) ulnar deviation of the wrist using a weighted bar.

Functional Progressions

Progress to controlled patterns of motion requiring stabilization of the wrist for functional hand activities such as repetitive gripping, picking up and releasing objects of var-

ious sizes and weights, and opening and closing the screw lid on a jar. Develop endurance and progress to the desired functional pattern by loading the upper extremity to the tolerance of the wrist stabilizers. When the stabilizers begin to fatigue, stop the activity.

To Strengthen Weak Intrinsic Musculature

NOTE: Imbalance from weak intrinsic muscles leads to a claw hand.

MCP Joint Flexion with IP Joint Extension (Lumbricales)

- Begin with the MCP joints stabilized in flexion. Have the patient actively extend the PIP joint against resistance along the middle phalanx. Increase the resistance by resisting the distal phalanx. Resistance may be applied manually or with rubber bands.
- Have the patient start with the MCP joints extended and the PIP joints flexed; then actively push the fingertips outward, performing the desired combined motion (Fig. 19.25 A&B). For resistance, have the patient push the fingers into the palm of the other hand (Fig. 19.25C), or push the fingers into exercise putty with the desired motion.

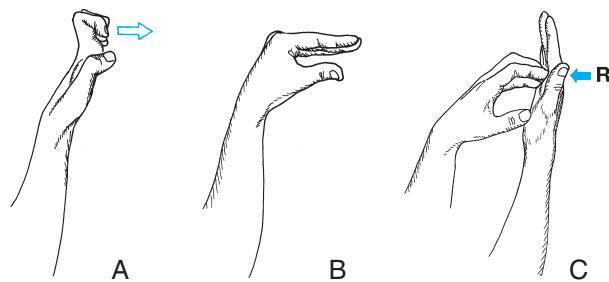

FIGURE 19.25 To strengthen intrinsic muscle function for combined MCP flexion and IP extension, the patient begins with (A) MCP extension and IP flexion and (B) pushes his fingertips outward. The same motion is resisted by (C) pushing the fingertips against the palm of the other hand.

- Begin with all the finger joints extended. Have the patient maintain the IP joints in extension and flex the MCP joints to the table-top position. Apply resistance against the proximal phalanx.

Isolated or Combined Abduction/Adduction of Each Finger (Dorsal and Volar Interossei)

- Have the patient rest the palm of the hand on a table. Apply resistance at the distal end of the proximal phalanx, one finger at a time, for either abduction or adduction.
- To resist adduction, have the patient interlace the fingers of both hands (or with your hand) and squeeze the fingers together or squeeze exercise putty between two adjacent fingers.
- To resist abduction, place a rubber band around two digits and have the patient spread them apart.

Abduction of the Thumb (Abductor Pollicis Brevis and Longus)

- The patient rests the dorsum of the hand on a table. Apply resistance at the base of the first phalanx of the thumb as the patient lifts the thumb away from the palm of the hand.
- Place a rubber band or band of exercise putty around the thumb and base of the index finger and have the patient abduct the thumb against the resistance.

Opposition of the Thumb (Opponens Pollicis)

- Have the patient use various prehension patterns such as tip-to-tip and tip-to-pad, with the thumb opposing each digit in succession, and pad-to-side, with the thumb approximating the lateral side of the index finger.
- Use elastic resistance or have the patient pinch exercise putty, a pliable ball, or a spring-loaded clothespin.

To Strengthen Weak Extrinsic Musculature of the Fingers

NOTE: The wrist must be stabilized for the action of the extrinsic hand musculature to be effective. If wrist strength is inadequate for stabilization, manually stabilize it during exercises and splint it for functional usage.

Metacarpophalangeal Extension (Extensor Digitorum Communis, Indicus, and Digitii Minimi)

Have the hand resting on a table with the palm down and digits over the edge. Place a small strap over the distal end of the proximal phalanx with a small weight hanging down from it or secure. Elastic band or tubing around the proximal phalanx and have the patient extend the MCP joint.

Interphalangeal Flexion (Flexor Digitorum Profundus and Superficialis)

Teach the patient to apply self-resistance by starting with the hands pointing in opposite directions and placing the pads of each finger of one hand against the pads of each finger of the other hand (or against your hand), and then curl the fingers against the resistance provided by the other hand (Fig. 19.6). The same technique is used to resist thumb flexion.

Mechanical Resistance Techniques for Combined Intrinsic and Extrinsic Muscle Function

NOTE: Proper stabilization is important; either the patient's stabilizing muscles must be strong enough or

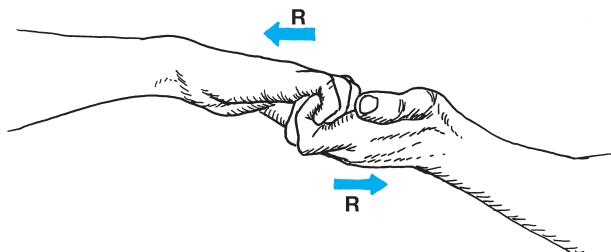

FIGURE 19.26 Self-resistance to strengthen extrinsic finger flexor muscles.

the weakened areas must be supported manually. If a weight causes stress because the patient cannot control it, the exercise is detrimental rather than beneficial.

Towel or Newspaper Crumple

Spread a towel out on a table. Have the patient place the palm of the hand down at one end of the towel and crumple the towel into the hand while maintaining contact with the heel of the hand. The same exercise can be carried out by placing a stack of newspapers under the hand. The patient crumples the top sheet into a ball (and tosses it into a basket for coordination and skill practice), then repeats it with each sheet in succession.

Disk Weight

Have the patient grasp a disk weight in the manner described in each of the following exercises.

- With the forearm pronated (palm down), pick up the disk with the tips of all five digits spread around the outer edge. Have the patient hold the position for isometric resistance. To increase the effect of the resistance to the flexors, have the patient extend one digit at a time.
- Pick up the side of the disk with either tip-to-tip or pad-to-pad prehension of thumb and fingers.
- With the hand palm down on a table, place the disk on the dorsum of the fingers and then hyperextend the fingers by lifting the disk.

Other Resistance Aids

Resistive devices such as putty, spring-loaded hand exercisers, and various grades and sizes of soft balls can be used for specific muscles or general strengthening. Observe the pattern used by the patient and be sure he or she does not substitute or develop damaging forces.

Fine-Finger Dexterity

Functional use of the hand for manipulating small objects or skillfully controlling delicate devices requires use of the thumb in opposition to the index and middle fingers. Have the patient perform activities such as picking up small objects of various sizes, twisting nuts on and off bolts, drawing, writing, tying, opening, and closing small bottles or boxes, and typing on a keyboard.

Functional Activities

Progress to specific patterns needed for ADL, job activities, hobbies, or recreational function. For the patient to return to independent function using the hand, he or she must not only have neuromuscular control and strength but must have muscular endurance, coordination, and fine finger dexterity for the desired activity. This requires careful questioning and analysis of the patient's desired outcomes. Each of the power grips and prehension patterns should be considered. Exercises should be adapted to meet the goals.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Falling on an outstretched hand can cause several injuries, including posterior shoulder dislocation, radial head subluxation (pushed elbow), Colles' fracture, and scaphoid fracture. Complications can develop including complex regional pain syndrome (reflex sympathetic dystrophy) and carpal tunnel syndrome. Describe the mechanism and typical clinical signs and symptoms for each of these injuries and identify how to recognize the development of complications.
2. Review all the power grips and prehension patterns and identify the primary muscles that function when performing each action.
3. Summarize the sensory and motor impairments, deformities, and functional limitations that occur in the wrist and hand as the result of a lesion of: (1) the median nerve, (2) the radial nerve, and (3) the ulnar nerve.
4. Differentiate between a boutonnière deformity and a swan-neck deformity of the fingers. What are the underlying factors that contribute to these deformities? After surgical repair of each of these deformities, how should an exercise program be designed to increase hand function but prevent recurrence of these deformities?
5. Identify key structures by the zone in the hand and wrist that could be damaged as the result of a laceration at

each zone of the dorsal and volar aspects of the hand and wrist. What functional impairments occur as the result of damage in each zone?

6. Make a case for the use of early controlled motion after surgical repair of a flexor or extensor tendon injury. Explain the key features of different approaches to the use of early motion in an exercise program. Also identify circumstances in which the use of early controlled motion would be inadvisable or not possible.
7. Analyze and summarize the similarities and differences in the components and progression of exercise programs after flexor or extensor tendon repairs using early controlled mobilization versus delayed mobilization approaches.

● Laboratory Practice

1. Mobilize each forearm, wrist, and finger joint with joint mobilization and passive stretching techniques.
2. Practice each tendon-gliding exercise and identify the purpose for each one.
3. Teach your partner strengthening exercises for each muscle or muscle group in the hand using resistance putty.
4. Identify three alternative resistance devices that can be used to strengthen each muscle and patterns of motion in the hand.

5. Observe someone tying laces on a shoe, identify the muscles functioning, and design an exercise program that could be used to develop neuromuscular control or strengthen each of the muscles.

Case Studies

1. A patient is referred to you early in the development of symptoms that stem from RA. He currently is in remission after his first serious flare of the disease and desires a home exercise program to safely improve the use of his hands. He is a salesman who travels frequently. He keeps his records on a computer. His grip strength is reduced 50%; he has 25% loss of joint ROM and decreased joint play in the wrist, MCP, and IP joints. Detectable synovial hypertrophy is minimal, and there are no joint subluxations. Consider what precautions should be followed with this disease to prevent the deforming forces of improperly applied exercises and daily forces. Establish a program of intervention for this patient.
2. A patient is referred to you 2 months after a Colles' fracture. Her hand is swollen and sensitive to touch, and she currently is developing contractures and weakness in the hand related to reflex sympathetic dystrophy (see Chapter 13). Joint contractures exist in the forearm, wrist, and hand. You determine that the patient is in the second stage of the disease. Establish a plan for intervention.
3. A patient with RA who has just undergone MCP implant arthroplasties of the ring and small fingers has been referred to you for an exercise program. The patient has

been wearing a dynamic extension splint for the past 4 weeks that allows active MCP flexion and assists MCP extension. The patient is now allowed to remove the splint for active ROM of the wrist and hand. Your examination reveals that the patient has an extensor lag and also has restricted flexion of the fingers. Design and progress an exercise program for this patient. What precautions should be incorporated into each phase of the program?

4. A patient has been referred to you who underwent a ligament reconstruction tendon interposition arthroplasty for post-traumatic arthritis of the CMC joint of the thumb 4 weeks ago. The thumb spica cast was removed at $3\frac{1}{2}$ weeks postoperatively, and the patient is now wearing a thumb spica splint that may be removed for exercise. Develop and progress an exercise program for the patient. The patient has already returned to his or her position in an office. The patient would like to be able to resume golf on a recreational basis.
5. An 8-year-old child who sustained a zone III laceration of the volar aspect of the index and middle fingers of the nondominant hand while carving a pumpkin has been referred to you after surgical repair of the FDP and FDS tendons. The child's hand has been immobilized in a cast for 3 weeks after the repair in a position of wrist and finger flexion. The child is now wearing a dorsal blocking splint that may be removed for exercise. The child's active and passive extension is significantly limited. Design and progress an exercise program for this child. Identify activities that the child must do under direct supervision and those that he or she may do independently.

The hip is often compared with the shoulder in that it is a triaxial joint, able to function in all three planes, and that it is also the proximal link to its extremity. In contrast to the shoulder, which is designed for mobility, the hip is a stable joint, constructed for weight bearing. However, to carry out activities of daily living (ADL) in what is considered a “normal” manner, at least 120° of hip flexion and at least 20° each of abduction and external rotation are necessary.⁹⁷ Forces from the lower extremities are transmitted upward through the hips to the pelvis and trunk during gait and

other lower extremity activities. The hips also support the weight of the head, trunk, and upper extremities.

This chapter is divided into three major sections. The first section briefly reviews highlights of the anatomy and function of the hip and its relation to the pelvis and lumbar spine. The second section then describes common disorders of the hip and guidelines for conservative and postoperative management, expanding on the information and principles of management presented in Chapters 10 through 13. The reader should be familiar with that materi-

al as well as the components of a comprehensive examination of the hip and pelvis before determining a diagnosis and proceeding to establish a therapeutic exercise program. The last section describes exercise interventions commonly used to meet the goals of treatment for the hip region.

STRUCTURE AND FUNCTION OF THE HIP

The pelvic girdle links the lower extremity to the trunk and plays a significant role in the function of the hip as well as the spinal joints. The bones of the hip joint consist of the proximal femur and the pelvis (Fig. 20.1). The unique characteristics of the pelvis and femur that affect hip function are reviewed in this section. The function of the pelvis with respect to spinal mechanics is described in greater detail in Chapter 14.

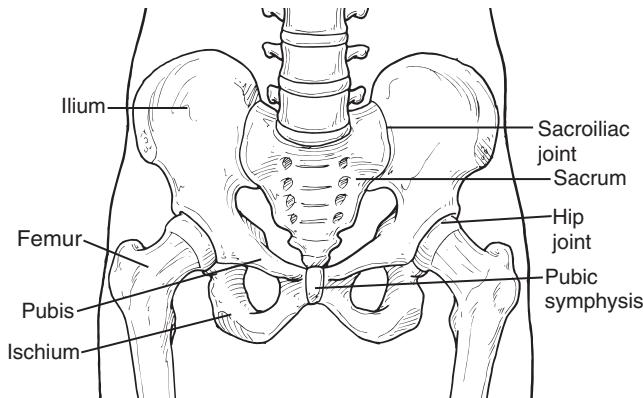

FIGURE 20.1 Bones and joints of the pelvis and hip.

ANATOMICAL CHARACTERISTICS OF THE HIP REGION

Bony Structures

The structure of the pelvis and femur are designed for weight bearing and transmitting forces through the hip joint.

The Pelvis

Each innominate bone of the pelvis is formed by the union of the ilium, ischium and pubis bones and therefore is a structural unit. The right and left innominate bones articulate anteriorly with each other at the pubic symphysis and posteriorly with the sacrum at the sacroiliac joints.⁶⁹ Slight motion occurs at these three joints to attenuate forces as they are transmitted through the pelvic region, but the pelvis basically functions as a unit in a closed chain.

The Femur

The shape of the femur is designed to bear body weight and to transmit ground reaction forces through the long bone, neck, and head to the acetabulum of the pelvis. In the frontal plane there is an angle of inclination (normally 125°) between the axis of the femoral neck and the shaft of the femur. The angle of torsion formed by the transverse axis of the femoral condyles and the axis of the neck of the femur ranges from 8° to 25°, with an average angle of 12°. There is also slight bowing of the shaft in the sagittal plane.⁶⁹

Hip Joint Characteristics and Arthrokinematics

Characteristics

The hip is a ball-and-socket (spheroidal) triaxial joint made up of the head of the femur and acetabulum of the pelvis. It is supported by a strong articular capsule that is reinforced by the iliofemoral, pubofemoral, and ischiofemoral ligaments. The two hip joints are linked to each other through the bony pelvis and to the vertebral column through the sacroiliac and lumbosacral joints.^{69,123}

Articular Surfaces

The concave bony partner of the hip joint, the acetabulum, is located in the lateral aspect of the pelvis and faces laterally, anteriorly, and inferiorly (see Fig. 20.1). The acetabulum is deepened by a ring of fibrocartilage, the acetabular labrum. The articular cartilage is horseshoe-shaped, being thicker in the lateral region where the major weight-bearing forces are transmitted. The central portion of the acetabular surface is nonarticular.

The convex bony partner is the spherical head of the femur, which is attached to the femoral neck. It projects anteriorly, medially, and superiorly.

The shapes of the articulating surfaces of the hip joint and the reinforcing properties of the capsule and ligaments, as well as the hip musculature, lend mobility coupled with stability for functional tasks that require wide ranges of combined movements, such as squatting, tying shoes while seated, standing up from a chair or walking.

Ligaments

Of the three ligaments that reinforce the joint capsule, the iliofemoral and pubofemoral ligaments are situated anteriorly (Fig. 20.2A), whereas the ischiofemoral ligament is located posteriorly (Fig. 20.2B).^{69,94,98}

There is general agreement in the literature that these three capsular ligaments limit excessive extension of the hip and that the iliofemoral ligament, also known as the Y ligament of Bigelow, is the strongest of the hip ligaments.^{53,69,94,98} However, there is some dispute as to the functions of each of these ligaments on an individual basis. The iliofemoral ligament, which reinforces the anterior portion of the capsule, also is thought to limit external rotation of the hip^{94,98}; and the pubofemoral ligament, lending support to the inferior as well as anterior portion of the

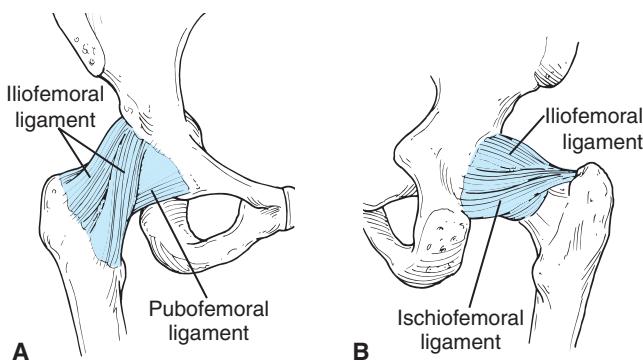

FIGURE 20.2 Ligaments supporting the hip joint. (A) Anterior view. (B) Posterior view.

capsule, is believed to limit abduction.^{94,98} Lastly, the ischiofemoral ligament, although reinforcing the posterior aspect of the capsule, may also limit internal rotation and, when the hip is flexed, adduction.^{53,94,98}

Arthrokinematics of the Hip Joint

During many activities, such as squatting, walking, or doing leg-press exercises, both the pelvis and femur are moving. Therefore, joint mechanics can be described by the movement of the femur in the acetabulum or as the pelvis moving on the femur.

Motions of the femur. The convex femoral head slides in the direction opposite the physiological motion of the femur. Thus, with hip flexion and internal rotation the articulating surface slides posteriorly; with extension and external rotation it slides anteriorly; with abduction it slides inferiorly; and with adduction it slides superiorly (Box 20.1).

Motions of the pelvis. When the lower extremity is stabilized (fixated) distally, as when standing or during the stance phase of gait, the concave acetabulum moves on the convex femoral head, so the acetabulum slides in the same direction as the pelvis. The pelvis is a link in a closed chain; therefore, when the pelvis moves, there is motion at both hip joints as well as the lumbar spine.

BOX 20.1 Summary of Arthrokinematics of the Femoral Head in the Hip Joint

Physiological Motions of the Femur

	Roll	Slide
Flexion	Anterior	Posterior
Extension	Posterior	Anterior
Abduction	Lateral	Inferior
Adduction	Medial	Superior
Internal rotation	Medial	Posterior
External rotation	Lateral	Anterior

Influence of the Hip Joint on Balance and Posture Control

The joint capsule is richly supplied with mechanoreceptors that respond to variations in position, stress, and movement for control of posture, balance, and movement. Reflex muscle contractions of the entire kinematic chain, known as balance strategies, occur in a predictable sequence when standing balance is disturbed and regained. Joint pathologies, restricted motion, or muscle weakness can impair balance and postural control.^{33,48} Refer to Chapter 8 for an in-depth discussion of these concepts.

FUNCTIONAL RELATIONSHIPS OF THE HIPS AND PELVIS

Pelvic Motions and Muscle Function

The pelvis is the connecting link between the spine and lower extremities (Fig. 20.3A). Movement of the pelvis causes motion at the hip joints and lumbar spine articulations. The hip musculature causes pelvic motion through reverse action. Hip flexors cause an anterior pelvic tilt; hip extensors, a posterior pelvic tilt; and abductors and adductors, a lateral pelvic tilt. Rotators cause pelvic rotation. To prevent excessive pelvic motion when moving the femur at the hip joint, the pelvis must be stabilized by the abdominals, erector spinae, multifidus, and quadratus lumborum muscles.

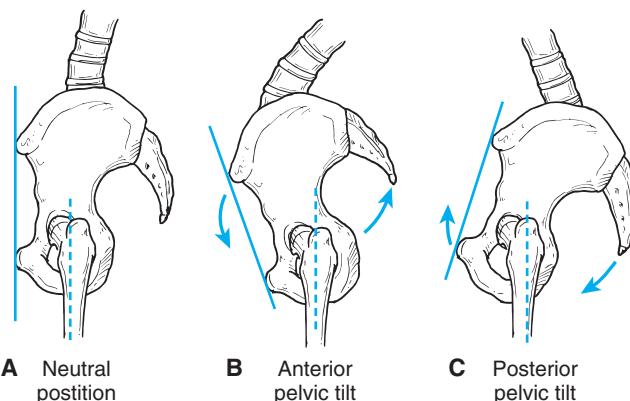

FIGURE 20.3 (A) Neutral position of the pelvis. (B) Anterior pelvic tilt. (C) Posterior pelvic tilt. With anterior pelvic tilt the decreased angle between the pelvis and femur results in hip flexion, and with posterior pelvic tilt the increased angle results in hip extension.

Anterior Pelvic Tilt

The anterior superior iliac spines of the pelvis move anteriorly and inferiorly and thus closer to the anterior aspect of the femur as the pelvis rotates forward around the transverse axis of the hip joints (Fig. 20.3B). This results in hip flexion and increased lumbar spine extension.⁶⁹

- Muscles causing this motion are the hip flexors and back extensors.
- During standing, the line of gravity of the trunk falls anterior to the axis of the hip joints; the effect is an anterior pelvic tilt moment. Stability is provided by the abdominal muscles and hip extensor muscles.

Posterior Pelvic Tilt

The posterior superior iliac spines of the pelvis move posteriorly and inferiorly, thus closer to the posterior aspect of the femur as the pelvis rotates backward around the axis of the hip joints (Fig. 20.3C). This results in hip extension and lumbar spine flexion.⁶⁹

- Muscles causing this motion are the hip extensors and trunk flexors.
- During standing when the line of gravity of the trunk falls posterior to the axis of the hip joints, the effect is a posterior pelvic tilt moment. Dynamic stability is provided by the hip flexors and back extensors and passive stability by the iliofemoral ligament.

Pelvic Shifting

During standing, a forward translatory shifting of the pelvis results in extension of the hip and extension of the lower lumbar spinal segments. There is a compensatory posterior shifting of the thorax on the upper lumbar spine with increased flexion of these spinal segments. This is often seen with slouched or relaxed postures (see Fig. 14.12B in Chapter 14). Little muscle action is required; the posture is maintained by the iliofemoral ligaments at the hip, anterior longitudinal ligament of the lower lumbar spine, and posterior ligaments of the upper lumbar and thoracic spine.

Lateral Pelvic Tilt

Frontal plane pelvic motion results in opposite motions at each hip joint. Pelvic motion is defined by what is occurring to the iliac crest of the pelvis that is opposite the weight-bearing extremity (that is, the side of the pelvis that is moving). When the pelvis elevates, it is called hip hiking; when it lowers, it is called hip or pelvic drop. On the side that is elevated, there is hip adduction; on the side that is lowered, there is hip abduction (Fig. 20.4A). During standing, the lumbar spine laterally flexes toward the side

of the elevated pelvis (convexity of the lateral curve is toward the lowered side).⁶⁹

- Muscles causing lateral pelvic tilting include the quadratus lumborum on the side of the elevated pelvis and reverse muscle pull of the gluteus medius on the side of the lowered pelvis.
- With an asymmetrical slouched posture, the person shifts the trunk weight onto one lower extremity and allows the pelvis to drop on the other side. Passive support comes from the iliofemoral ligament and iliotibial band on the elevated side (stance leg).
- When standing on one leg, there is an adduction moment at the hip, tending to cause the pelvis to drop on the unsupported side (hip or pelvic drop). This is prevented by the gluteus medius stabilizing the pelvis on the stance side.

Pelvic Rotation

Rotation occurs around one lower extremity that is fixed on the ground. The unsupported lower extremity swings forward or backward along with the pelvis. When the unsupported side of the pelvis moves forward, it is called *forward rotation* of the pelvis.⁶⁹ The trunk concurrently rotates in the opposite direction, and the femur on the stabilized side concurrently rotates internally. When the unsupported side of the pelvis moves backward, it is called *posterior rotation*; the femur on the stabilized side concurrently rotates externally, and the trunk rotates opposite (Fig. 20.4B).

Lumbopelvic Rhythm

A coordinated movement between the lumbar spine and pelvis occurs during maximum forward bending of the trunk²⁵ as when reaching toward the floor or the toes. As the head and upper trunk initiate flexion, the pelvis shifts posteriorly to maintain the center of gravity over the base of support. The trunk continues to forward-bend, being controlled by the extensor muscles of the spine, until at approximately 45°. At this point for an individual with relatively normal flexibility, the posterior ligaments become taut, and the facets of the zygapophyseal joints approximate. Both of these factors provide stability for the intervertebral joints, and the muscles relax.¹²⁶ Once all of the

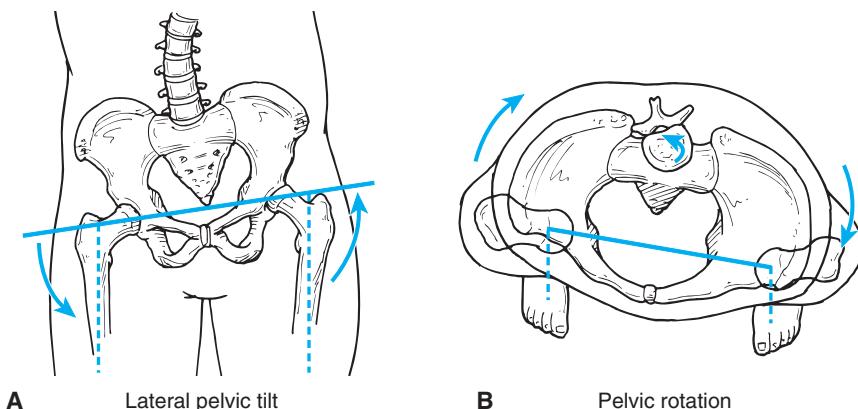

FIGURE 20.4 (A) Lateral pelvic tilt. Elevation of the iliac crest (hip hiking) causes relative adduction of the hip on the elevated side; and lowering of the iliac crest (hip drop) causes relative abduction of the hip on the lower side. (B) Pelvic rotation. Forward motion (forward rotation) of the pelvis causes relative external rotation of the hip; and backward motion (posterior rotation) of the pelvis causes relative internal rotation of the hip.

vertebral segments are at the end of the range and stabilized by the posterior ligaments and facets, the pelvis begins to rotate forward (anterior pelvic tilt), being controlled by the gluteus maximus and hamstring muscles. The pelvis continues to rotate forward until the full length of the muscles is reached. Final range of motion (ROM) in forward bending is dictated by the flexibility of the various back extensor muscles and fasciae as well as hip extensor muscles.

The return to the upright position begins with the hip extensor muscles rotating the pelvis posteriorly through reverse muscle action (posterior pelvic tilt) then the back extensor muscles extending the spine from the lumbar region upward. Variations in the normal synchronization of this activity occur because of training (as with dancers and gymnasts), faulty habits, restricted muscle or fascia length, or injury and faulty proprioception.

Pathomechanics in the Hip Region

Abnormal structure or impaired function of the hip—such as a leg-length discrepancy, decreased flexibility, or muscle imbalances—can contribute to stress in the spine or other joints of the lower extremities.

Decreased Flexibility

Decreased flexibility in the structures around the hip joint cause weight-bearing forces and movement to be transmitted to the spine rather than absorbed in the pelvis. Tight hip extensors cause increased lumbar flexion when the thigh flexes. Tight hip flexors cause increased lumbar extension as the thigh extends. Hip flexion contractures with incomplete hip extension during weight bearing also place added stresses on the knee because the knee cannot lock while the hip is in flexion unless the trunk is bent forward. During weight bearing tight adductors cause lateral pelvic tilt opposite the side of tightness and side bending of the trunk toward the side of tightness. The opposite occurs with tight abductors.

Asymmetrical Leg Length

Functional as well as structural asymmetries of the lower extremities affect the posture of the pelvis.

Unilateral short leg. A unilateral short leg causes lateral pelvic tilting (drop on the short side) and side-bending of the trunk away from the short side (convexity of lateral lumbar curve toward side of short leg). This may lead to a functional or eventually a structural scoliosis. Causes of a short leg could be unilateral lower extremity asymmetries such as flat foot, genu valgum, coxa vara, tight hip muscles, anteriorly rotated innominate bone, poor standing posture, or asymmetry in bone growth.

Coxa valga and coxa vara. A pathologically large angle of inclination between the femoral neck and shaft of the femur is called *coxa valga*, and a pathologically smaller angle is called *coxa vara*. Unilateral coxa valga results in a relatively longer leg on that side and associated genu varum. Unilateral coxa vara leads to a relatively shorter leg with associated genu valgum.

Anteversion and retroversion. An increase in the torsion of the femoral neck is called *anteversion* and causes the shaft of the femur to be rotated medially; a decrease in the torsion is called *retroversion* and causes the shaft of the femur to be rotated laterally. Anteversion often results in genu valgum and pes planus. Unilateral anteversion results in a relatively shorter leg on that side; retroversion causes the opposite effects.

Hip Muscle Imbalances and Their Effects

Muscles function through habit. Faulty mechanics from inadequate or excessive length and an imbalance in strength cause hip, knee, or back pain.¹¹⁶ Overuse syndromes, soft tissue stress, and joint pain develop in response to continued abnormal stresses. The related muscle imbalances due to postural impairments are summarized in Box 20.2. Common muscle length-strength imbalances include the following.

- **Shortened iliobial (IT) band with shortened tensor fasciae latae (TFL) or gluteus maximus.** Postural impairments often associated with a shortened TFL or gluteus maximus include an anterior pelvic tilt posture, slouched posture, or flat back posture (see Chapter 14).
- **Dominance of the two-joint hip flexor muscles (TFL, rectus femoris, sartorius) over the iliopsoas.** This imbalance may cause faulty hip mechanics or knee pain from overuse of these muscles as they cross the knee.

BOX 20.2 Hip Muscle Imbalances Related to Postural Impairments

Anterior Pelvic Tilt Posture

- Short TFL and IT band
- General limitation of hip external rotation
- Weak, stretched posterior portion of the gluteus medius and piriformis
- Excessive medial rotation of the femur during the first half of stance phase of gait with increased stresses on the medial structures of the knee
- Associated lower extremity compensations including medial rotation of the femur, genu valgum, lateral tibial torsion, pes planus, and hallux valgus

Slouched Posture

- Shortened rectus femoris and hamstrings
- General limitation of hip rotators
- Weak, stretched iliopsoas
- Weak and shortened posterior portion of the gluteus medius
- Weak, poorly developed gluteus maximus
- Associated lower extremity compensations including hip extension, sometimes medial rotation of the femur, genu recurvatum, genu varum, and pes valgus

Flat Back Posture

- A shortened rectus femoris, IT band, and gluteus maximus
- Variations of the above two postures

- *Dominance of the TFL over the gluteus medius.* This imbalance leads to lateral knee pain from IT band tension or medial rotation of the femur with medial knee stresses from an increased bowstring effect.
- *Dominance of hamstring muscles over the gluteus maximus.* The gluteus maximus becomes short and the range of hip flexion decreases; compensation occurs with excessive lumbar spine flexion whenever the thigh is flexed. Limited mobility in the gluteus maximus also causes increased tension on the IT band with associated trochanteric or lateral knee pain. Overuse of the hamstring muscles causes decreased flexibility as well as muscle imbalances with the quadriceps femoris muscle at the knee. The hamstrings dominate the stabilizing function by pulling posteriorly on the tibia to extend the knee in closed-chain activities. This alters the mechanics at the knee and may lead to overuse syndromes in the hamstring tendons or anterior knee pain from imbalances in quadriceps pull.
- *Use of lateral trunk muscles for hip abductors.* This results in excessive trunk motion and increased stress in the lumbar spine.

THE HIP AND GAIT

During the normal gait cycle, the hip goes through a ROM of 40° of flexion and extension (10° extension at terminal stance to 30° flexion at midswing and initial contact). There is also some lateral pelvic tilt and hip abduction/adduction of 15° (10° adduction at initial contact, 5° abduction at initial swing); and hip internal/external rotation along with pelvic rotation totaling 15° transverse plane motion (peak internal rotation at the end of loading, peak external rotation at the end of pre-swing). Loss of any of these motions affects the smoothness of the gait pattern.¹⁰⁵

Hip Muscle Function During Gait

Hip Flexors

The hip flexors control hip extension at the end of stance, then contract concentrically to initiate swing.¹⁰⁵ With loss of flexor function, a posterior lurch of the trunk to initiate swing is seen. Contractures in the hip flexors prevent complete extension during the second half of stance; the stride is shortened. To compensate, a person increases the lumbar lordosis or walks with the trunk bent forward.

Hip Extensors

The hip extensors control the flexor moment at initial foot contact, and the gluteus maximus initiates hip extension.¹⁰⁵ With loss of extensor function, a posterior lurch of the trunk occurs at foot contact to shift the center of gravity of the trunk posterior to the hip. With contractures in the gluteus maximus, some decreased range occurs in the terminal swing as the femur comes forward, or the person

may compensate by rotating the pelvis more forward. The lower extremity may rotate outward because of the external rotation component of the muscle, or the gluteus maximus may place greater tension on the iliotibial band through its attachment, leading to irritation along the lateral aspect of the knee with excessive activity.

Hip Abductors

The hip abductors control the lateral pelvic tilt during swinging of the opposite leg.¹⁰⁵ With loss of function of the gluteus medius, lateral shifting of the trunk occurs over the weak side during stance when the opposite leg swings. This lateral shifting also occurs with a painful hip because it minimizes the torque at the hip joint during weight bearing. The tensor fasciae latae also functions as an abductor and may become tight and affect gait with faulty use.

Effect of Musculoskeletal Impairments on Gait

Bony and joint deformities change alignment of the lower extremity and therefore the mechanics of gait. Painful conditions cause antalgic gait patterns, which are characterized by minimum stance on the painful side to avoid the stress of weight bearing.

REFERRED PAIN AND NERVE INJURY

The hip is innervated primarily from the L3 spinal level; hip joint irritation is usually felt along the L3 dermatome reference from the groin, down the front of the thigh to the knee.^{35,72} For a detailed description of referred pain patterns and peripheral nerve injuries in the hip and buttock region, see Chapter 13.

Major Nerves Subject to Injury or Entrapment

Sciatic nerve. Entrapment may occur when the sciatic nerve passes deep to the piriformis muscle (occasionally it passes over or through the piriformis).

Obturator nerve. Isolated injury is rare, although uterine pressure and damage during labor may occur.

Femoral nerve. Injury may result from fractures of the upper femur or pelvis, during reduction of congenital dislocation of the hip, or from pressure during a forceps labor and delivery.

Common Sources of Referred Pain in the Hip and Buttock Region

If painful symptoms are referred to the hip and buttock region from other sources, primary treatment must be directed to the source of the irritation. Common sources of referred pain into the hip and buttock region include:

- Nerve roots or tissues derived from spinal segments L1, L2, L3, S1, and S2
- Lumbar intervertebral and sacroiliac joints

MANAGEMENT OF HIP DISORDERS AND SURGERIES

To make sound clinical decisions when treating patients with hip disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and identify presenting impairments, functional limitations, and possible disabilities. In this section common pathologies and surgeries are presented and related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*¹ (Table 20.1). Conservative and postoperative management of these conditions is also described in this section.

JOINT HYPOMOBILITY: NONOPERATIVE MANAGEMENT

Related Pathologies and Etiology of Symptoms

Osteoarthritis (Degenerative Joint Disease)

Osteoarthritis is the most common arthritic disease of the hip joint. The etiology may be the aging process, joint trauma, repetitive abnormal stresses, obesity, or disease. The degenerative changes include articular cartilage breakdown and loss, capsular fibrosis, and osteophyte formation at the joint margins.⁴⁰ These effects usually occur in regions undergoing the greatest loading forces, such as along the superior weight-bearing surface of the acetabulum (see Fig. 11.6).

Other Joint Pathologies

Rheumatoid arthritis, aseptic necrosis, slipped epiphyses, dislocations, and congenital deformities can also lead to degenerative changes in the hip joint (see Fig. 11.2).

TABLE 20.1 Hip Pathologies and Related Preferred Practice Patterns

PATHOLOGY/SURGICAL PROCEDURE	PREFERRED PRACTICE PATTERNS AND ASSOCIATED IMPAIRMENTS ¹
• Abnormal posture (anterior pelvic tilt posture, posterior pelvic tilt posture, rotated or shifted pelvis related to spinal and lower extremity flexibility and strength imbalances or structural malalignment)	Pattern 4B—Impaired posture
• Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis) • Aseptic necrosis • Slipped epiphyses • Dislocation • Postimmobilization arthritis (stiffness)	Pattern 4D—Impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
• Acute arthritis • Acute tendonitis, bursitis, muscle pull	Pattern 4E—Impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
• Fracture (femoral or pelvic)	Pattern 4G—Impaired joint mobility, muscle performance, and ROM associated with fracture
• Total hip arthroplasty • Surface replacement arthroplasty • Hemiarthroplasty	Pattern 4H—Impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
• Labral tear • Osteotomy • Open reduction and internal fixation of femoral fracture or fracture-dislocation	Pattern 4I—Impaired joint mobility, motor function, muscle performance, and ROM associated with bony or soft tissue surgery
• Sciatic, obturator, or femoral nerve injury or entrapment in the pelvis and hip region	Pattern 5F—Impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

Postimmobilization Hypomobility

A restriction in the capsular tissues leading to joint hypomobilities as well as tightness in the surrounding periarticular tissues may occur anytime the joint is immobilized after a fracture or surgery.

Common Impairments

- Pain experienced in the groin and referred along the anterior thigh and knee in the L3 dermatome.
- Stiffness after rest.
- Limited motion with a firm capsular end-feel. Initially, limitation is only in internal rotation; in advanced stages the hip is fixed in adduction, has no internal rotation or extension past neutral, and is limited to 90° flexion.³⁵
- Antalgic gait usually with a compensated gluteus medius (abductor) limp.
- Limited hip extension leading to increased extension forces on the lumbar spine and possible back pain.
- Limited hip extension preventing full knee extension when standing or during gait leading to increased knee stresses.
- Impaired balance and postural control.⁴⁸

Common Functional Limitations/Disabilities

Hip joint impairments interfere with many weight-bearing activities and ADL.^{30,49}

Early stages. There is progressive pain with continued weight bearing and gait or at the end of the day after repetitive lower extremity activities. The pain may interfere with work (job-specific) or routine household activities that involve weight bearing, such as meal preparation, cleaning, and shopping.

Progressive degeneration. The individual experiences increased difficulty arising from a chair, climbing stairs, squatting, and other weight-bearing activities, as well as restricted routine ADL such as bathing, toileting, and dressing (putting on pants, hose, socks).

Management: Protection Phase

Chapter 11 describes the general principles and plan of care in the treatment of osteoarthritis and rheumatoid arthritis, and Chapter 10 describes general management of joints during acute, subacute, and chronic stages of tissue injury and repair. In conjunction with medical management of the disease for inflammation and pain, correction of faulty mechanics is an integral part of decreasing pain in the hip. Faulty hip mechanics may be caused by conditions such as obesity, leg-length differences, muscle length and strength imbalances, sacroiliac dysfunction,³⁰ poor posture, or injury to other joints in the chain.²³ The following goals and interventions are emphasized during the acute stage of tissue healing and the protection phase of nonoperative management.

Decrease Pain at Rest

- Apply grade I or II oscillation techniques with the joint in the resting position.
- Have the patient rock in a rocking chair to provide gentle oscillations to the lower extremity joints as well as a stimulus to the mechanoreceptors in the joints.¹³⁸

Decrease Pain During Weight-Bearing Activities

- Provide assistive devices for ambulation to help reduce stress on the hip joint. If the pain is unilateral, teach the patient to walk with a single cane or crutch on the side opposite the painful joint.
- If leg-length asymmetry is causing hip joint stress, gradually elevate the short leg with lifts in the shoe.
- Modify chairs to provide an elevated and firm surface, and adapt commodes with an elevated seat to make sitting down and standing up easier.

Decrease Effects of Stiffness and Maintain Available Motion

- Teach the patient the importance of frequently moving the hips through their ROM throughout the day. When the acute symptoms are medically controlled, have the patient perform active ROM if he or she can control the motion or with assistance if necessary.
- If a pool is available, have the patient perform ROM in the buoyant environment.
- Initiate nonimpact activities such as swimming, gentle water aerobics, or stationary cycling.

Management: Controlled Motion and Return to Function Phases

As healing progresses and symptoms subside, the emphasis of management includes the following goals and interventions.

Progressively Increase Joint Play and Soft Tissue Mobility

Joint mobilization techniques. Progress joint mobilization to stretch grades (grade III sustained or grade III and IV oscillation) using the glides that stretch restricting capsular tissue at the end of the available ROM (see Box 20.1 and Figs. 5.45 through 5.47 in Chapter 5). Vigorous stretching should not be undertaken until the chronic stage of healing.

Passive stretching, neuromuscular inhibition, and self-stretching techniques. Stretch any range-limiting tissues. Suggested techniques are described in Chapter 4 and in the exercise section later in this chapter.

Improve Joint Tracking and Pain-Free Motion

Mobilization with movement (MWM) techniques⁸⁷ may be applied through the use of a mobilization belt to produce a pain-free inferolateral glide and then superimposing motion to the end of the available range. As with all MWM techniques, no pain should be experienced during application of the technique. Principles of MWM are described in Chapter 5; specific hip MWM techniques are described here.

Increase Internal Rotation

Patient position: Supine with the involved hip flexed and a mobilization belt secured around the proximal thigh and your pelvis.

Procedure: Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free inferolateral glide while the caudal hand grips around the flexed thigh and shin to create pain-free end-range internal rotation (Fig. 20.5A).

Increase Flexion

Patient position: Supine with the involved hip flexed and a mobilization belt secured around the proximal thigh and the pelvis.

Procedure: Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free inferolateral glide while the caudal hand grips around the flexed thigh and shin to create pain-free end-range flexion (Fig. 20.5B).

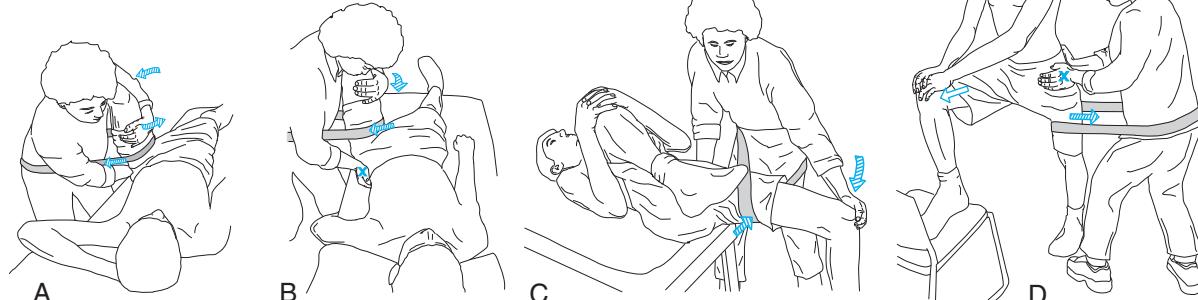

FIGURE 20.5 Mobilization with movement using an inferolateral glide increasing (A) pain-free internal rotation, (B) pain-free flexion, (C) pain-free extension, and (D) extension during weight bearing.

Improve Muscle Performance in Supporting Muscles

- Initiate exercises that develop strength and control of the hip musculature (especially the gluteus maximus, gluteus medius, and rotators) and that improve stability and balance when performing weight-bearing activities. Begin with submaximal isometric resistance; progress to dynamic resistance as the patient tolerates movement. If any exercises exacerbate the joint symptoms, reduce the intensity. Also reassess the patient's functional activities and adapt them to reduce the stress.
- Progress to functional exercises as tolerated using closed-chain and weight-bearing activities. The patient may require assistive devices while weight bearing. Use a pool or tank to reduce the effects of gravity to allow partial weight-bearing exercises without stress.
- Develop postural awareness and balance.
- Progress the low-impact aerobic exercise program (swimming, cycling, or walking within tolerance).

Increase Extension

Patient position: Supine with the pelvis near the end of the treatment table in the Thomas test position (opposite thigh held against the chest) and a mobilization belt secured around the proximal thigh and your pelvis.

Procedure: Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free inferolateral glide while the caudal hand presses against the extended thigh to create pain-free end-range extension (Fig. 20.5C).

Increase Extension During Weight Bearing

Patient position: Standing with the unaffected foot up on a stool and a mobilization belt secured around the proximal thigh and your pelvis.

Procedure: Stabilize the pelvis with both hands and apply a pain-free lateral glide with the mobilization belt while the patient lunges forward to produce painless extension of the affected hip (Fig. 20.5D).

Patient Education

Help the patient establish a balance between activity and rest and learn the importance of minimizing stressful deforming forces by maintaining muscle strength and flexibility in the hip region.

Focus on Evidence

Two systematic reviews of studies designed to examine evidence of the effects of exercise in the management of hip and knee OA describe support for aerobic exercise and strengthening exercises to reduce pain and disability.^{112,113} The consensus of expert opinion cited by Roddy et al.¹¹² is that there are few contraindications and that exercise is relatively safe in patients with OA; however, exercise should be individualized and patient-centered with consideration for age, co-morbidity, and general mobility.

An outcome review³⁶ summarized that moderate- or high-intensity exercises in patients with rheumatoid arthri-

tis (RA) have minimal effect on the disease activity, but there is insufficient radiological evidence on the effect in large joints. Long-term moderate- or high-intensity exercises that are individualized to protect radiologically damaged joints improve aerobic capacity, muscle strength, functional ability, and psychological well-being in patients with RA.

JOINT SURGERY AND POSTOPERATIVE MANAGEMENT

Many joint surgeries are available to treat early- and late-stage joint disease of the hip and some fractures that compromise the vascular supply to the head of the femur. As a result of advances in arthroscopy of the hip over the past decade, small to medium-size full-thickness lesions of the articular cartilage of the acetabulum and head of the femur, as well as other joint pathologies such as acetabular labral tears and capsular laxity, now can be managed arthroscopically.³⁸ One such procedure, *microfracture*, involves creating small fractures of subchondral bone in the area of the chondral lesion to stimulate growth of fibrocartilage to replace the damaged hyaline cartilage.³⁸

Surgical procedures to manage late-stage deterioration of the hip joint include *osteotomy* (which is actually an extra-articular procedure) and arthroplasty, specifically *resurfacing arthroplasty (surface replacement)*,⁴⁷ *hemiarthroplasty*,⁷⁹ and *total joint replacement arthroplas-*

ty.^{31,61,75} *Arthrodesis* and *resection arthroplasty* of the hip are considered salvage procedures after failure of arthroplasty and when revision arthroplasty is contraindicated or not feasible.⁷⁵

The goals of joint surgery and postoperative management are to provide a patient with (1) a pain-free hip, (2) a stable joint for lower extremity weight bearing and functional ambulation, and (3) adequate ROM and strength of the lower extremity for functional activities.

It is important for the therapist to have a basic understanding of the more common surgical procedures for management of joint disease and deformity and a thorough knowledge of appropriate therapeutic exercise interventions and their progression for an effective, safe postoperative rehabilitation program. An overview of two of the more common procedures, total hip arthroplasty and hemiarthroplasty, and guidelines for postoperative management are described in the following sections.

Total Hip Arthroplasty

One of the most widely performed surgical interventions for advanced arthritis of the hip joint is total hip arthroplasty (Fig. 20.6). Osteoarthritis is the underlying pathology that accounts for most primary total hip procedures.³¹

Indications for Surgery

The following are common indications for total hip arthroplasty (THA), also referred to as total hip replacement (THR).^{26,31,39,44,75,81}

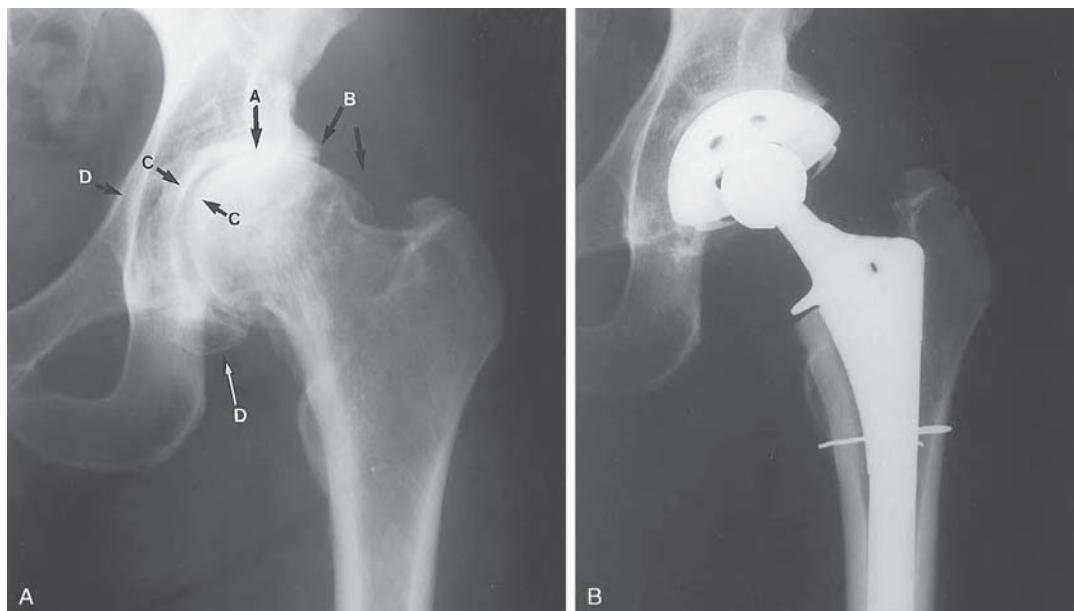

FIGURE 20.6 Total hip arthroplasty. (A) The preoperative film of a severely degenerative hip joint demonstrates the classic signs of degenerative joint disease. A, N; B, arrowed, joint space with superior migration of the femoral head; B, osteophyte formation at the joint margins of both the acetabulum and femoral head; C, sclerosis of subchondral bone on both sides of the joint surface; D, acetabular protrusion (a bony outpouching of the acetabular cup in response to the progressive superior and medial migration of the femoral head). (B) Postoperative film shows a total hip arthroplasty. Both the acetabular and femoral portions of the joint have been resected and replaced with prosthetic components. (From McKinnis,⁷⁸ p. 312, with permission.)

- Severe hip pain with motion and weight bearing and marked limitation of motion as the result of joint deterioration and loss of articular cartilage associated with osteoarthritis, rheumatoid or traumatic arthritis, ankylosing spondylitis, or osteonecrosis (avascular necrosis) leading to impaired function and health-related quality of life
- Nonunion fracture, instability or deformity of the hip
- Bone tumors
- Failure of conservative management or previous joint reconstruction procedures (osteotomy, resurfacing arthroplasty, femoral stem hemiarthroplasty, total hip replacement)

Historically, primary THA was reserved for patients older than 60 to 65 years of age or the very inactive younger patient with multiple joint involvement because the projected life span of primary THA procedures is less than 20 years.^{31,44} For the younger patient with significant hip joint deterioration, surface replacement (resurfacing) arthroplasty, a more bone-conserving surgery than THA, is an alternative that may be considered.⁴⁷ However, with advances in designs, materials, and particularly cementless fixation and subsequent broadening of patient selection criteria, THA also is considered an option for some younger, moderately active patients after evaluation on a case-by-case basis.⁵ These individuals are counseled by the surgeon to anticipate the need for revision arthroplasty later in life.

There are a number of instances in which THA is contraindicated. Absolute and relative contraindications are noted in Box 20.3.^{5,14,31}

Preoperative Management

Preoperative patient education has been advocated as an important aspect of the overall rehabilitation plan for many

BOX 20.3 Contraindications to Total Hip Arthroplasty

Absolute

- Active joint infection
- Systemic infection or sepsis
- Chronic osteomyelitis
- Significant loss of bone after resection of a malignant tumor or inadequate bone stock that prevents sufficient implant fixation
- Neuropathic hip joint
- Severe paralysis of the muscles surrounding the joint

Relative

- Localized infection, such as bladder or skin
- Insufficient function of the gluteus medius muscle
- Progressive neurological disorder
- Highly compromised/insufficient femoral or acetabular bone stock associated with progressive bone disease
- Patients requiring extensive dental work—dental surgery should be completed before arthroplasty
- Young patients who must or are most likely to participate in high-demand (high-load, high-impact) activities

years.^{8,12} Patient-related instruction in past years took place the day before surgery when patients were often admitted to the hospital for preoperative tests. In the current health care environment, hospital stays have been shortened dramatically. Preoperative contact with a patient prior to elective surgery now occurs on an outpatient basis individually or in a group several days before surgery. Preoperative management typically includes assessment and documentation of a patient's status as well as patient education about the procedure and what to expect during the early postoperative period.^{13,55,75,89,114} Patient information sessions are often coordinated and conducted by a team of professionals from multiple disciplines who are likely to be involved with a patient's postoperative care. Box 20.4 summarizes possible components of preoperative management.^{13,55,75,89,114}

Procedures

Background

Prosthetic designs and materials. Total hip arthroplasty has been successfully performed since the early 1960s.^{28,31,41,44,86} Sir John Charnley,²⁸ a surgeon from England, is credited with the initial research and clinical application of THA, which subsequently has evolved into contemporary hip arthroplasty. A variety of implant designs, materials, and surgical approaches have been developed and modified over the years since the early replacements.^{31,41,44} Today total hip implant systems typically are composed of an inert metal (cobalt-chrome and titanium) modular femoral component and a high-density polyethylene acetabular component. Other designs in use are metal-on-metal systems¹²² and systems that utilize ceramic surfaces in the design.³¹

Cemented versus cementless fixation. The revolutionary aspect of the early THA procedures was the use of acrylic cement, methylmethacrylate, for prosthetic fixation. Cement fixation allowed very early postoperative weight bearing and shortened the period of rehabilitation, whereas

BOX 20.4 Components of Therapy-Related Preoperative Management: Preparation for Total Hip Arthroplasty

- Examination and evaluation of pain, ROM, muscle strength, balance, ambulatory status, leg lengths, gait characteristics, use of assistive devices, general level of function, perceived level of disability
- Information for patients and their families about joint disease and the operative procedure in nonmedical terms
- Postoperative precautions and their rationale including positioning and weight bearing
- Functional training for early postoperative days including bed mobility, transfers, gait training with assistive devices
- Early postoperative exercises
- Criteria for discharge from the hospital

prior to the use of cement fixation patients were subjected to months of restricted weight bearing and limited mobility.³¹ Cement fixation continues to be used today but has been noted to have its drawbacks.^{15,73,100,109}

A significant postoperative complication, identified a number of years after the first THA procedures were performed, was aseptic (biomechanical) loosening of the prosthetic components at the bone–cement interface. It was shown that loosening subsequently led to a gradual recurrence of hip pain and the need for surgical revision.^{31,44,75,109} Patients who most often developed loosening were identified as the younger, physically active patients. In contrast, loosening was not shown to be a particularly prevalent problem in elderly patients or in young patients with multiple joint involvement who typically have a limited degree of physical activity.^{44,109}

The long-term problem of mechanical loosening of some cemented implants, most often the acetabular component, gave rise to the development and use of cementless (biological) fixation.^{31,44,75} Cementless fixation is achieved either by use of porous-coated prostheses that allow osseous ingrowth into the beaded or mesh-like surfaces of an implant or by a cementless press-fit technique.^{16,70,106,131} Smooth (nonporous) femoral components also are being used with cementless arthroplasty. Some components are manufactured with a coating of a bioactive compound called hydroxyapatite designed to promote initial osseous ingrowth.²⁷ Ingrowth of bony tissue occurs over a 3- to 6-month period with continued bone remodeling beyond that time period.

Improvements in cemented fixation^{15,73,100,109,110} as well as noncemented fixation^{16,70,106,131} have continued, as has debate over the benefits, indications, and disadvantages of both forms of fixation. Cement fixation is routinely used for patients with osteoporosis and poor bone stock and typically with elderly patients.^{15,73,100,109} In contrast, cementless fixation is more often the choice for the patient under 60 years of age who is physically active and has good bone quality.^{16,21,70,106,131}

In response to a low rate of loosening of cemented femoral implants but continued problems of loosening of cemented acetabular components, the use of a hybrid procedure with a noncemented acetabular component and a cemented femoral prosthesis is a current alternative.⁹⁰

During the first few postoperative weeks, the method of component fixation may influence a patient's weight-bearing status during ambulation and functional activities.

Overview of Operative Procedures

The operative approaches used to gain access to the involved joint and to implant the prosthetic components during THA can be divided into two broad categories: *standard* and *minimally invasive* approaches. For decades hip arthroplasty procedures have involved the use of rather long surgical incisions (15 to 25 cm) to expose the joint. Although long-term outcomes have been successful, standard surgical approaches impose substantial trauma to soft tissues and contribute to a lengthy postoperative recovery period.

A recent advance in primary hip arthroplasty—the use of minimally invasive approaches through “mini-incisions”—allows adequate exposure of the joint for insertion of the prosthetic components but reportedly lessens the trauma of soft tissues. Brief overviews of the various types of standard and minimally invasive surgical approaches follow, focusing on which muscles are incised or left intact during the procedure because the integrity of these muscles and other soft tissues that surround the prosthetic hip influences its postoperative stability and the extent of restrictions placed on the patient, most notably during the early phase of postoperative recovery.^{2,51,75}

Standard surgical approaches. There are several standard (conventional) approaches that may be used during traditional THA procedures: posterior (or posterolateral), lateral, and anterior (or anterolateral). Each has its advantages and disadvantages.^{2,51}

- **Posterolateral approach.** This is the most frequently used approach for primary THA. To access the joint, the gluteus maximus is split in line with the muscle fibers. The short external rotator tendons are transected near their insertion. Consequently, this approach preserves the integrity of the gluteus medius and vastus lateralis muscles. Trochanteric osteotomy is not necessary. The capsule is incised posteriorly in preparation for posterior dislocation of the hip. The primary disadvantage of this approach is that it is associated with the highest incidence of postoperative joint instability and resulting subluxation or dislocation of the hip.^{66,83,84} To reduce the risk of postoperative dislocation, repair of the posterior capsule (posterior capsulorrhaphy) is advocated to provide maximal soft tissue constraint to the posterior aspect of the capsule.²⁹
- **Direct lateral approach.** This approach requires longitudinal division of the tensor fasciae latae, release of up to one-half of the proximal insertion of the gluteus medius, and longitudinal splitting of the vastus lateralis.^{2,51} The gluteus minimus also is partially detached from the trochanter. A lateral approach may, but typically does not, involve a trochanteric osteotomy. Disruption of the abductor mechanism is associated with postoperative weakness and gait abnormalities (positive Trendelenburg sign).
- **Anterolateral approach.** This approach and an anterior approach were frequently used for primary THA during the early years of this procedure.^{28,31,51} Today, however, it is most often reserved for revision arthroplasty or arthroplasty that involves complex reconstruction. It is also indicated for patients with muscle imbalances associated with stroke or cerebral palsy whose standing posture is characterized by hip flexion and internal rotation.^{2,51} Patients exhibiting this posturing are at high risk of dislocation with a posterolateral approach. The anterolateral approach provides excellent stability of the hip postoperatively but involves detachment and subsequent repair of the gluteus medius muscle, or it may necessitate an osteotomy of the greater trochanter for adequate

exposure of the hip joint. In addition to the gluteus medius, soft tissues disturbed in an anterolateral approach include the gluteus minimus, tensor fasciae latae, iliopsoas, rectus femoris, and vastus lateralis muscles as well as the anterior capsule.

If a trochanteric osteotomy is performed, the trochanter must be reattached and wired in place to stabilize the osteotomy site until bone healing occurs. The trochanter is often reattached in a position to improve the mechanical efficiency of the gluteus medius muscle.^{2,51} Complications associated with trochanteric osteotomy include nonunion, abductor muscle weakness, and greater than usual soft tissue irritation and pain from a considerable amount of internal fixation.

Minimally invasive approaches. As with traditional THA, minimally invasive THA is an open procedure. However, with minimally invasive procedures, the joint is approached through one or two small incisions, usually defined as ≤ 10 cm in length.¹⁴ The characteristics of minimally invasive approaches for THA are summarized in Box 20.5.

The rationale for minimally invasive THA is that, compared with traditional THA, the use of smaller incisions potentially lessens soft tissue trauma during surgery and therefore should improve and accelerate a patient's postoperative recovery.^{6,14} Benefits cited by advocates of

minimally invasive THA are reduced blood loss, reduced postoperative pain, shorter length of hospital stay and lower cost of hospitalization, more rapid recovery of functional mobility, and a better cosmetic appearance of the surgical scar.^{3,6,13,14,115} However, proponents also note that minimally invasive THA procedures are more technically challenging, specifically with regard to insertion and alignment of the prosthetic components, and that there is likely to be a higher rate of complications depending on the surgeon's experience with the new approach and selection of patients.^{3,7}

Although most investigators have indicated that minimally invasive THA procedures hold promise and many reports have provided data about a variety of positive outcomes associated with minimally invasive approaches,^{13,14,76} these reports have been limited to descriptions of practitioner or institutional experiences with selected patient populations and did not include a comparison group. Only recently have studies become available that call into question some of the reported benefits and document the rate of surgery-related complications or that directly compare minimally invasive THA procedures with traditional THA.^{99,137}

Focus on Evidence

Woolson et al.¹³⁷ conducted a retrospective comparative study of 135 patients who had undergone primary, unilateral THA with either a standard posterior approach (85 patients, mean age 63 years) or a minimally invasive posterior approach (50 patients, mean age 60 years). Several surgery-related, in-hospital variables and discharge outcomes were evaluated. The participating surgeons determined which patients met the criteria for the minimally invasive procedure with regard to health history and body mass index. Consequently, the minimally invasive group was thinner and healthier than the conventional THA group. Despite these demographic differences, there were no significant differences found between the groups with respect to the surgery itself (operating time, blood loss, need for transfusion), nor were there significant differences in length of hospital stay or the percentage of patients discharged directly home. However, an independent investigator, who was blind to the type of approach used, identified a higher rate of complications in the minimally invasive group, including wound complications, component malpositioning, and leg-length discrepancy.

Ogonda and colleagues⁹⁹ reported the first randomized controlled trial comparing minimally invasive and traditional THA in 219 patients who underwent primary, unilateral, hybrid THA performed by the same surgeon. In both groups a single incision, posterior approach was used, with the only differences being the length of the skin incision (the minimally invasive incision ≤ 10 cm and the standard incision 16 cm) and the extent of tensor fasciae latae disturbance during the approach (less in the mini-incision group). All patients and evaluators were blinded to the length of the incision, and all participated in exercise and functional training after surgery. No significant differences were found

BOX 20.5 Features of Minimally Invasive Total Hip Arthroplasty

- Length of incision: ≤ 10 cm, depending on the location of the approach and the size of the patient¹⁴
- Most if not all muscles and tendons left intact
- Single-incision or two-incision approach
 - *Single incision:* usually posterior⁴⁵ or anterior,⁷⁶ or occasionally lateral.^{7,57}
 - *Two-incision:* approach: two 4- to 5-cm incisions, one anterior for insertion of acetabular component and one posterior for placement of femoral component.^{4,13,115,125}
- Incision location and muscles disturbed
 - *Posterior approach:* a 7- to 10-cm posterior incision extending mostly distal to the greater trochanter between the gluteus medius and piriformis muscles; short external rotators may or may not be incised (later repaired), but the abductor mechanism consistently is left intact.^{45,137}
 - *Anterior approach:* approximately a 10 cm incision beginning just lateral and distal of the anterior superior iliac spine extending in a distal and slightly posterior direction along the belly of the tensor fasciae latae (TFL); sartorius and rectus femoris retracted medially and the TFL laterally leaves all muscles intact; no postoperative precautions.^{13,76}
 - *Lateral approach:* least commonly used; splits the middle-third of the gluteus medius; anterolateral incision into the capsule leaves the posterior capsule intact, eliminating the need to postoperative precautions.^{7,57}

between groups at the conclusion of the study with respect to the variables evaluated, including postoperative pain and use of pain medication, ability to transfer and ambulate with an assistive device, length of hospital stay, and discharge to home or to a transitional facility. At 6 weeks after surgery there continued to be no significant differences between groups related to function or complications.

The investigators in both studies concluded that there was no objective evidence to support that there are short-term benefits of minimally invasive THA compared with traditional THA. Both indicated that long-term, follow-up studies must be conducted.

Implantation of components and closure. After dislocation of the joint, an osteotomy is performed at the femoral neck, and the head is removed. Another option used by some surgeons for minimally invasive procedures is to cut the femoral neck *in situ* without dislocating the hip.^{13,76,125} The acetabulum is reamed and remodeled, and a high-density polyethylene cup is inserted into the prepared acetabulum.^{100,110} A patient with developmental dysplasia of the hip may require acetabular bone grafting to improve the stability of the prosthetic joint. The intramedullary canal of the femur may be broadened, primarily when cement fixation is to be used; and a stemmed, metal prosthesis is inserted into the shaft of the femur.^{15,109} It is important to note that trial components are inserted and checked radiographically to verify alignment of the components, and the hip is moved through a full ROM to assess its stability before the permanent implants are inserted.

After the prosthetic hip is reduced, the capsule usually is repaired. The remaining layers of soft tissues that were incised or detached are securely repaired and appropriately balanced prior to closure.

Complications

The incidence of intraoperative and postoperative complications after primary, traditional THA is relatively low. However, there may be a higher incidence of complications

after minimally invasive procedures due to decreased exposure of the hip joint and the more technically demanding nature of minimally invasive approaches.^{3,7} Although only a small percentage of complications require revision arthroplasty, any complication can hamper rehabilitation and restoration of functional mobility.

Intraoperative complications associated with THA include malpositioning of the prosthetic components, femoral fracture, and nerve injury. In addition to medical complications, such as infection, deep vein thrombosis (DVT), or pneumonia that can occur after any surgery, postoperative complications that may occur during the early period of recovery (before 6 weeks or up to 2 to 3 months) include wound healing problems, dislocation of the prosthetic joint, disruption of a bone graft site before sufficient bone healing has occurred, and leg-length discrepancy.⁸³ Late complications include dislocation, mechanical loosening of either implant at the bone–cement or bone–implant interface, polyethylene wear, and in rare instances heterotopic ossification.

Dislocation of the operated hip is a complication that occurs most frequently during the first 2 to 3 months postoperatively when soft tissues around the hip joint are healing. The frequency of early dislocation after current-day primary THA is reported to be < 1% to slightly more than 10%, with a mean of just less than 2%.⁸⁰ However, this rate increases to 5% at 5 years.⁸⁰ Most dislocations are nontraumatic and occur in a posterior direction.^{66,84} Posterior dislocations are often but not always associated with a posterior surgical approach.^{2,51} However, dislocation also occurs after anterior/anterolateral and direct lateral approaches.^{66,75,83,84,104,139} Patient-related and surgery/prosthesis-related risk factors that may contribute to dislocation are noted in Table 20.2.⁸⁰ Precautions to reduce the risk of dislocation after THA are addressed in the following section on postoperative management (see Box 20.7). Recurrent dislocation after THA usually must be managed surgically.

Inequality of leg lengths is a complaint of some patients during the early period of recovery after THA.¹⁰³ Although asymmetry of the pelvis and trunk may be evident

TABLE 20.2 Risk Factors Contributing to Joint Dislocation after Total Hip Arthroplasty

Patient-Related Factors	Surgery/Prosthesis-Related Factors
<ul style="list-style-type: none"> • Age > 80 to 85 years^{80,84} • THA for femoral neck fracture • Medical diagnosis: higher risk in patients with inflammatory arthritis (mostly RA) than patients with OA¹³⁹ • Poor quality soft tissue from chronic inflammatory disease • History of prior hip surgery • Preoperative and postoperative muscle weakness and contractures • Cognitive dysfunction, dementia 	<ul style="list-style-type: none"> • Surgical approach: higher risk with posterior than anterior or lateral approaches • Malpositioning of the acetabular component • Inadequate soft tissue balancing during surgery or poor quality soft tissue repair • Experience of the surgeon

during standing and walking, in most instances this is the result of muscle spasm, muscle weakness (particularly the gluteus medius), and residual contracture of hip muscles, which can be managed conservatively. However, a true leg-length discrepancy, associated with low back and hip pain or hip dislocation, may be the result of malpositioning of the prosthetic implants (usually the acetabular component). If significant, it may necessitate revision arthroplasty.¹⁰³

Postoperative Management

Immobilization

After THA there is no need for immobilization of the operated hip. To the contrary, postoperative rehabilitation emphasizes early movement. Depending on the type of surgical approach used and the stability of the prosthetic hip, the operated limb may need to remain in a position of slight abduction and neutral rotation when the patient is lying in bed in the supine position. An abduction pillow or wedge typically is sufficient to maintain the position.⁷⁵

Weight-Bearing Considerations

After cemented THA, typically patients are permitted to bear as much weight as tolerated almost immediately after surgery.^{15,73,100,109} In contrast, with cementless or hybrid THA, it is often necessary to limit weight bearing on the operated limb for the first few weeks or up to 3 months. A number of factors affect the extent and duration of postoperative weight-bearing restrictions and the need for an ambulation aid during transfers, walking, and ascending and descending stairs. Box 20.6 summarizes these factors.

BOX 20.6 Early Postoperative Weight-Bearing Restrictions After Total Hip Arthroplasty

Method of Fixation

- *Cemented.* Immediate postoperative weight bearing as tolerated.^{15,73,75,100}
- *Cementless and hybrid.* Recommendations vary from partial weight bearing (toe-touch or touch-down) for at least 6 weeks^{16,70,75,90} to weight bearing as tolerated (no restrictions) immediately after surgery.^{13,19,21}

Surgical Approach

- *Standard versus minimally invasive.* Weight-bearing usually more restricted after standard (traditional) approach because of more extensive surgical disturbance and repair than minimally invasive approach.¹⁴ Weight bearing as tolerated may be permissible immediately after minimally invasive procedure.¹³
- *Trochanteric osteotomy.* Although used infrequently, restricted weight bearing at least 6 to 8 weeks or possibly 12 to 16 weeks for bone healing

Other Factors

- *Use of bone grafts.* Non-weight-bearing or restricted weight bearing during bone healing.
- *Poor quality of patient's bone.* Extended restrictions so as not to jeopardize the stability of the prosthetic implants.

Although it is customary to limit weight bearing on the operated lower extremity after cementless and hybrid THA,^{16,59,131} this practice deserves a closer look. The rationale for restricting weight bearing is based on the assumption that early, excessive loading of the operated limb could cause micromovement at the bone–implant interface, thereby jeopardizing the initial stability of the implant(s), interfering with osseous ingrowth, and contributing to eventual loosening of the prosthetic implants.

Nonetheless, there are also potential benefits of safe levels of early weight bearing after THA, specifically the reduction of bone demineralization from decreased weight bearing and the earlier recovery of functional mobility.^{19,21} It has been established that many patients have difficulty learning and integrating prescribed weight-bearing limitations into daily functional activities and consequently place greater loads than recommended on the operated extremity, particularly once postoperative pain has subsided.¹³³ It is also known that in the supine position resisted movements of the lower extremity impose loads on the hip considerably greater than body weight.⁹⁷

In light of these considerations, the need for weight-bearing restrictions after cementless THA currently is being re-examined.

Focus on Evidence

In two recent randomized, controlled investigations,^{19,21} the effects of immediate weight bearing as tolerated during ambulation and other functional activities after cementless or hybrid arthroplasty were compared with the effects of restricted weight bearing. No short-term or long-term adverse effects of immediate weight bearing were identified in either study. It is important to note that patients in both studies were relatively young compared with most patients undergoing hip arthroplasty, and their bone quality was described as excellent. In addition, all patients in both studies participated in a comprehensive, supervised postoperative rehabilitation program.

In one study,²¹ patients assigned to the immediate weight-bearing group were placed on no weight-bearing restrictions. These patients were also encouraged to discontinue use of ambulation aids as soon as possible. In contrast, those in the restricted weight-bearing group were required to ambulate with two crutches and were limited to toe-touch weight bearing for 6 weeks. After 6 weeks these patients were permitted to bear weight as tolerated.

In the other study,¹⁹ patients in the immediate weight-bearing group initially used one crutch but were encouraged to place as much weight as tolerated on the operated lower extremity. Patients in the delayed weight-bearing group ambulated with two crutches and were allowed to place only 10% of body weight on the operated leg for 3 months.

There were no significant differences found between the two groups in either study on several follow-up evaluations. Authors of both studies suggested that early weight bearing as tolerated after cementless or hybrid primary THA can be safe in a young patient population (< 60 to 65 years of age) with excellent bone quality. However, in

the clinical setting, the responsibility of determining the need for protected weight bearing during the early phase of postoperative rehabilitation after THA remains with the surgeon.

Exercise and Functional Training

The use of therapeutic exercise interventions for patients after THA has been reported in the literature for several decades.^{12,24,34,54,111} Although the time frame for and extent of patient-therapist contact have decreased substantially since these early descriptive reports were published, the ultimate goal of rehabilitation remains the same: to optimize a patient's postoperative level of function. However, specific components, frequency, and progression of rehabilitation programs have not been consistent or standardized.³⁷ More often than not rehabilitation programming has centered on protocols developed by and based on the opinions or assumptions of individual surgeons or therapy departments rather than on evidence-based research on the effects of specific exercises or weight-bearing activities on the hip joint or on functional outcomes. In addition, exercise protocols often must be adjusted to meet the needs and abilities of individual patients. Consequently, the effectiveness of postoperative exercise has not been clearly supported.

A report from the National Institutes of Health (NIH) has identified the need for consistently applied and evaluated long- and short-term intervention strategies for rehabilitation after THA.⁹⁵ A consensus survey on physical therapy-related intervention for early inpatient total hip (and knee) rehabilitation is a step forward in the development of consistent guidelines for postoperative management.³⁷ The exercises and functional activities identified in the consensus document were elements common to most postoperative programs and only those agreed upon by the participating physical therapists.

The goals, guidelines, and precautions for exercise and functional activities after THA discussed in this section represent not only those interventions identified in the aforementioned consensus survey but also exercises selected from other resources in the current literature,^{22,26,56,75,89,134} including those for an accelerated rehabilitation program after minimally invasive THA.¹³ The suggested exercises, functional activities, and precautions are also based on the results of the available, albeit limited, research on the impact of specific exercises and functional activities on the hip joint.

Focus on Evidence

Several related, single-subject studies have measured in vivo forces acting on the hip and acetabular contact pressures during exercise and gait.^{46,64,65,124} Although these studies involved only two patients after insertion of a femoral endoprosthesis, not a total joint replacement, the results raise questions about assumptions made by clinicians with regard to the selection and progression of common exercises and functional activities during rehabilitation after hip arthroplasty. The results of these studies suggest that active or resistive exercises, per-

formed statically or dynamically, should be initiated and progressed cautiously. During the acute or postacute phases of rehabilitation some exercises, such as maximal effort gluteal setting or unassisted heel slides typically used during the acute phase of rehabilitation and manually resisted isometric abduction during the postacute stage in preparation for gait and other weight-bearing activities, may actually generate greater acetabular contact pressures than the weight-bearing activities themselves.^{46,124}

Exercise: Maximum Protection

Phase After Traditional THA

Common impairments exhibited by patients during the acute and subacute stages of soft tissue healing and the initial phase of postoperative rehabilitation after THA are pain secondary to the surgical procedure, decreased ROM, muscle guarding and weakness, impaired postural stability and balance, and diminished functional mobility (transfers and ambulation activities). Depending on the type of THA procedure and the surgeon's preference, weight-bearing restrictions initially may interfere with functional activities.

The emphasis of this phase rehabilitation after a standard surgical approach is on patient education to reduce the risk of early postoperative complications, in particular dislocation of the operated hip. (Risk factors for dislocation after THA are noted in Table 20.2.) Precautions during functional activities are determined by the surgical approach used and input from the surgeon about the stability of the hip replacement (Box 20.7).^{66,75,83,84,104} (Also refer to Box 20.6 for weight-bearing restrictions.)

Although a posterior surgical approach is associated with the highest risk of dislocation, all patients routinely are asked to limit flexion of the hip to < 90° and rotation to < 45° for about 6 weeks regardless of the approach used.¹⁰⁴

Selected exercises and functional training begin the day of or after surgery. The frequency of treatment by a therapist is often twice a day until the patient is discharged from the hospital,³⁷ typically by 3 to 4 days postoperatively. Ideally, the prescribed exercises are performed hourly by the patient.

Goals and interventions. The following goals and interventions apply to the initial postoperative days while the patient is hospitalized, continuing through the first few weeks after surgery when the patient is at home or in another health care facility.

● Prevent vascular and pulmonary complications.

- Ankle pumping exercise to prevent venous stasis, thrombus formation, and the potential for pulmonary embolism.
- Deep breathing exercise and bronchial hygiene to prevent postoperative atelectasis or pneumonia continued until the patient is up and about on a regular basis.

● Prevent postoperative dislocation or subluxation of the operated hip.

- Patient and caregiver education about motion restrictions, safe bed mobility, transfers, and precautions during other ADL (see Box 20.7).

BOX 20.7 Early Postoperative Motion Precautions After Total Hip Arthroplasty*
Posterior/Posterolateral Approaches
ROM

- Avoid hip flexion > 80° to 90° and adduction and internal rotation beyond neutral.

ADL

- Transfer to the sound side from bed to chair or chair to bed.
- Do not cross the legs.
- Keep the knees slightly lower than the hips when sitting.
- Avoid sitting in low, soft chairs.
- If the bed at home is low, raise it on blocks.
- Use a raised toilet seat.
- Avoid bending the trunk over the legs when rising from or sitting down in a chair or dressing or undressing.
- For bathing, take showers or use a shower chair in the bathtub.
- When ascending stairs, lead with the sound leg. When descending, lead with the operated leg.
- Pivot on the sound lower extremity.
- Avoid standing activities that involve rotating the body toward the operated extremity.

- Sleep in supine position with an abduction pillow; avoid sleeping or resting in a side-lying position.

Anterior/Anterolateral and Direct Lateral Approaches With or Without Trochanteric Osteotomy
ROM

- Avoid flexion > 90°.
- Avoid hip extension, adduction, and external rotation past neutral.
- Avoid the combined motion of flexion, abduction, and external rotation.
- If the gluteus medius was incised and repaired or a trochanteric osteotomy was done, do not perform active, antigravity hip abduction for at least 6 to 8 weeks or until approved by the surgeon.

ADL

- Do not cross the legs.
- During early ambulation, step to, rather than past, the operated hip to avoid hyperextension.
- Avoid activities that involve standing on the operated extremity and rotating away from the involved side.

Note: These precautions apply to traditional total hip arthroplasty and may or may not be necessary after minimally invasive procedures, depending on the surgeon's guidelines.

- Monitor the patient for signs and symptoms of dislocation, such as shortening of the operated lower extremity not previously present.

● Achieve independent functional mobility prior to discharge.

- Bed mobility and transfer training, integrating weight-bearing and motion restrictions.
- Ambulation with an assistive device (usually a walker or two crutches) immediately after surgery, adhering to weight-bearing restrictions and gait-related ADL precautions.

NOTE: Arising from a low chair imposes particularly high loads across the hip joint, producing loads approximately eight times body weight.⁹⁷ If the posterior capsule was incised during surgery, this places the involved hip at a high risk of posterior dislocation until soft tissues around the hip joint have healed sufficiently (at least 6 weeks) or until the surgeon indicates that unrestricted functional activities are permissible.

● Maintain a functional level of strength and muscular endurance in the upper extremities and unoperated lower extremity.

- Active-resistive exercises in functional movement patterns, targeting muscle groups used during transfers and ambulation with assistive devices.

● Prevent reflex inhibition and atrophy of musculature in the operated limb.

- Submaximal muscle-setting exercises of the quadriceps, hip extensor, and hip abductor muscles—just enough to elicit a muscle contraction.

PRECAUTION: If a trochanteric osteotomy was performed, avoid even low-intensity isometric contractions of the hip abductors during the early postoperative phase unless initially approved by the surgeon and performed strictly at a minimum intensity. (See Box 20.7 for additional precautions after trochanteric osteotomy.)

● Regain active mobility and control of the operated extremity.

- While in bed, active-assistive (A-AROM) exercises of the hip within protected ranges.
- Active knee flexion and extension exercises while seated in a chair, emphasizing terminal extension progressing to active hip and knee flexion (heel slides), gravity-eliminated hip abduction (if permissible) by sliding the leg on a low-friction surface, and active rotation between external rotation or internal rotation to neutral depending on the surgical approach. Do these exercises while lying supine in bed.
- Active hip exercises in the standing position with the knee flexed and extended with hands on a stable surface to maintain balance.
- Closed-chain hip flexion and extension, placing only the allowable amount of weight on the operated extremity.

● Prevent a flexion contracture of the operated hip.

- Avoid use of a pillow under the knee of the operated extremity.

Exercise: Moderate and Minimum Protection Phases

After traditional THA the intermediate and late phases of rehabilitation begin about 4 to 6 weeks postoperatively.

The degree of protection of the operated hip required varies substantially from patient to patient. Some degree of moderate protection may be necessary for 12 weeks postoperatively. However, full healing of soft tissue and bone continues for up to a year after surgery.

The exercises described for these phases usually are a part of a home program that a patient has learned during home-based therapy, on an outpatient basis, or in an extended care facility. Exercises and functional training focus on restoration of strength, postural stability and balance, muscular and cardiopulmonary endurance, and ROM to functional levels and gradual resumption and necessary modification of functional activities. Postoperative precautions during ADL are continued for at least 12 weeks and often considerably longer.^{75,89} Patient education continues throughout these phases of rehabilitation in preparation for a return to anticipated activities in the home, workplace, or recreational setting. Return to a full level of functional activities may take 6 to 8 months.

To prolong the life of the prosthesis, particularly in patients under 50 to 60 years of age, patients are routinely advised to refrain from high-impact sports and recreational activities.⁷⁷ If a patient's employment involves heavy labor, vocational retraining or an adjustment in work-related activities is advised.

Goals and interventions. The following are the goals and interventions during the intermediate and advanced phases of rehabilitation.

● **Regain strength and muscular endurance.**

- Open-chain exercises within the permissible ranges in the operated leg against light resistance. Emphasize increasing the number of repetitions rather than the resistance to improve muscular endurance.
- Bilateral closed-chain exercises such as mini-squats against light-grade elastic resistance or while holding light weights in both hands when unsupported standing is permitted.
- Unilateral closed-chain exercises such as forward and lateral step-ups (to a low step) and partial lunges with the involved foot forward when full weight bearing is permitted on the operated lower extremity.
- Resistive exercises to other involved areas in order to improve function.

● **Improve cardiopulmonary endurance.**

- Nonimpact aerobic conditioning program, such as progressive stationary cycling, swimming, or water aerobics.

● **Reduce contractures while adhering to motion precautions.**

- Gravity-assisted supine stretch to neutral in the Thomas test position. Pull the unininvolved knee to the chest while relaxing the operated hip. (At least 10° of hip extension beyond neutral is needed for a normal gait pattern.)
- Resting in a prone position for a prolonged passive stretch of the hip flexor muscles when rolling to prone-lying is permissible and is also tolerable.
- Integrate gained ROM into functional activities.

PRECAUTION: Check with the surgeon before initiating a stretch of the hip flexors to neutral or into hyperextension if the patient has undergone an anterolateral approach.

● **Improve postural stability, balance, and gait.**

- Emphasize use of a cane (in the hand *contralateral* to the operated hip) and progressive weight bearing on the operated limb.
- While using a cane, walk over uneven and soft surfaces to challenge the balance system.
- Integrate posture training during ambulation, emphasizing an erect trunk, vertical alignment, equal step lengths, and a neutral symmetrical position of the legs.
- Continue cane use until weight-bearing restrictions are discontinued or if the patient exhibits gait deviations, such as a positive Trendelenburg sign on the operated lower extremity, indicating gluteus medius weakness. Cane use is also recommended during extended periods of ambulation to decrease muscle fatigue.

● Focus on Evidence

Use of a cane in the contralateral hand by patients after a hip replacement has been shown to decrease electromyographic (EMG) activity in the hip abductor muscles to a significant degree regardless of whether moderate or near-maximum force is applied on the cane.⁹³ In the same study, ipsilateral cane use produced no significant decrease in EMG activity in the hip abductor muscles. The degree to which the decreases in EMG activity reflected a reduction in forces imposed on the prosthetic hip joint was not determined in this study. However, in single-subject studies of two patients with femoral endoprostheses, acetabular contact pressures were reduced by using a cane in the contralateral hand.^{46,64,65}

● **Prepare for a full level of functional activities.**

- Integrate strength, endurance, and balance exercises into functional activities but continue to avoid applying high loads during exercise. When weight-bearing restrictions have been discontinued, strengthen hip and knee musculature with functional activities such as ascending and descending stairs step over step.
- Progressively increase the length of time and distance of a low-intensity walking program 2 to 4 days a week.
- When walking and carrying a heavy object in one hand, suggest that the patient hold it on the same side as the operated hip. Theoretically, this reduces the amount of stress imposed over time on the prosthetic hip replacement.
- Through patient education reinforce the importance of selecting activities that reduce or minimize the forces and demands placed on the prosthetic hip.

● Focus on Evidence

The results of research suggest that the forces imposed on the abductor muscles of the prosthetic hip, as measured by EMG, are significantly lower when a load is carried in the arm on the same side as the prosthetic hip compared to when the load is carried in the contralateral arm. This was

found to hold true with and without cane usage.^{91,92} As the patient's activity level increases, have the patient avoid high-impact activities or activities that impose heavy rotational forces on the operated limb. Both factors can contribute to long-term loosening and wear of the prosthetic implants and eventual failure of the hip replacement.

Accelerated Rehabilitation After Minimally Invasive THA

For carefully selected patients who have undergone minimally invasive primary THA, an accelerated rehabilitation program may be feasible to achieve optimal outcomes as rapidly as possible. However, few guidelines have been published to date.

Berger and colleagues¹³ developed and implemented a program specifically designed for patients undergoing primary cementless THA with a two-incision approach. Patients eligible for the minimally invasive surgery and accelerated rehabilitation program had to be between the ages of 40 to 75 years with a body mass index of < 35, no previous hip surgery, and no history of cardiac, vascular, or pulmonary disorders. The following are key elements of the accelerated program described by Berger et al.¹³

Preoperative activities. Prior to surgery, educate the patient about the surgical procedure and postoperative rehabilitation program, wound care, and the home exercise program. Initiate gait training (weight bearing as tolerated) using crutches and a cane.

Immediate postoperative therapy. Approximately 5 to 6 hours after surgery, if the patient is medically stable, begin the following activities.

- Postoperative bed and chair transfers (weight bearing as tolerated)
- Ambulation with crutches, progressing to a cane as tolerated
- Ascending and descending stairs, one step at a time

Criteria for hospital discharge. The patient is discharged from the hospital to home when able to perform the following tasks independently while using an ambulation aid.

- Transfer in and out of bed
- Stand up from and sit down in a standard, firm chair
- Walk 100 feet
- Ascend and descend a flight of stairs

Berger et al.¹³ reported that 97 of the 100 participants in the study met the criteria for same-day discharge. The three remaining patients, who delayed therapy because of nausea or orthostatic hypotension, were discharged the day after surgery.

Home-based and outpatient therapy. Patients participate in a home-based therapy program followed by outpatient therapy once able to drive. There are no specific positioning or ROM precautions or weight-bearing restrictions.

- Progress to ambulation with a cane as soon as possible. Continue cane use until able to ambulate with a symmetrical gait pattern and no noticeable limp.

- Have patient maintain an activity log to document functional outcomes.

Some of the short-term outcomes of this accelerated rehabilitation program reported by Berger et al.¹³ were that patients discontinued use of narcotic pain medication, transitioned to a cane, and started driving after an average of 6 days. Patients who worked returned to work at an average of 8 days. Patients walked without an assistive device at an average of 9 days. At 3 months there were no serious complications identified.¹³

PRECAUTION: These highlights are presented as an example of a rapid rehabilitation program after minimally invasive primary THA performed by the same surgeon and carried out at one institution with a carefully selected group of patients. Such a program is not appropriate for many patients undergoing minimally invasive THA and should be implemented only with necessary planning and ongoing communication between the surgeon, therapist, and patient.

Outcomes

The assessment of outcomes of THA has focused on numerous variables, ranging from patient satisfaction and the impact of THA on function and quality of life to the assessment of prosthetic designs, materials, methods of fixation, and rates of complications. The number of follow-up studies on any one of these areas is extensive. A 1990s NIH report pointed out that THA and subsequent rehabilitation have resulted in a high degree of success related to pain reduction, improvement in physical function, and health-related quality of life.^{68,95} The report went on to say that THA results in good to excellent long-term results for 90% to 95% of patients.⁹⁵ However, the findings of numerous follow-up studies reflect considerable variability of outcomes.

Pain relief, patient satisfaction, and quality of life.

Patient satisfaction after THA as well as the assessment of pain and perceived level of function and quality of life as judged by the patient and/or the surgeon generally reflect a marked decrease in pain and improvement in function.¹⁰⁷ Historically, patient-related outcomes were assessed by the surgeon rather than the patient. During the past decade or two, assessing outcomes from a patient's perspective has become increasingly evident in the literature. One outcomes study, in particular, pointed out why there is a need for evaluations by both the patient and the surgeon to fully assess the long-term outcomes of THA. During postoperative follow-up when patients reported little or no pain, patients' and physicians' assessments of pain and level of satisfaction were similar. However, as a patient's report of continuing pain increased, the disparity increased between the patient's and the physician's assessment of the level of patient satisfaction.⁷¹

Two recent studies have identified several factors that contribute to unsatisfactory outcomes. Fortin and colleagues⁴² investigated the timing of THA and outcomes. Although intuitively known by experienced practitioners, this study confirmed that patients who had the worst physical function and pain before surgery had the

poorest outcomes 2 years after surgery. The findings of a long-term (mean 3.6 years), prospective study by Nilsson et al.⁹⁶ of patients who had undergone unilateral THA for OA also confirmed that a higher preoperative level of pain predicted poorer outcomes. In addition, their study revealed that an older age at the time of surgery and postoperative low back pain were predictors of poor self-assessed outcomes.

Improvements in physical function. Improvements in ROM, postural stability, strength, and functional mobility are significant but occur gradually after THA. Patients typically achieve 90% of their expected level of overall functional improvement by the end of the first year. During the next 1 to 2 years, patients have self-reported additional gains in strength, with improvement in function reaching a plateau at approximately 2 to 3 years.¹⁰⁷

Several studies have documented deficits in physical function that persist at 1 year and beyond after THA. Trudelle-Jackson and co-investigators,¹³² compared ROM, static muscle strength, and postural stability (balance during one-leg stance) in a group of 15 patients with a mean age 62 years (range 51–77 years) 1 year after unilateral THA. They found no significant differences in ROM for the operated and uninvolved hips and small but not statistically significant differences in the strength of hip and knee musculature. However, they did find substantial differences between the operated leg and the uninvolved leg for all parameters of postural stability measured during one-leg stance. In addition, patients' self-assessed level of physical function was moderately associated with muscle strength but only weakly with postural stability.

In another study, Shih and colleagues¹²⁰ identified muscle weakness in the operated lower extremity compared with the uninvolved side in all patients 2 years after THA, with strength in the hip flexors showing the slowest rate of recovery. The investigator suggested that persistent muscle weakness and muscle fatigue during activities that require endurance may increase the stresses placed on the prosthetic implants and contribute to biomechanical loosening of the implant over time.¹²⁰ The findings of both of these studies suggest that some patients benefit from a long-term program of strength and balance training, even after returning to a full level of functional activity.

Implant design, fixation, and surgical approach. Two to three decades of studies indicate that both cemented and cementless THA have yielded equally positive postoperative outcomes in all areas of assessment, with the most consistent being reduction of pain.^{70,109} Despite the success of both cemented and uncemented THA, debate continues as to the benefits and limitations of both types of fixation. What can be said is that as surgical technique, prosthetic designs, and materials continue to improve the rate of failure because of wear and loosening continues to decrease. A higher rate of loosening continues to occur in the acetabular component.^{109,110}

Results of a study of 92 cementless THA procedures revealed a 100% survival rate of the femoral component after 10 years and a 96.4% rate for the acetabular component.³ In-depth analyses and current information on outcomes of specific prosthetic designs⁴¹ as well as outcome assessments of cemented,^{15,73,100,109} uncemented,^{16,70,106,131} and hybrid⁹⁰ procedures can be found in the references noted.

Outcomes of minimally invasive THA compared with traditional THA are just beginning to be investigated.^{99,137} Significantly more short- and long-term studies are needed before the value of minimally invasive approaches can be determined.

Impact of rehabilitation. Despite the number of sources in the literature that emphasize the importance of rehabilitation programs or, more specifically, a postoperative exercise and ambulation program after THA, the impact of these postoperative interventions has not been clearly established. The NIH reported that there is currently insufficient evidence to determine what constitutes an appropriate level of physical therapy utilization after THA. The report went on to say that there does appear to be a role for these interventions but that the efficacy of these postoperative programs has not yet been determined.⁹⁵ Studies have demonstrated that access to inpatient physical therapy services does^{43,88} and does not⁶⁷ decrease a patient's length of stay in an acute care facility after THA. The use of physical therapy services after THA also has been shown to increase the probability of discharge to the home setting rather than to another health-care facility.⁴³

Studies with control groups that have evaluated the impact of exercise on functional outcomes in patients who have undergone THA are few in number. Most of these studies have looked at the effect of exercise several months or even a year or two after surgery, not during the first 6 to 12 weeks. However, Wang and colleagues¹³⁴ conducted a randomized, controlled investigation to determine if a customized exercise program initiated before scheduled THA had an effect on the ambulatory abilities of patients after surgery. Gait velocity was measured by the 25-meter walk test, and walking endurance was measured by the 6-minute walk test. Participants in the exercise group ($n = 15$) took part in two facility-based and two home-based exercise sessions of stationary bicycling and resistance training two times per week for 8 weeks prior to surgery. At 3 weeks postoperatively, these patients resumed their individualized exercise regimens, modified to incorporate postoperative precautions, and continued until 12 weeks. Patients in the control group ($n = 13$) underwent no preoperative intervention and received routine post-THA functional training. At 3 weeks postoperatively the exercise group demonstrated significantly greater gait velocity and stride length and at 12 weeks significantly greater 6-minute walking distance than the control group. The investigators concluded that a customized strength and endurance training program

prior to and after THA improved the rate of recovery of ambulatory function.

In a nonrandomized study of the effectiveness of a 6-week home exercise program with patients who were 6 to 48 months post-THA, the two exercise groups (one performing ROM and isometric exercises of the hip and the other performing ROM, isometric, and eccentric exercises) increased their walking speed, whereas a control group (no exercise program) did not. Interestingly, strength improvements were noted in all three groups.¹¹⁷ The results of these two studies provide useful information, but a great deal more research needs to be done on the effects of exercise on function after THA.

Hemiarthroplasty of the Hip

Indications for Surgery

The following are possible indications for prosthetic replacement of the proximal femur.^{61,63,73}

- Acute, displaced intracapsular (subcapital, transcervical) fractures of the proximal femur in an elderly patient with poor bone stock and an anticipated low-demand level of activity after surgery^{61,81,101,102,127}
- Failed internal fixation of intracapsular fractures associated with osteonecrosis of the head of the femur^{61,81,101}
- Severe degeneration of the head of the femur (but an intact acetabulum) associated with long-standing hip disease or deformity resulting in disabling pain and loss of function that cannot be managed with nonoperative procedures^{61,81,102}

NOTE: Patients with preexisting degenerative hip disease who sustain a femoral fracture are candidates for primary THA rather than hemiarthroplasty.^{39,81} Acute, severely comminuted intertrochanteric fractures are *infrequently* managed by primary hemiarthroplasty.^{81,128}

Procedures

Background. Historically, acute displaced fractures of the proximal femur in the elderly were treated with unipolar (fixed head), uncemented metal-stemmed endoprostheses with marginal results. With the introduction of cement fixation during the 1960s, these results improved.⁸¹ The primary complication associated with the single-component unipolar implants, regardless of design or fixation, was progressive erosion of the acetabular cartilage and subsequent pain.

To decrease the problem of acetabular wear, the bipolar hemiarthroplasty was developed. The bipolar design is composed of multiple components: a metal ball-and-stem femoral prosthesis (may be modular) that moves within a free-riding polyethylene shell, which in turn inserts into a metal cup that moves within the acetabulum. The purpose of the multiple-surface, load-bearing design is to displace forces incurred by the acetabulum through the interposed components rather than directly to the acetabulum to lessen erosion of the acetabular cartilage.^{58,81,101} Both current-day modular unipolar and bipolar prostheses are in use today.

Considerable differences of opinion exist among surgeons regarding the advantages and disadvantages of one design versus the other.^{58,81,101}

Operative procedure. As with THA, a posterolateral approach is most commonly used. After removing the head of the femur, the metal-stemmed prosthesis is inserted into the shaft of the proximal femur. The femoral stem is usually cemented in place, although bioingrowth fixation has also been used. Procedures for closure are consistent with THA.

Postoperative Management

There are no studies in the literature that have examined the effects of comprehensive postoperative exercise programs exclusively for patients who have undergone current-day hemiarthroplasty. This is because, for the most part, considerations and precautions for positioning and ADL, as well as the components and progression of the exercise and ambulation program, are similar to those for postoperative management of THA. These guidelines are detailed in the previous section of this chapter. As with postoperative management after THA, selection and progression of exercises and functional activities after hemiarthroplasty also tend to be based on the opinions of surgeons and therapists as to the potential of specific exercises to remediate impairments and improve functional performance. Consequently, the effectiveness of exercise after hemiarthroplasty also remains unclear. Only limited information on the impact of specific exercises and gait-related activities on the hip joint per se after hemiarthroplasty is available in the literature. Some findings from several single-subject studies of two patients with femoral endoprostheses have already been discussed in the previous section of this chapter on THA.^{46,64,65,124}

PRECAUTION: Given the significant concerns for long-term erosion of acetabular cartilage after hemiarthroplasty, it may be even more critical to avoid exercises that impose the greatest compressive or shearing forces across the hip joint and therefore pose the greatest potential for eroding the cartilaginous surface of the acetabulum. Exercises should be performed initially at a submaximal level and then progressed gradually. *Unassisted* heel slides and *maximum* effort gluteal setting exercises may need to be avoided during the acute phase of postoperative rehabilitation.¹²⁴ During the postacute period of rehabilitation exercises, such as maximum-effort manually resisted hip abduction may actually generate greater forces across the hip than protected weight-bearing activities.⁴⁶

Outcomes

Present-day modular unipolar and bipolar hemiarthroplasty procedures appear to yield similar results in pain relief, functional outcomes, and type and rate of complications.^{61,81,101} Although acetabular wear was identified as the primary concern after the unipolar replacement used during the 1960s and 1970s, the mechanical effectiveness of the bipolar prosthesis in preventing acetabular erosion has yet to be firmly established.⁶¹ In a study of community-dwelling patients age 65 years or older

(mean age 80 years) who had undergone hemiarthroplasty with either a bipolar implant or a modular unipolar implant, there were no significant differences between the two groups at 1 year and 4 to 5 years of follow-up with regard to functioning in daily activities or rates of dislocation, infection, or mortality.¹³⁵ Another study has suggested that joint ROM may decrease over time after bipolar hemiarthroplasty possibly due to the design of the implants. This decreased range was not associated with diminished functional abilities.⁵⁸

FRACTURES OF THE HIP—SURGICAL AND POSTOPERATIVE MANAGEMENT

Hip Fracture—Incidence and Risk Factors

One of the more common musculoskeletal problems in the elderly is fracture of the hip or, more correctly, fracture of the most proximal portion of the femur in the hip joint area. The acute signs and symptoms of hip fracture are pain in the groin or hip region, pain with active or passive motion of the hip, or pain with lower extremity weight bearing. The lower extremity appears to be shorter by several centimeters and assumes a position of external rotation.^{61,102}

More than 70% of hip fractures occur in individuals who are more than 70 years of age, and they occur in women significantly more often than in men.^{18,61} In the United States, for example, women sustain 84.6% of all hip fractures.¹⁰⁸ Worldwide, the incidence of hip fracture has stabilized; but the total number of hip fractures per year is increasing, in part because of the aging of the population.^{18,61,74,102} Fewer than 2% to 3% of fractures are sustained by persons who are less than 50 years of age.^{61,102} These fractures or fracture-dislocations are usually associated with high-force, high-impact trauma but may also be seen with repetitive microtrauma.^{61,102}

Multiple factors contribute to the increasing incidence of hip fracture with age. Osteoporosis, a condition associated with age-related loss of bone density and strength, typically occurs in the proximal femur and the distal radius and spine.^{61,102} A sudden twisting motion of the lower extremity or the impact from a fall can cause pathological fracture of a fragile proximal femur. Although 90% of all hip fractures in the elderly are associated with a fall,⁶¹ there is always the question of whether trauma from the fall caused the hip fracture or a pathological fracture of the hip caused the fall. Despite the increasing incidence of osteoporosis with age, the cause of most hip fractures appears to be impaired functional mobility rather than osteoporosis.¹⁰

Balance, protective reactions, and muscle power deteriorate with age, thus increasing the likelihood of a fall. These changes, combined with decreasing ability to absorb the impact of a fall, contribute to the risk of sustaining a fracture.¹⁰² Characteristics of falling change with age, which may also increase the risk of hip fracture in the elderly. As walking speed decreases with age, particularly past 70 to 80 years, when a loss of balance and fall occurs

an older person usually drops and falls to the side, rather than falling forward on outstretched hands as occurs with faster walking speeds.^{61,102}

Hip fracture in the elderly is associated with a high rate of disability because of a loss of independence in mobility.³² Many patients require long-term nursing care and often are permanently institutionalized in extended care or assisted living facilities. For example, among women who sustain a hip fracture, approximately 15% to 25% lose the ability to live independently within the first year.¹⁸ Although postoperative mortality rates remain high (approximately 20%),³² improved surgical techniques over the past few decades have decreased the need for prolonged immobilization or restricted weight bearing, thus decreasing postoperative complications such as pneumonia and thromboemboli.

Sites and Types of Hip Fracture

Fractures of the proximal femur are broadly classified as intracapsular or extracapsular and then further subdivided by specific location. Sites and specific types of hip fracture are noted in Box 20.8.^{61,78,81,102,127-129} Of these sites, fractures in the intertrochanteric region are most common, accounting for approximately 50% of all fractures of the proximal femur.⁷⁸ Intracapsular fractures can potentially compromise the vascular supply to the head of the femur, which in turn increases the risk of delayed healing, nonunion, or osteonecrosis (avascular necrosis) of the head of the femur. These complications occur far more frequently with displaced versus nondisplaced intracapsular fractures.^{61,81} Intracapsular fractures are most often sustained by elderly women.^{61,81}

In contrast, fracture-dislocation and acetabular trauma are most common in the young, active individual.⁶¹ Most fracture-dislocations occur in a posterior direction. This

BOX 20.8 Common Sites and Types of Hip Fracture

Intracapsular

- Fracture site proximal to the attachment of the hip joint capsule
- Further subdivided into *femoral head*, *subcapital* and *femoral neck* (*transcervical* or *basicervical* fractures)
- May be displaced, nondisplaced, or impacted
- May disturb the blood supply to the head of the femur resulting in avascular necrosis or nonunion

Extracapsular

- Fracture site distal to the capsule to a line 5 cm distal to the lesser trochanter
- Further subdivided into *intertrochanteric* (between the greater and lesser trochanters) or *subtrochanteric* and *stable* or *unstable* (comminuted)
- Does not disturb the blood supply to the head of the femur, but nonunion may occur as the result of fixation failure

type of fracture often causes traumatic disruption of the vascular supply to the head of the femur and damage to joint cartilage, resulting in osteonecrosis and post-traumatic arthritis, eventually necessitating prosthetic replacement of the hip joint. However, this need may not arise for many years.

Open Reduction and Internal Fixation of Hip Fracture

Indications for Surgery

Surgical intervention by means of open (or possibly closed) reduction followed by stabilization with internal fixation (Figs. 20.7 and 20.8) is indicated for the following types of fractures of the proximal femur.^{61,102,127-129}

- Displaced or nondisplaced intracapsular femoral neck fractures
- Fracture-dislocations of the head of the femur
- Stable or unstable intertrochanteric fractures
- Subtrochanteric fractures

In the elderly patient, displaced intracapsular fractures are typically managed with prosthetic replacement of the femoral head to avoid a relatively high incidence of nonunion.¹⁰¹ Some severely comminuted (unstable) intertrochanteric fractures also may be managed in this manner.^{61,81,128}

In a few situations, nonoperative management is the only option for treatment after hip fracture. Traction is an appropriate alternative for nonambulatory individuals or for medically unstable patients who cannot undergo a sur-

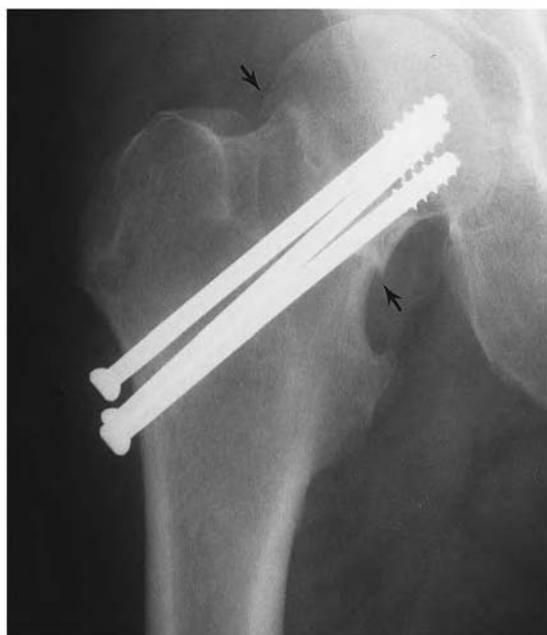

FIGURE 20.7 Reduction and internal fixation of a complete fracture of the femoral neck. Restoration of alignment and good compression is obtained via fixation with three compression screws. The black arrows mark the extent of the fracture line. (From McKinnis,⁷⁸ p. 309, with permission.)

FIGURE 20.8 Intertrochanteric fracture of the hip. This postoperative image shows fracture fixation via a side plate and screw combination device. The fracture line is evident, extending through the intertrochanteric region to the proximal femoral shaft. Some comminution is evident, and a large fragment on the medial shaft is noted. The imposed added densities of swelling of the soft tissues is seen. (From McKinnis,⁷⁸ p. 310, with permission.)

gical procedure.^{61,102} The patient remains in bed in traction just long enough for early healing to occur. Bed to chair mobilization follows. If weight bearing or ambulation is feasible, it is delayed until bone healing is sufficient, usually 10 to 12 weeks or as long as 16 weeks postoperatively.

Procedures

The goal of surgery is to achieve maximum stability and restore alignment of bony structures of the hip. Surgery is indicated during the first 24 to 48 hours after injury, particularly with femoral neck fractures where the risk of disruption of the vascular supply to the head of the femur is high. A variety of internal fixation devices are used after open or closed reduction to stabilize the many types of fracture of the proximal femur. The type and severity of the fracture and the associated injuries as well as the patient's age and physical and cognitive status all influence the surgeon's choice of procedure.^{61,102} The type of procedure performed, in turn, affects the progression of postoperative rehabilitation.

Types of fixation and surgical approach. The most common current-day internal fixation devices used, based on the type of fracture, include the following.^{61,102,127-129}

- In situ fixation with multiple parallel cancellous lag screws or pins for nondisplaced or impacted femoral neck fractures and possibly for displaced femoral neck fractures in active patients less than 65 years of age.
- Dynamic extramedullary fixation with a sliding (compression) hip screw and lateral side plate for stable intertrochanteric fractures; may be combined with an osteotomy for unstable (comminuted) fractures. The dynamic hip screw allows sliding between the screw and plate and creates compression across the fracture site during early weight bearing.
- Static interlocking intramedullary nail fixation or a sliding hip screw coupled with an intramedullary nail for subtrochanteric fractures.

An open surgical approach along the lateral aspect of the hip is used for these procedures. Aspects of some of the procedures may be performed percutaneously. Soft tissue disruption differs with each procedure. The tensor fasciae latae, vastus lateralis, or gluteus medius may be incised (parallel to the fibers); a capsulotomy is generally performed with femoral neck fractures.

Postoperative Management

The ultimate goal of surgical intervention and postoperative care after hip fracture is to return a patient to his or her preferred living environment⁸⁵ at a preinjury level of function.^{54,61,102} With this goal in mind, a national, interdisciplinary consensus conference of health professionals met and developed recommendations for optimal care. Among the recommendations was the need for rehabilitation services during recovery, including postoperative exercise and functional training across the continuum of care.⁸⁵

During the initial phase of postoperative rehabilitation, which begins in the acute care setting, the focus is to get the patient up and moving as quickly as possible to prevent or minimize the adverse effects of prolonged bed rest, including thromboemboli and pulmonary complications, while protecting the surgically stabilized fracture site. In addition to helping the patient learn to move safely in bed, transfer, and ambulate independently with an assistive device, early postoperative rehabilitation typically includes patient or caregiver education for wound care, deep breathing and coughing exercises, edema control (use of compressive stockings), proper positioning in bed to avoid contractures, and an exercise program.

After discharge from the hospital, postoperative functional training and exercise typically continue in a transitional, subacute rehabilitation or skilled nursing facility or at home. Despite consensus that rehabilitation after hospital discharge is an essential aspect of postoperative care,⁸⁵ according to the results of a recent systematic review of the literature¹¹ there is little evidence derived from randomized controlled investigations of patients' functional outcomes to support that one setting for rehabilitation is superior to another; nor is there sufficient evidence to identify the optimal timing for or components of subacute rehabilitation.

What is known, however, is that most patients are discharged from rehabilitation services after achieving independence in ambulation using an assistive device and necessary daily living activities, parameters typically set by health care plans. Often services must be discontinued despite persistent deficits in muscle performance (strength and endurance impairments) and well before patients have attained a preinjury level of function, which in turn increases the risk of future injury.¹⁷

Weight-Bearing Considerations

The amount of weight bearing permissible during early ambulation and transfers is always determined by the surgeon for each patient on an individual basis. Factors that influence the decision are the patient's age and bone quality, the fracture location and pattern, the type of fixation used to stabilize the fracture site, and the degree of intraoperative stability achieved.^{54,61,63,102} Recommendations range from non-weight-bearing, toe-touch, or touch-down weight bearing (<10 lb) to weight bearing as tolerated. Current methods of internal fixation of the fracture site have decreased the need for an extended non-weight-bearing status after surgery.

Many fixation procedures used today make early weight bearing possible. Some examples of fractures and fixation procedures in which weight bearing as tolerated is permissible immediately after surgery are:

- Undisplaced, rigidly fixed, or impacted femoral neck fractures managed with in situ fixation^{61,63,102,127}
- Stable (noncomminuted) intertrochanteric fractures managed with a dynamic (sliding) hip screw and lateral side plate fixation^{61,102,128}
- Stable subtrochanteric fractures managed with interlocking intramedullary nailing and bone-to-bone fixation^{61,102,129}

Even when weight bearing is curtailed during ambulation and transfers, the fracture site is still subjected to significant forces. For example, moving in bed, getting up to the side of the bed, and active and resisted ROM exercises all generate forces across the hip that approach or even exceed those incurred during unsupported (full weight bearing) ambulation.⁹⁷ Considering this, studies have been implemented to investigate the risks associated with early weight bearing after open reduction and internal fixation of hip fractures.

Focus on Evidence

In one such study, elderly patients with stable as well as comminuted intertrochanteric fractures treated with dynamic hip screw and plate fixation were all allowed to bear weight as tolerated during ambulation with an assistive device immediately after surgery. One year postoperatively there was no significant difference between the rate of implant failure and revision surgery in the patients with stable fractures and those with comminuted fractures. The investigators concluded that at least in elderly patients with comminuted and noncomminuted intertrochanteric frac-

tures that could be stabilized intraoperatively there was little biomechanical justification for non-weight-bearing restrictions postoperatively.⁶³

Excluded from this generalization were patients with complex fractures in whom satisfactory intraoperative stabilization could not be achieved, young patients with displaced femoral neck fractures with *in situ* fixation, and patients with severe bone disease (e.g., as the result of malignancy).

Despite the finding of this study and the recognized benefits of early ambulation and exercise, there is always risk, albeit small, of failure of an internal fixation device in some patients. Therefore, it is important to recognize the signs of possible displacement or loosening of the fracture stabilization device as summarized in Box 20.9. The presence of any of these signs or symptoms should be reported immediately to the surgeon.^{54,61,102}

Exercise

Impaired joint mobility, ROM, muscle performance, and balance are the most common impairments after open reduction and internal fixation of hip fracture. Exercise is one of the interventions routinely included in postoperative rehabilitation to reduce these impairments.

Hip and even knee motions are quite painful during the initial postoperative period, affecting ROM and strength of the operated lower extremity. In addition, some degree of protection is necessary over the course of soft tissue healing (approximately 6 weeks) and bone healing (10 to 16 weeks).¹²⁷⁻¹²⁹ All of these factors affect the progression of exercise, as do the location and stability of the fracture site, type of internal fixation used, and which soft tissues were traumatized at the time of the injury and during surgery. Special considerations for exercise and ambulation after various types of hip fracture and with specific surgeries are noted in Box 20.10.^{51,102,127-129}

The following sections outline a progression of exercises after open reduction and internal fixation of hip fractures.

Exercise: Maximum Protection Phase

Exercises begin on the first postoperative day to prevent postoperative complications and to restore a patient's con-

BOX 20.9 Signs and Symptoms of Possible Failure of the Internal Fixation Mechanism

- Severe, persistent groin, thigh, or knee pain that increases with limb movement or weight bearing
- Progressive limb length inequality (shortening of the involved lower extremity) that was not present immediately after surgery
- Persistent external rotation of the operated limb
- A positive Trendelenburg sign during weight bearing on the involved limb that does not resolve with strengthening exercises

BOX 20.10 Special Considerations for Exercise and Gait After Internal Fixation of Fractures of the Proximal Femur

- Multiple hip muscles are traumatized by fracture of the hip leading to postoperative pain, reflex inhibition, and weakness. Fractures that involve the following sites cause damage to the following muscles.
 - Greater trochanter: gluteus medius
 - Lesser trochanter: iliopsoas
 - Subtrochanteric region: gluteus maximus
- The tensor fasciae latae (TFL) and vastus lateralis (VL) are usually incised during surgery, causing postoperative pain, inhibition, and weakness during hip abduction and knee flexion.
- Adhesion formation may develop between the incised TFL and VL and restrict motion. Hip adduction and internal rotation and knee flexion place a stretch on the TFL and VL, respectively, during ROM exercises and therefore are often painful.
- If there is shortening of the involved limb after fracture and internal fixation, the distance between the distal insertion of the gluteus medius on the greater trochanter and the center of axis of hip motion is often decreased, thus diminishing the mechanical advantage of the muscle and causing weakness and a positive Trendelenburg sign during ambulation.
- Intracapsular fractures typically traumatize the capsule, and internal fixation requires an incision into the capsule (capsulotomy). Both predispose the capsule to postoperative restriction.

trol of the operated hip during functional activities. All exercises are performed within a patient's level of comfort. Initially, exercises are directed toward restoring ROM of the operated hip and developing strength in the upper extremities and unoperated lower extremity to facilitate ambulation with an assistive device. It is reasonable to expect to achieve 80° to 90° of active hip flexion (with the knee flexed) by 2 to 4 weeks postoperatively.^{54,61}

There is lack of consensus about the appropriate time to begin resistance exercises to strengthen the operated lower extremity. Low-intensity resistance exercises of the operated hip often are delayed until 4 to 6 weeks postoperatively to allow time for the hip muscles incised during surgery to heal. However, resistance exercises of knee and ankle musculature may be initiated sooner.

Focus on Evidence

Mitchell and colleagues⁸² conducted a randomized controlled trial to determine the effects of 6 weeks of quadriceps resistance exercises during the early phase of postoperative rehabilitation after hip fracture. All of the 80 patients in the study, described as "frail elderly" (all ≥ 65 years of age, mean 80 years), began a program of ROM exercises and functional training (described as "standard" therapy) after surgery. In addition, at 16 days postopera-

tively half of the patients (intervention group) performed three sets of 12 repetitions of resisted knee extension of the operated and unoperated lower extremities initially at the 50% 1-RM intensity twice a week, progressing to 80% intensity by the fifth week. Of the 80 patients in the study, 75% completed the 6-week study.

After 6 weeks of resistance training the quadriceps strength of the intervention group increased bilaterally to a significantly greater extent than that of the control group. The intervention group also demonstrated significantly greater improvement and, as such, a greater reduction in disability than the control group on a functional mobility test measuring locomotion, balance, and transfers. However, there were no significant differences in improvement between groups regarding gait velocity or on a test that measures independence in ADL. There were no training-related adverse events during the study.

The authors concluded that moderate- to high-intensity postoperative quadriceps resistance training during early recovery after hip fracture was functionally beneficial and well tolerated by the participants despite their age and frailty.

The following are goals and exercise-related interventions for the initial phase of postoperative rehabilitation.

● Prevent vascular and pulmonary complications.

- Active ankle exercises (pumping exercises) performed regularly throughout the day to maintain circulation and reduce the risk of DVTs and thromboemboli.
- Deep breathing exercises and airway clearance to prevent pulmonary complications.

● Improve strength in the upper and sound lower extremities.

- Exercises against progressive levels of resistance targeting key muscle groups used to lift body weight during bed mobility, standing transfers, and ambulation with assistive devices.
- Emphasis on closed-chain training to simulate the movement patterns used during these activities.

● Prevent postoperative reflex inhibition of hip and knee musculature.

- Low-intensity isometric (setting) exercises of the hip and knee musculature of the operated extremity. Depending on the fracture site and its stability, perform submaximal gluteal, abductor, adductor, and quadriceps and hamstring setting exercises.

● Restore active mobility and dynamic control of the involved hip and adjacent joints.

- Assisted, progressing to active ROM of the involved hip and knee in progressively more challenging positions as pain and fracture healing permit. For example, in the supine position, perform heel slides before straight leg raises (SLRs) in the supine position. The shorter moment arm when the knee is flexed places lower rotational loads on the fracture site than a long moment arm.

- Unassisted SLRs (flexion, abduction, extension) *while standing* on the sound leg and holding onto a stable surface for balance before progressing to SLRs in a horizontal position.
- Pelvic tilts and knee-to-chest movements with the *uninvolved* leg to prevent stiffness in the low back region.
- Low-intensity dynamic resistance exercises in weight-bearing and non-weight-bearing positions as the stability of the fracture site allows.

PRECAUTION: When initiating setting and dynamic exercises of the operated hip after comminuted subtrochanteric fractures that required medial cortex reconstruction, postpone contractions of the abductor and adductor muscles for 4 to 6 weeks to avoid stresses across the fracture site.¹²⁹

Exercise: Moderate and Minimum Protection Phases

By 6 weeks soft tissues are healed; and by 8 to 12 weeks, depending on the age and health of the patient, some degree of bone healing has occurred. By the sixth week of rehabilitation, except in unusual situations, at least partial weight bearing or full weight bearing as tolerated, if not initiated previously, now is permissible. By 8 to 12 weeks, although a patient gradually can be weaned from use of an assistive device during ambulation, most continue to use at least a cane well beyond this time frame.

The emphasis during the intermediate and final phases of rehabilitation focuses on increasing strength and functional control of the involved lower extremity and gradually increasing the patient's level of functional activities. Patients typically are discharged from therapy no later than 8 to 12 weeks postoperatively and often earlier.

Extended exercise programs after hip fracture. For many years there was lack of agreement about the value of an extended exercise program or if it was appropriate to include moderate-intensity resistance exercises of the operated extremity in an elderly patient's rehabilitation program before and even after the fracture site was fully healed.⁵⁴ (Bone healing typically takes 8 to 16 weeks and up to 6 months in some patients.) However, during the past few years the findings of several studies have demonstrated that after a standard course of postoperative rehabilitation and with clearance from the patient's surgeon, an extended program of properly supervised, carefully progressed resistance exercises for strength training, begun 6 to 19 weeks postoperatively, is safe and effective.^{17,52,74,118,119}

The intensity, frequency, and duration of the extended exercise program varied in these studies, and the equipment used for resistance training ranged from elastic resistance products to weight machines. Features of the exercise programs implemented in three of the studies are summarized in Table 20.3. Additional details and outcomes of these studies are addressed at the conclusion of this section on postoperative management after hip fracture.

The following goals and exercises are appropriate during the intermediate and advanced phases of rehabilitation.

TABLE 20.3 Summary of Studies of Extended Exercise Programs Following Surgery for Hip Fracture

First Author and Type of Study	Subjects: (n) and Mean Age	Setting, Format, and Timing of Intervention	Frequency, Duration, and Types of Exercise	Features of PRE Training
Binder ¹⁷ RCT with two groups	n = 90 Intervention group: n = 46; 80 years Control group: n = 44; 81 years	Facility-based; group format for intervention group and home-based program for control group Begin no more than 16 weeks postsurgery	<i>Intervention group:</i> Two 3-month phases, three weekly sessions Phase 1: total of 22 exercises (flexibility, balance, aerobic training, low-intensity resistance exercises) Phase 2: Moderate- to high-intensity PRE added to shortened phase 1 program <i>Control group:</i> A portion of phase 1 exercises, no PRE	One or two sets, six to eight reps at 65% of initial 1-RM progressing to three sets, 8 to 12 reps at 85–100% initial 1-RM Weight machines Exercises: bilateral knee flexion and extension, leg press, seated bench press, biceps curl, seated rowing
Hauer ⁵² RCT with two groups	n = 28; all at least 75 years Intervention group: n = 15; 81.7 years Control group: n = 13; 80.8 years	Facility-based; group format; begun 6–8 weeks postfracture	<i>Intervention group:</i> Three weekly sessions for 3 months; PRE, balance, and functional training <i>Control group:</i> Stretching, seated calisthenics, memory tasks.	Two sets at 70–90% of 1-RM intensity Weight machines and body weight resistance Exercises: leg press, hip/knee extension, plantarflexion
Mangione ⁷⁴ RCT with three groups	n = 33 Resistance group: n = 11; 77.9 years Aerobic group: n = 12; 79.8 years Control group: n = 10; 77.8 years	Home-based; individual format; begun 19.4, 19.7, and 12.6 weeks after surgery, respectively, for resistance, aerobic, and control groups	Total of 3 months: two sessions weekly for 2 months, followed by 1 session weekly for 1 month	Three sets of eight reps at the 8-RM intensity Portable resistance unit or body weight resistance Exercises: supine hip and knee extension, hip abduction, standing hip extension; standing plantarflexion (heel raises)

PRE, progressive resistance exercise; RCT, randomized controlled trial; RM, repetition maximum.

- **Increase flexibility of any chronically shortened muscles.** Muscles typically involved include the ankle plantarflexors, hip flexors and hamstrings. Suggested stretching techniques include:

- Heel cord stretching with a towel while sitting on a bed with the knee straight or the assistance of a caregiver and later while standing.
- Hip flexor stretching in the supine/Thomas test position.
- Hamstring stretching by sitting on the edge of a table with one leg supported in hip flexion and knee extension and the other in extension over the side of the support surface (see Fig. 20.15).

- **Improve strength and muscular endurance in the lower extremities for functional activities.** Refer to the section on exercise interventions later in the chapter for descriptions of the following exercises.

- Bilateral closed-chain active exercises, such as mini-squats and heel raises using a table or walker for support and balance and body weight as the source of resistance as soon as partial-weight bearing on the operated lower extremity is permissible.
- Lunges and forward and lateral step-ups when weight bearing to tolerance is allowable.

- Open-chain hip and knee exercises initially against light to moderate resistance (up to 5 lb) with elastic resistance or cuff weights. Emphasize hip extension and abduction for a positive impact on ambulation.
- Task-specific training, such as stair-climbing or carrying small loads while ambulating.

● Improve postural stability and standing balance.

- A progression of balance activities appropriate for the patient's age and desired activity level.
- Progressive ambulation on various surfaces.

● Increase aerobic capacity/cardiorespiratory endurance.

- Stationary bicycling, upper body ergometry, or treadmill walking.
- Aerobic conditioning activities, possibly in an age-appropriate, community-based exercise class, to increase walking distance and velocity.

Outcomes

General outcomes. The true measure of success of surgical intervention and postoperative rehabilitation after hip fracture is the extent to which a patient can return to his or her prefracture level of function. The level of preinjury functional mobility in patients with femoral neck fractures has been shown to be a critical factor in postoperative survival.⁵⁵ In one follow-up study of patients after hip fracture, only 33% had regained their preinjury level of function in basic ADL and IADL 1 year postoperatively.⁵⁹ Given the advanced age and health status of the “average” patient who sustains a hip fracture, it is not surprising that mortality rates 1 year postoperatively are high, ranging from 12% to 36% depending on the mean age, general health status, and severity of the fracture.⁶¹ After 1 year mortality rates are equal to age-matched subjects who have not sustained a hip fracture.⁶¹

Among patients who survive 1 year postoperatively, the ability to ambulate independently (50 feet on an uncarpeted surface) was seen in 83% in one study.⁹ In a more recent study 92% of patients returned to independent ambulation, but only 41% regained their prefracture level of ambulation.⁶² In a follow-up study¹²¹ of 90 community-dwelling older adults (mean age 83.4 years) 6 months after discharge from the hospital following a fall-related hip fracture, 53.3% (48/90) had experienced one or more falls. The need for an assistive device during ambulation after hip fracture and the patient's prefracture fall history were predictors of a fall after hospital discharge.

Impact of rehabilitation. According to a report of the National Center for Medical Rehabilitation Research (NCMRR), the use of therapeutic exercise is one of the least examined factors affecting outcomes after hip fracture.¹³⁶ However, there are at least a few studies, some of which are randomized controlled trials, available that have addressed the impact of exercise and functional training on outcomes. For example, the number of visits to physical therapy has been positively associated with the ability to ambulate independently.⁹ The results of

another study indicated that the frequency of physical therapy visits increased the likelihood of regaining functional independence and going directly home from an acute care setting after hip fracture surgery.⁵⁰

As noted previously, the benefits and risks of resistance training have been investigated. In an early randomized, controlled study, subjects (most of whom were living in the community and were an average of 7 months postfracture surgery) who participated in a 1-month home exercise program increased the strength of the knee extensors and increased their walking velocity to a greater extent than the control group.¹¹⁸ Another study compared the effects of a 2-week program of weight-bearing versus non-weight-bearing exercises initiated during inpatient rehabilitation. It found that both groups demonstrated substantial improvements in lower extremity muscle strength, balance, gait, and other functional tasks. However, there were no significant differences between groups.¹¹⁹ This study lends support to the value of both types of exercise during early rehabilitation.

Recently, studies of the effects of extended, comprehensive exercise programs after hip fracture have included moderate- to high-intensity resistance training of multiple muscle groups (see Table 20.2). In the three studies described in Table 20.2, muscle strength and performance on a variety of functional mobility and ADL tests improved to a significantly greater extent in the groups who participated in resistance training than in the groups who participated in low-intensity or no resistance training.^{17,52,74} The resistance training group in the study by Binder and colleagues¹⁷ also reported a significant decrease in the perceived levels of disability, whereas the control group, who performed only low-intensity exercises, did not. The resistance training group in the investigation by Hauer et al.⁵² noted improved perception of walking steadiness but no change in fear of falling.

Moderate- to high-intensity resistance training after discharge from a “standard” postoperative program of exercise and functional training appears to be not only feasible but safe. Other than reports of mild muscle soreness during the early weeks of resistance exercise programs, training-related adverse events were reported in only one study (3 of 46 participants in the resistance training group).¹⁷ One individual fell during exercise and sustained a rib fracture; another incurred a metatarsal fracture that was discovered a few days after an exercise session; and a third developed ecchymosis at the ankle after an exercise session. All three participants chose to complete the program.

Not all types of extended rehabilitation after hip fracture have been shown to be effective. The results of a study of individuals in a long-term, home-based, multi-faceted rehabilitation program (including extensive ADL and IADL training) for 6 months postoperatively in comparison to a traditional postoperative exercise and ambulation program for an equal period of time demonstrated no significant differences.¹³⁰

PAINFUL HIP SYNDROMES/ OVERUSE SYNDROMES: NONOPERATIVE MANAGEMENT

Related Pathologies and Etiology of Symptoms

Tendinitis or Muscle Pull

Overuse or trauma to any of the muscles in the hip region can result from excessive strain while the muscle is contracting (often in a stretched position) or from repetitive use and not allowing the injured tissue to heal between activities. Common problems include hip flexor, adductor, and hamstring strains. Poor flexibility and fatigue may predispose an individual to strain and injury during an activity or sporting event; and sudden falls, such as slipping on ice, may cause a strain.

Trochanteric Bursitis

Pain is experienced over the lateral hip and possibly down the lateral thigh to the knee when the iliotibial band rubs over the trochanter. Discomfort may be experienced after standing asymmetrically for long periods with the affected hip elevated and adducted and the pelvis dropped on the opposite side. Ambulation and climbing stairs aggravate the condition. Muscle flexibility and strength imbalances and the resulting faulty posture of the pelvis may be the predisposing factors leading to bursal irritation (see Box 20.2).

Psoas Bursitis

Pain is experienced in the groin or anterior thigh and possibly into the patellar area. It is aggravated during activities requiring excessive hip flexion.

Ischiogluteal Bursitis (Tailor's or Weaver's Bottom)

Pain is experienced around the ischial tuberosities, especially when sitting. If the adjacent sciatic nerve is irritated from the swelling, symptoms of sciatica may occur.

Common Impairments and Functional Limitations/Disabilities

Pain. Symptoms occur when the involved muscle contracts, when it is stretched, or when the provoking activity is repeated.

Gait deviations. Slightly shorter stance occurs on the painful side. There may be a slight lurch when the involved muscle contracts to protect the muscle resulting in impaired gait.

Imbalance in muscle flexibility and strength. Muscle flexibility or dominance in use may be the precipitating factor in many painful hip syndromes. Common imbalances are described in the introductory section of this chapter; and imbalances from postural impairments are summarized in Box 20.2. Overuse syndromes are associated with (1) dom-

inance of the tensor fasciae latae and rectus femoris as hip flexors and abductors, with weak gluteus medius and minimus muscles; (2) dominance of the hamstrings over the gluteus maximus; and (3) shortened lateral rotators. Because of the relationship of these muscles with the pelvis and knee, patients may present with low back or knee symptoms.

Decreased muscular endurance. Muscle fatigue may lead to faulty postures, stress, and flexibility imbalances as described above.

Management: Protection Phase

Control Inflammation and Promote Healing

When there is chronic irritation or inflammation from an acute injury, follow the guidelines as described in Chapter 10, with emphasis on resting the involved tissue by not stressing or putting pressure on it. Have the patient avoid the provoking activity; and if necessary, decrease the amount and time walking or use an assistive device.

Develop Support in Related Areas

Initiate exercises to develop neuromuscular control for alignment of the pelvis and hip. Avoid stressing the inflamed tissue. Patient education and cooperation are necessary to reduce repetitive trauma.

Management: Controlled Motion Phase

NOTE: When the acute symptoms have decreased, initiate a progressive exercise program within the tolerance of the involved tissues to improve muscle performance. The program should emphasize regaining a balance in length, neuromuscular control, strength, and endurance in the muscles of the hip and the rest of the lower extremity.

Develop a Strong Mobile Scar and Regain Flexibility

Remodel the scar in muscle or tendon by applying cross-fiber massage to the site of the lesion followed by multiple-angle submaximal isometrics in pain-free positions.

Develop a Balance in Length and Strength of the Hip Muscles

Specific exercises are described in the exercise sections of this chapter.

- Stretch any muscles that are restricting motion with gentle, progressive neuromuscular inhibition techniques. Instruct the patient to do self-stretching with proper stabilization to ensure that the stretches are performed safely and effectively.
- Begin developing neuromuscular control to train the involved muscles to contract and control alignment of the femur. Initially, the emphasis is on control, not strengthening.
- Once the patient is aware of proper muscle control and is able to maintain alignment, progress to strengthening the weakened muscles through the range.

- Muscles not directly injured should be stretched and strengthened if they are contributing to asymmetrical forces. The patient may not have sufficient trunk coordination or strength, which may be contributing to the overuse because of compensations in the hip. See Chapter 16 for suggestions on developing control and stabilizing function in the trunk muscles.

Develop Stability and Closed-Chain Function

- Initiate controlled weight-bearing exercises when tolerated. Because the individual is probably standing and walking, he or she may not tolerate much more closed-chain activities than those previously initiated early during the healing stage, so proceed with caution. Carefully observe the exercises so proper movement patterns are used.
- Use exercises such as biking or partial weight-bearing and weight-shifting activities in the parallel bars. Observe coordination between trunk, hip, knee, and ankle motions; and exercise only to the point of fatigue, substitute motions, or pain in the weakest segment in the chain.

Develop Muscle and Cardiopulmonary Endurance

- For muscle endurance, teach the patient how to perform each exercise safely for 1 to 3 minutes before progressing to the next level of difficulty.
- Determine aerobic activities that do not exacerbate the patient's symptoms. It may be that the patient just needs to modify the intensity or the techniques used in his or her current program.

Patient Education

Initiate a home exercise program as soon as the patient has learned neuromuscular control techniques and correct stretching, strengthening, and aerobic activities. Provide follow-up instruction for modification and progression of the program.

Management: Return to Function Phase

Progress Strength and Functional Control

- Progress closed-chain and functional training to include balance and muscular endurance for each activity.
- Use specificity principles; increase eccentric resistance and demand for controlled speed if necessary for return-to-work activity or sporting events.
- Progress to patterns of motion consistent with the desired outcome. Use acceleration/deceleration drills and plyometric training; assess the total body functioning while doing the desired activity. Practice timing and sequencing of events.

Return to Function

Prior to returning to the desired function have the patient practice the activity in a controlled environment and for a limited period. As tolerated, introduce variability in the environment and increase the intensity of the endurance activities.

EXERCISE INTERVENTIONS FOR THE HIP REGION

No matter what the cause, muscle strength or flexibility imbalance in the hip can lead to abnormal lumbopelvic and hip mechanics, which predisposes a patient to or perpetuates low back, sacroiliac, or hip pain. (See Chapters 14 through 16 for discussion of impaired posture, common spinal diagnoses, plans of care, and exercise interventions for the spinal regions.) Poor hip mechanics from muscle flexibility and strength imbalances can also affect the knee and ankle during weight-bearing activities, causing overuse syndromes or stress to these regions.

EXERCISE TECHNIQUES TO INCREASE FLEXIBILITY AND RANGE OF MOTION

The exercise techniques in this section are suggestions for correcting limited flexibility of the musculature and periaricular tissues crossing the hip. Principles and techniques of passive stretching and neuromuscular inhibition are presented in Chapter 4 and those of joint mobilization in Chapter 5. Specific manual and self-stretching techniques are described in this section.

Flexibility (self-stretching) exercises, chosen according to the degree of limitation and ability of the patient to participate, can be valuable for reinforcing therapeutic interventions performed by the therapist. Not all of the following exercises are appropriate for every patient; the therapist should select each exercise and intensity appropriate for each patient's level of function and progress each exercise as indicated. Whenever the patient is able to contract the muscle opposite the range-limiting muscle, there are the added benefits of reciprocal inhibition of the shortened muscles as well as training the agonist (the muscle opposite the tight muscle) to function for effective control in the gained ROM.

Techniques to Stretch Range-Limiting Hip Structures

NOTE: Two-joint muscles can restrict full ROM at the hip. This first section describes stretches to increase just hip motions, so the two-joint muscles are kept on a slack across the knee during these stretches. Techniques to stretch the specific two-joint muscles are described in the second section.

To Increase Hip Extension

Prone Press-Ups

Patient position and procedure: Prone with hands on a table at shoulder level. Have the patient press the thorax upward and allow the pelvis to sag (see Fig. 15.7).

PRECAUTION: This exercise also moves the lumbar spine into extension; if it causes radiating pain down the patient's leg, rather than just a stretch sensation in the anterior trunk, hip, and thigh, it must not be performed.

“Thomas Test” Stretch

Patient position and procedure: Supine with the hips near the end of the treatment table, both hips and knees flexed, and the thigh on the side opposite the tight hip held against the chest. Have the patient slowly lower the thigh to be stretched toward the table in a controlled manner and allow the knee to extend so the two-joint rectus femoris does not limit the range. Do not allow the thigh to externally rotate or abduct. Direct the patient to let the weight of the leg cause the stretch force and to relax the tight muscles at the end of the range (Fig. 20.9). A passive stretch force may be applied manually, or a hold-relax technique may be used by applying a force to the distal thigh (see Fig. 4.26).

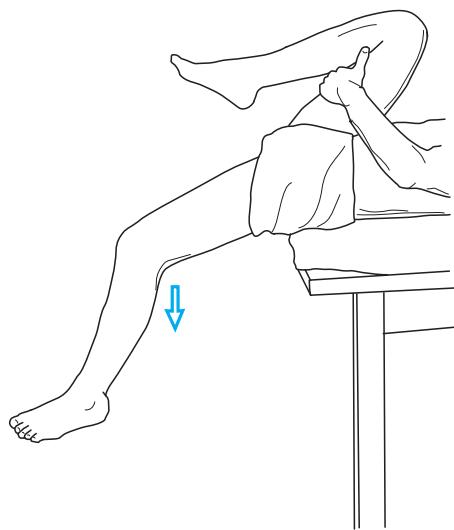

FIGURE 20.9 Self-stretching to increase hip extension. The pelvis is stabilized by holding the opposite hip in flexion. The weight of the thigh provides a stretch force as the patient relaxes. Allowing the knee to extend emphasizes the one-joint hip flexors (iliopsoas), whereas maintaining the knee in flexion and hip neutral to rotation as the thigh is lowered emphasizes the two-joint rectus femoris and tensor fasciae latae muscles.

Modified Fencer Stretch

Patient position and procedure: Standing in a fencer’s lunge-like posture, with the back leg in the same plane as the front leg and the foot pointing forward. Have the patient first do a posterior pelvic tilt and then shift the body weight onto the anterior leg until a stretch sensation is felt in the anterior hip region of the back leg (Fig. 20.10). If the heel of the back foot is kept on the floor, this exercise may also stretch the gastrocnemius muscle.

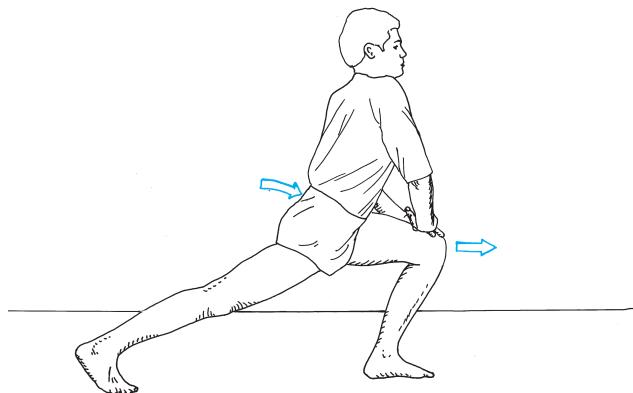

FIGURE 20.10 Self-stretching of hip flexor muscles and soft tissue anterior to the hip using a modified fencer’s squat posture.

To Increase Hip Flexion

Bilateral Knee to Chest

Patient position and procedure: Supine. Have the patient bring both knees toward the chest and grasp the thighs firmly until a stretch sensation is felt in the posterior hip region. Monitor the position carefully because if the pelvis lifts up off the mat the lumbar spine flexes and the stretch force is transmitted there instead of to the hips.

Unilateral Knee to Chest

Patient position and procedure: Supine. Have the patient bring one knee to the chest and grasp the thigh firmly against the chest while keeping the other lower extremity extended on the mat. This position isolates the stretch force to the hip being flexed and helps stabilize the pelvis. To emphasize a stretch of the gluteus maximus, have the patient pull the knee toward the opposite shoulder.

Quadruped (All Fours) Stretch

Patient position and procedure: On hands and knees. Have the patient rock the pelvis into an anterior tilt, causing lumbar extension (Fig. 20.11A); then maintain the lumbar extension and shift the buttocks back in an attempt to sit on the heels. The hands remain forward (Fig. 20.11B). It is important not to let the lumbar spine flex while holding the stretch position so the stretch affects the hip.

Chair Stretch

Patient position and procedure: Sitting in a chair with the pelvis rotated anteriorly and the low back extended to stabilize the spine. Have the patient grasp the front of the chair seat and lean or pull the trunk forward, keeping the back arched so the motion occurs only at the hips.

To Increase Hip Abduction

Patient position and procedure: Supine with both hips flexed 90°, knees extended, and legs and buttocks against the wall. Have the patient abduct both hips as far as possible with gravity causing the stretch force (Fig. 20.12).

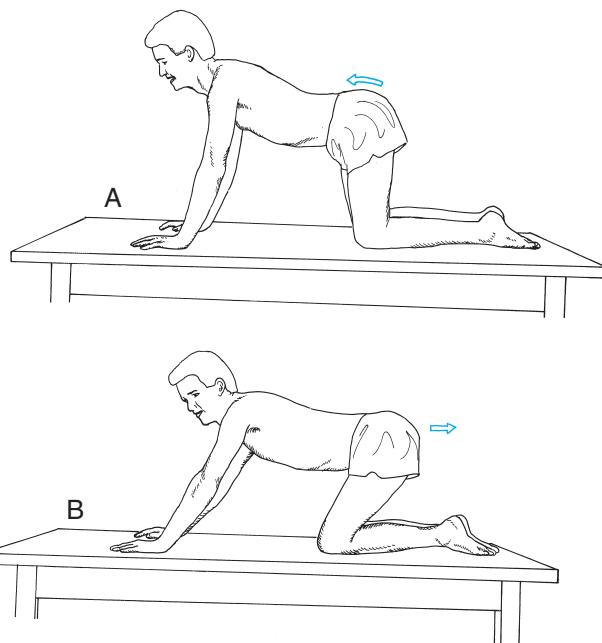

FIGURE 20.11 Gluteus maximus self-stretch with lumbar spine stabilization. (A) The patient on all fours rocks into an anterior pelvic tilt, causing lumbar extension. (B) While maintaining lumbar extension, the patient shifts the buttocks back, attempting to sit on the heels. When lordosis can no longer be maintained, the end-range of hip flexion is reached; this position is held for the stretch.

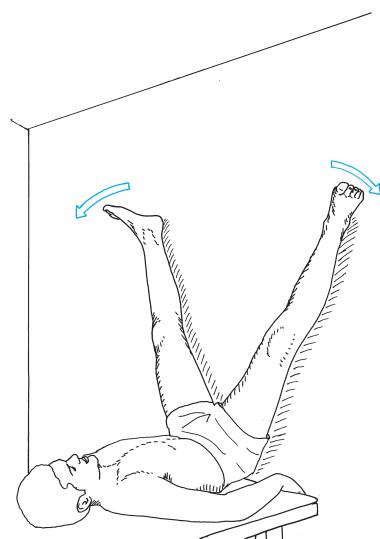

FIGURE 20.12 Self-stretching of the adductor muscles with the hips at 90° of flexion.

To Increase Hip Abduction and External Rotation Simultaneously

Patient position and procedure: Sitting or supine with soles of feet together and hands on the inner surface of the knees. Have the patient push the knees down toward the floor with a sustained stretch. The stretch can be increased by pulling the feet closer to the trunk.

PRECAUTION: When this stretch is performed supine, teach the patient to stabilize the pelvis and lumbar spine by actively contracting the abdominal muscles and maintaining a neutral spinal position.

Patient position and procedure: Standing in a fencer's position but with the hind leg externally rotated. Have the patient shift the weight onto the front leg until a stretch sensation is felt along the medial thigh in the hind leg.

Techniques to Stretch Range-Limiting Two-Joint Muscles

Rectus Femoris Stretches

“Thomas Test” Stretch

Patient position and procedure: Supine with the hips near the end of the treatment table, both hips and knees flexed, and the thigh on the side opposite the tight hip held against the chest with the arms. While keeping the knee flexed, have the patient lower the thigh to be stretched toward the table in a controlled manner. Do not allow the thigh to externally rotate or abduct. Direct the patient to let the weight of the leg cause the stretch force and to relax the tight muscles at the end of the range. The patient can attempt to further extend the hip by contracting the extensor muscles. (See Figure 20.10 but with the knee flexed.)

NOTE: This is the same stretch used to increase hip extension—except to stretch the rectus femoris the knee is kept flexed so the range for hip extension is less.

Prone Stretch

Patient position and procedure: Prone with the knee flexed on the side to be stretched. Have the patient grasp the ankle on that side (or place a towel or strap around the ankle to pull on) and flex the knee. As the muscle increases in flexibility, place a small folded towel under the distal thigh to further extend the hip.

NOTE: Do not let the hip abduct or laterally rotate or let the spine hyperextend.

Standing Stretch

Patient position and procedure: Standing with the hip extended and knee flexed and grasping the ankle. Instruct the patient to maintain a posterior pelvic tilt and not let the back arch or the side bend during this stretch (Fig. 20.13).

NOTE: If the rectus femoris is too tight to stretch safely in this manner, the patient may place his or her foot on a chair or bench located behind the body rather than grasping the ankle.

Hamstring Stretches

Straight Leg Raising

NOTE: Straight leg raising (SLR) exercises elongate the hamstrings by stretching them across the hip using hip flexion while maintaining the knee in extension.

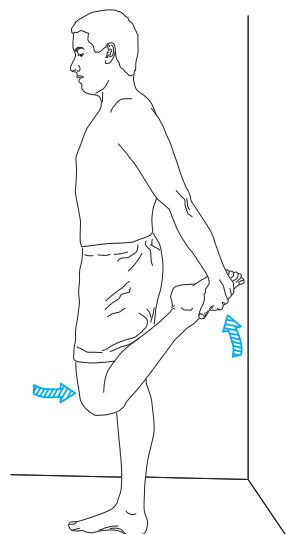

FIGURE 20.13 Self-stretch of the rectus femoris while standing. The femur is kept in line with the trunk. Care must be taken to maintain a posterior PT and not arch or twist the back.

Patient position and procedure: Supine with a towel under the thigh. Have the patient perform SLR with one extremity and apply the stretch force by pulling on the towel to move the hip into more flexion.

Doorway Stretch

Patient position and procedure: Supine, on the floor, with one leg through a doorway and the other leg (the one to be stretched) propped up against the door frame. For an effective stretch, the pelvis and opposite leg must remain on the floor with the knee extended.

- To increase the stretch when the patient is able, have the patient move the buttock closer to the doorframe, keeping the knee extended (Fig. 20.14A).
- Teach the patient to perform the hold–relax/agonist contraction technique by pressing the heel of the leg being stretched against the doorframe, causing an isometric contraction, relaxing it, then lifting the leg away from the frame (Fig. 20.14B).

Chair Stretch

Patient position and procedure: Sitting with the leg to be stretched extended across to another chair, or sitting at the edge of a treatment table, with the leg to be stretched on the table and the opposite foot on the floor. Have the patient lean the trunk forward toward the thigh, keeping the back extended so there is motion only at the hip joint (Fig. 20.15).

Bilateral Toe Touching

NOTE: Bilateral toe touching exercises are often used to stretch the hamstring muscles in exercise classes. It is important to recognize that having the patient reach for the toes does not selectively stretch the hamstrings but stretches the low back and mid-back as well. Toe touching

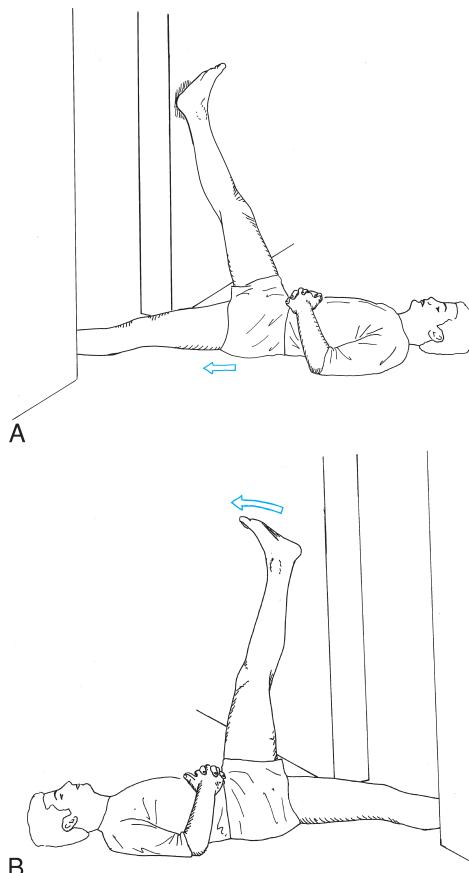

FIGURE 20.14 Self-stretching of the hamstring muscles. Additional stretch can occur if the person either (A) moves the buttock closer to the door frame or (B) lifts the leg away from the doorframe.

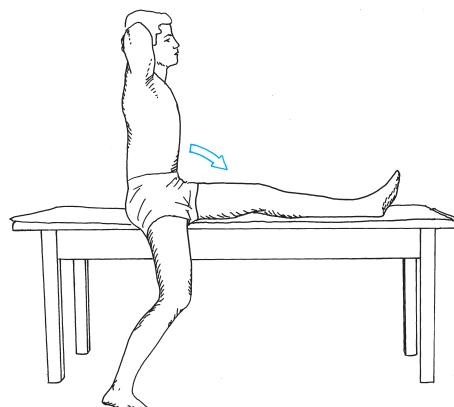

FIGURE 20.15 Self-stretching the hamstring muscles by leaning the trunk toward the extended knee, flexing at the hips.

is considered a general flexibility exercise and tends to mask shortening of soft tissues in one region and overstretch areas already flexible. Whether a person can touch the toes depends on many factors (e.g., body type; arm, trunk, and leg length; flexibility in the thoracic and lumbar regions; hamstring and gastrocnemius length).⁶⁰

Patient position and procedure: Standing. To discourage the “toe touch” idea, teach the patient to place the hands on the hips when bending forward. To specifically stretch the hamstrings using the standing forward-bend method, teach the patient to first do an anterior pelvic tilt to extend the spine; then keep the back stable and bend only at the hips (“hinge at the hips”) and go only through the range of forward bending where the spine can be maintained in extension. The stretch sensation should be felt in the hamstring region.

PRECAUTION: This stretching technique should not be used when the patient has low back impairments because forward bending greatly increases mechanical stress to the tissues of the low back.

To Stretch the Tensor Fasciae Latae

Standing Stretch

Patient position and procedure: Standing with the side to be stretched toward a wall and the hand on that side placed on the wall. Have the patient extend, adduct, and externally rotate the extremity to be stretched and cross it behind the other extremity. With both feet on the floor, have the patient shift his or her pelvis toward the wall and allow the normal knee to bend slightly (Fig. 20.16). There is a slight side-bending of the trunk away from the side being stretched.

Side-Lying Stretch

Patient position and procedure: Side-lying, with the leg to be stretched uppermost. The bottom extremity is flexed for support and the pelvis tilted laterally so the waist is against the mat or floor. Abduct the top leg and align it in the

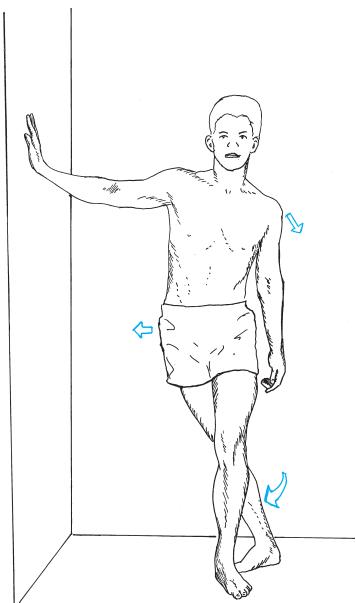

FIGURE 20.16 Self-stretching the tensor fasciae latae occurs as the trunk bends away from and the pelvis shifts toward the tight side. Increased stretch occurs when the extremity is positioned in external rotation prior to the stretch.

plane of the body (in extension). While maintaining this position, have the patient externally rotate the hip and then gradually lower (adduct) the thigh to the point of stretch (Fig. 20.17). Flex the knee to obtain additional stretch.

NOTE: It is critical to keep the trunk aligned and not allow it to roll backward because the hip would then flex and the iliotibial tract would slip in front of the greater trochanter, and an effective stretch would not take place.

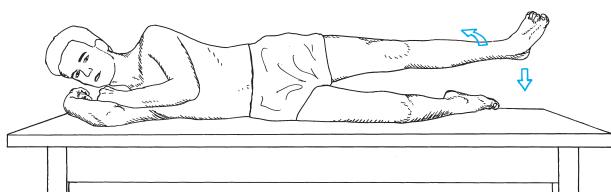

FIGURE 20.17 Tensor fasciae latae self-stretching: side-lying position. The thigh is abducted in the plane of the body; then it is extended and externally rotated, then slowly lowered. Additional stretch can occur by flexing the knee.

EXERCISES TO DEVELOP AND IMPROVE MUSCLE PERFORMANCE AND FUNCTIONAL CONTROL

During the controlled motion and return to function phases of intervention when only moderate or minimum protection of healing tissues is necessary, it is important that the patient learns to develop control of hip movement while using good trunk stability. For a muscle that has not been properly used or that has been dominated by another muscle, exercises begin with developing patient awareness of muscle contractions and movements through controlled ROM exercises. If muscle shortening has prevented full ROM, development of muscle control in any new range must immediately follow stretching activities. Principles for improving muscle performance as well as techniques for manual resistance exercise and methods of mechanical resistance are described in Chapter 6. Manually applied resistance should be used when muscles are weak or when helping the patient focus on specific muscles. Exercises described in the following sections may be adapted for home exercise programs. Choose exercises that challenge the patient to progress toward the functional goals established in the plan of care.

Non-Weight-Bearing Exercises

Even though weight-bearing activities dominate lower extremity function, when a patient is weak or has poor control of specific muscles or patterns of motion, it is advantageous to begin exercises in non-weight-bearing positions so the individual can learn to isolate muscle activity and control specific motions. In addition, many functional activities have a non-weight-bearing component,

such as the swing phase in gait, lifting the leg up to a step when going upstairs, and lifting the lower extremity into a car or onto a bed.

To Develop Control of and Strengthen Hip Abduction (Gluteus Medius and Tensor Fasciae Latae)

NOTE: Muscle imbalances in the hip that contribute to hip and/or low back pain may be seen if abduction is dominated by the tensor fasciae latae and the stabilizing forces from the gluteus medius are poorly controlled.¹¹⁶ This is seen if the patient flexes and internally rotates the thigh when abducting the hip. The posterior fibers of the gluteus medius must be trained to contract while the tensor relaxes. Techniques to do this are described below. If the patient has good control of rotation, abduction utilizing the synergy between these muscles is used.

Supine Abduction

Supine abduction is the easiest position in which to initiate motion because the effects of gravity on the abductors are eliminated. Have the patient concentrate on isolated hip abduction while keeping the trunk still. Do not let the femur roll outward into external rotation.

- For very weak patients, provide assistance or place a skate or towel under the leg to minimize the effects of friction.
- If the patient is not strong enough to progress to the side-lying position, place a weight, such as a sandbag, along the outside of the thigh or ankle and have the patient push the weight outward.

Side-Lying Abduction

Have the patient flex the bottom leg for balance, and then lift the top leg into abduction, keeping the hip neutral to rotation and in slight extension. Do not allow the hip to flex or the trunk to roll backward. Add ankle weights to provide resistance as the patient's strength improves.

If the patient has difficulty controlling hip abduction in the side lying position, use the following training sequence.

- First have the patient practice externally rotating the thigh. This may be done with the hip and knee in slight flexion while the patient lifts the uppermost knee off the mat or with the hip and knee extended while the patient rolls the uppermost extremity outward.
- Once the patient can control external rotation, have him or her extend the hip (without arching the spine) and then abduct the top leg (it should be aligned in the plane of the body). The patient then slowly adducts and abducts the thigh against gravity.

NOTE: If the tensor fasciae latae is tight, the range into extension or adduction may be limited. Stretching of this muscle should be done prior to this exercise (see Fig. 20.17). It is important that the patient does not let the hip flex or internally rotate during this exercise to minimize action of the tensor fasciae latae.

Standing Abduction

Have the patient, while standing on one leg, bring the other lower extremity out to the side. Instruct the patient to maintain the trunk upright, in neutral alignment, and not let the abducting hip flex or rotate.

- Add resistance by applying an ankle weight on the moving leg or by using pulleys or elastic resistance applied at right angles to the moving extremity.
- The abductors on the stationary lower extremity experience closed-chain resistance while stabilizing the pelvis, and the abductors on the moving extremity experience open-chain resistance.

To Develop Control of and Strengthen Hip Extension (Gluteus Maximus)

Gluteal Muscle Setting

Use gluteal setting exercises to increase awareness of the contracting muscle. Position the patient prone or supine and teach the patient to "squeeze" (contract) the buttocks.

Forward-Bending Leg Lifts

With the patient standing at the edge of the treatment table and the trunk flexed and supported on the table, have the patient alternately extend one hip, then the other. This is done with the knee flexed to train the gluteus maximus while relaxing the hamstrings. If the hamstrings cramp from active insufficiency, the patient is attempting to use them and should practice relaxing them before progressing with this exercise. Progress by adding weights or elastic resistance to the distal thigh.

Quadruped Leg Lifts

Have the patient alternately extend each hip while keeping the knee flexed (Fig. 20.18). Combine this exercise with trunk stabilization by first having the patient find the neutral pelvic position, drawing in the abdominal muscles, then extending the hip (see Chapter 16).

PRECAUTION: Care is taken not to extend the hip beyond the available range of hip extension; otherwise, the motion causes stress in the sacroiliac joint or lumbar spine.

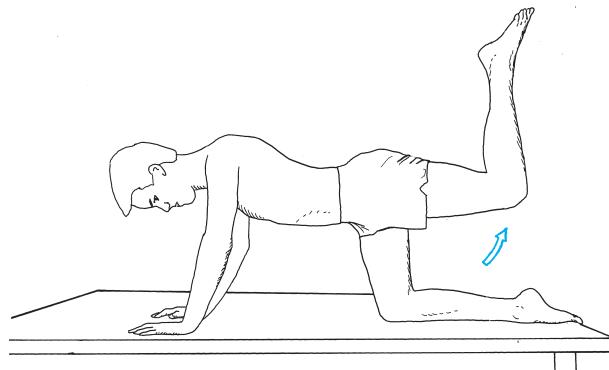

FIGURE 20.18 Isolated training and strengthening of the gluteus maximus. Starting in the quadruped position, extend the hip while keeping the knee flexed to rule out use of the hamstring muscles. Do not extend the hip beyond the available ROM to avoid causing stress to the sacroiliac or lumbar spinal joints.

To Develop Control of and Strengthen Hip External Rotation

Prone

The patient's knees are flexed and about 10 inches apart. Have the patient press the heels together, causing an isometric contraction of the external rotators.

Side-Lying

With both lower extremities partially flexed at the hips and knees and the heel of the top leg resting on the heel of the bottom leg, have the patient lift the knee of the top leg, keeping the heels together.

Progression. Have the patient extend the top hip and knee, aligning the lower extremity with the trunk, then rolling the leg outward. Progress this to lifting the entire lower extremity into abduction once the hip is externally rotated.

NOTE: Do not allow the patient to roll the trunk backward, as this exercise is done to minimize substitution with the hip flexor muscles.

Standing

With feet parallel and about 4 inches apart, have the patient flex the knees slightly, then externally rotate the thighs (so the knees are pointing laterally) while keeping the feet stationary on the floor. Tell the patient to maintain external rotation while extending the knees, then relax the rotation slightly until the patellae point forward.

Sitting

With knees flexed over the edge of the treatment table, secure elastic material around the patient's ankle and the table leg on the same side. Have the patient move the foot toward the opposite side, pulling against the resistance, causing external rotation of the hip.

NOTE: Do not allow substitution with knee flexion or extension or hip abduction.

To Develop Control of and Strengthen Hip Adduction

Side-Lying

With the bottom leg aligned in the plane of the trunk (hip extension) and the top leg flexed forward with the foot on the floor or with the thigh resting on a pillow, have the patient lift the bottom leg upward into adduction. Weights can be added to the ankle to progress strengthening (Fig. 20.19A). A more difficult position is to have the patient hold the top leg in abduction and adduct the bottom leg up to meet it (Fig. 20.19B).

Standing

Have the patient adduct the leg across the front of the weight-bearing leg. Add ankle weights to provide resistance, or fasten elastic resistance or a pulley at right angles to the moving leg.

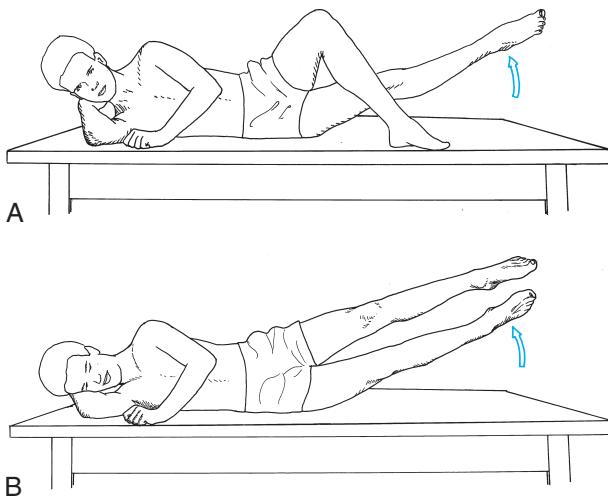

FIGURE 20.19 Training and strengthening the hip adductors. (A) The top leg is stabilized by flexing the hip and resting the foot on the mat while the bottom leg is adducted against gravity. (B) The top leg is isometrically held in abduction while the bottom leg is adducted against gravity.

Closed-Chain Weight-Bearing Exercises

Weight-bearing exercises in the lower extremity involve all of the joints in the closed chain and are therefore not limited to hip muscles. Most activities bring into play antagonistic two-joint muscles in which each muscle is being lengthened across one joint while it is shortening across another, thus maintaining an optimal length-tension relationship. In addition to causing motion, a prime function of the muscles in weight bearing is to control against the forces of gravity and momentum for balance and stability. Therefore, the exercises described in this section include balance and stabilization training as well as strengthening and functional exercises.

Closed-Chain Strengthening and Functional Training

Strengthening and balance activities in weight-bearing postures described in the following section are closely related and are progressed concurrently as the patient is able.

Hip Hiking/Pelvic Drop

Position the patient with one leg on a 2- to 4-inch block and alternately lower and elevate the pelvis on the side of the unsupported leg (Fig. 20.20). This develops control in the abductors of the stance leg and hip hikers on the unsupported side.

Focus on Evidence

In an EMG study by Bolgia and Uhl,²⁰ a series of 16 healthy subjects performing six different abductor exercises using a constant weight. The authors documented significantly greater maximum voluntary contraction of the gluteus medius in the stance leg (weight-bearing leg) during the pelvic drop exercise than during other hip abduction exercises. In addition, standing hip abduction showed significantly greater hip abductor activity on the

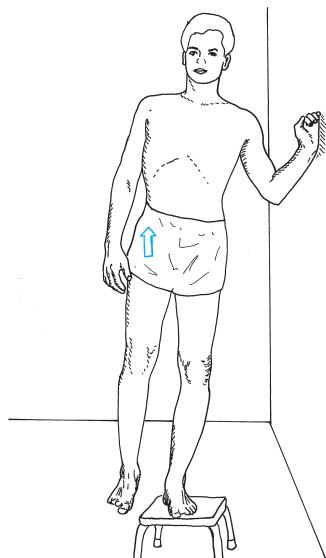

FIGURE 20.20 Training the hip abductor and hiker muscles for frontal plane strengthening and stability.

weight-bearing side than on the moving (open-chain) side; the activity on the weight-bearing side had a comparable maximum voluntary contraction as side-lying hip abduction.

Bridging

Beginning in the hook-lying position, have the patient press the upper back and feet into the mat, elevate the pelvis, and extend the hips (Fig. 20.21).

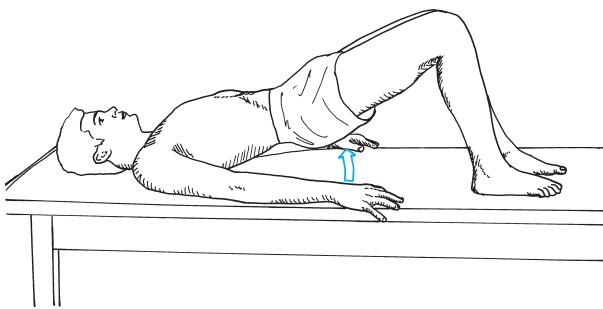

FIGURE 20.21 Training and strengthening the hip extensor muscles using bridging exercises. Resistance can be added against the pelvis.

Progressions. Apply resistance against the anterior pelvis manually or by strapping a weighted belt around the pelvis. To challenge proprioception and balance, have the patient perform bridging exercises using a large gym ball positioned either under the back with feet on the floor or under the feet while lying on the floor.

Single-Leg Stance Against Resistance

Have the patient stand on the involved leg. Place elastic resistance around the thigh of the other extremity and

secure it to a stable upright structure. If the knee is stable, the resistance can be applied around the ankle. Fatigue is determined when the patient can no longer hold the weight-bearing extremity or pelvis stable.

- To resist *hip flexion*, the patient faces away from where the resistance is secured.
- To resist *extension*, the patient faces toward where the resistance is secured (Fig. 20.22A).
- To resist *abduction* and *adduction* the patient faces so the band is directed toward one side and then the other (Fig. 20.22B).

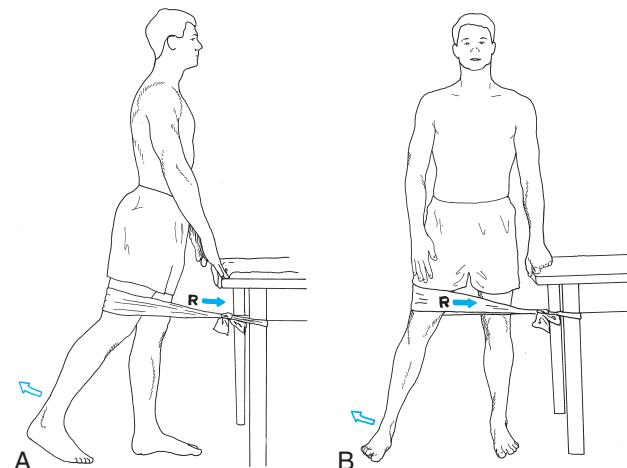

FIGURE 20.22 Closed-chain exercise with elastic resistance around the opposite leg. (A) Resisting extension on the right requires stabilization of anterior muscles of the left side. (B) Resisting abduction on the right requires stabilization of the left frontal plane muscles. To increase difficulty, the resistance is moved distally onto the leg.

NOTE: This activity is open-chain on the side of the moving extremity and closed-chain on the weight-bearing side.

Step-Ups

Begin with a low step, 2 to 3 inches in height; progress the height as the patient is able. Have the patient step up sideways, forward, or backward. Be sure that the entire foot is planted on the step and that the body is lifted and then lowered with smooth motion, with no lurching of the trunk or pushing off with the trailing extremity.

Progressions: In addition to increasing the step height, resistance can be added with a weight belt, with weights in the hands or around the ankle of the non-weight-bearing leg.

Lunges

Have the patient stride forward and flex the hip and knee of the forward extremity and then return upright. Repeat, or alternate legs. Begin with flexing the knee a small range and progressing to 90° knee flexion.

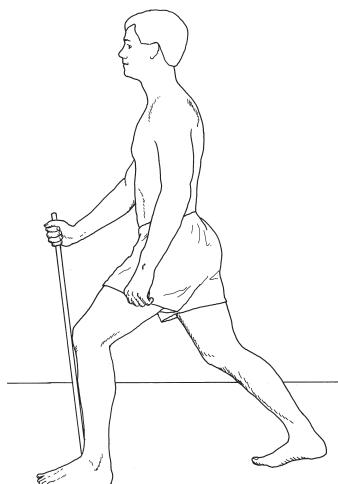

FIGURE 20.23 Lunge with cane assistance to develop balance and control for lowering body weight.

- If the patient has difficulty with balance or control, have him or her use a cane or rod for balance, or begin the activity holding on in the parallel bars or beside a treatment table (Fig. 20.23).
- It is important to instruct the patient to keep the toes pointing forward, bend the knee in the same plane as the feet, and keep the back upright.

Progressions: Progressions include using weights in the hands for resistance, taking a longer stride, or lunging forward onto a small step. This exercise is progressed to a functional activity by having the patient lunge and pick up objects from the floor.

NOTE: A patient with an anterior cruciate ligament (ACL) deficiency or a surgically repaired ACL should not flex the knee forward of the toes when performing lunges because this increases the shear force and stress to the ACL. Individuals with patellofemoral compression syndrome experience increased pain under these circumstances because the compressive force from the body weight is greater when it is kept posterior to the knee. Adapt the position of the knee based on the patient's symptoms and presenting pathology.

Wall Slides

Have the patient rest the back against a wall with feet forward and shoulder-width apart. Instruct the patient to slide the back down the wall by flexing the hips and knees and dorsiflexing the ankle; then slide up the wall by extending hips and knees and plantarflexing the ankles (Fig. 20.24A). If sliding the back directly against the wall causes excessive friction, place a towel behind the patient's back.

Progressions: A large exercise ball (Swiss ball) placed behind the back requires additional control because it is less stable (Fig. 20.24B). Add arm motions and weights to develop coordination or add resistance. To develop isometric strength, have the patient hold the flexed position and superimpose arm motions with weights.

Partial Squats/Mini-Squats

Have the patient lower the trunk by flexing the hips and knees as if sitting on a chair. Add resistance by having the patient hold weights in the hands or use elastic resistance secured under the feet (see Fig. 21.20). Progress to safe lifting techniques that involve squatting.

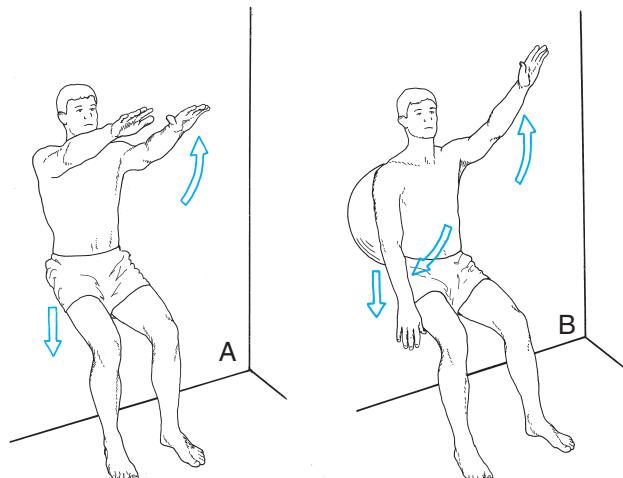

FIGURE 20.24 Wall slides/partial squats to develop eccentric control of body weight. (A) The back sliding down a wall, superimposing bilateral arm motion for added resistance. (B) The back rolling a gym ball down the wall, superimposing antagonistic arm motion to develop coordination.

NOTE: To protect the ACL, knee flexion range is limited to 0° to 60°, and the patient is instructed to lower the hips as if preparing to sit on a chair so the knees stay behind the toes. To protect a patellofemoral compression problem, instruct the patient to squat only through pain-free ranges and avoid deep knee bends.

Equipment

Mechanical equipment such as a leg press, Total Gym® treadmill, bicycle, slide board, or Profitter™ may be used for strengthening, balance, coordination, and endurance.

Postural Control and Balance Activities

As noted earlier, weight-bearing control and balance training begin as soon as the patient tolerates partial weight bearing. For a detailed discussion on balance, see Chapter 8.

Weight Shifting

- If the patient cannot bear full weight, begin in the parallel bars with part of the weight borne by the hands. An overhead harnessing system can also be used to unweight the lower extremities.
- Have the patient shift anterior to posterior, side to side, and obliquely.
- Add manual resistance to the motion by applying pressure against the patient's pelvis.

Balance Activities with Arm Movements

- Begin with bilateral weight bearing and progress to unilateral weight bearing. First have the patient move his or her arms in the sagittal and frontal planes, then progress to the transverse and diagonal planes.
- As the patient demonstrates the ability to balance with simple arm movements, progress to moving the arms and following the movement with the eyes and head. Then progress to moving the entire trunk through planes of motion following the arm motions.

Marching and Resisted Walking

- Once the patient can shift weight and maintain balance with arm movements, have him or her alternately pick up each foot and march in place.
- Progress to moving each leg forward and backward and learning to accept weight on the moving leg.
- Once the patient can step and walk, progress to resisted walking by applying resistance at the pelvis or have the patient walk against an elastic or pulley resistance secured around the pelvis (Fig. 20.25).

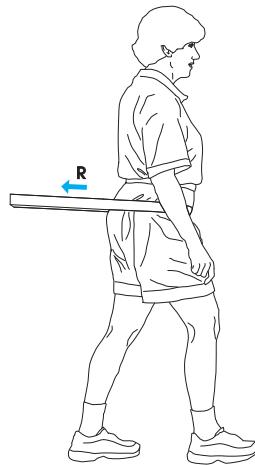

FIGURE 20.25 Resisted walking using a large elastic resistance band secured around the pelvis.

Alternating Isometrics and Rhythmic Stabilization

Alternating isometrics and rhythmic stabilization develop postural adjustments to applied forces.

- Apply manual resistance against the pelvis in alternating directions and ask the patient to hold (with isometric contractions). There should be little or no movement.
- Vary the force and direction of resistance; also vary where the force is applied by shifting the resistance from the pelvis to the shoulders and eventually against outstretched arms (see Fig. 22.15).
- At first, use verbal cueing. Then, as the patient learns control, apply the varying forces without warning. Progress the patient to unilateral standing.

- Teach the patient a self-applied stabilization technique using elastic resistance secured around the thigh or leg of one extremity and then rapidly move the extremity forward and backward against the elastic force (see Fig. 20.22 for the setup). The rapid motion requires stabilization on the weight-bearing side.

Balance Training on Unstable Surfaces

- Have the patient stand with bilateral support on foam, a rocker board, wobble board, or BAPS board and begin with single-plane weight shifting forward/backward and side to side.
- Progress by placing the extremities in a diagonal plane and have the patient shift the weight from one extremity to the other.
- When able, have the patient progress to single-leg activities on an unstable surface.

Advanced Stability and Balance Activities

- Have the patient stand on an unstable surface, such as a rocker or wobble board, and maintain balance without the edges of the board touching the ground while a partner tosses a weighted ball to the patient from various angles.
- Have the patient hold onto the two ends of an elastic resistance band while someone pulls against it in various directions and with varying speeds.

Functional Training

The level of challenge of the exercise program depends on the activities the patient is required to perform in his or her ADL, IADL, work, or sport-related tasks; and the challenge level therefore affects the desired outcomes. An outcome may be simply learning how to ambulate forward, backward, and around obstacles safely, or it may involve developing a high level of coordination, balance, and skill to climb, perform complicated dance maneuvers, engage in gymnastics, or run and jump. Analyze the patient's exercise techniques and adapt them whenever necessary to avoid unsafe stresses.

Suggestions for progressive functional training include:

- Increase challenges for ambulation, such as having the patient walk on uneven surfaces, turn, maneuver backward, and walk up and down ramps first under supervision and then unassisted. As soon as the patient is able, have him or her practice rising up and sitting down from chairs of various heights and climbing and descending flights of stairs.
- Incorporate exercises that prepare the musculature for safe body mechanics such as repetitive squats and lunges. Progress the exercises by having the patient lift and carry or push and pull various loads as part of the exercise routine. Utilize safe patterns of motion that replicate functional requirements.

- Use agility drills such as maneuvering around and stepping over obstacles. Incorporate running, jumping, hopping, skipping, and side-shuffle drills.
- If the patient is returning to activities that require strength and power, incorporate plyometric drills. For example, have the patient jump from a box or step; flex the hips, knees, and ankles to absorb the impact of landing; and immediately jump back up to the box or step.
- Use maximum eccentric loading. Any of the previously described exercises can be adapted, but it is critical to assist the patient through the concentric phase of the exercise and guard him or her through the eccentric phase as the resistance is great. These are not exercises the patient can do alone.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Describe the function of the primary muscle groups of the hip joint in open- and closed-chain situations. Include their role in stabilizing the pelvis during single leg stance and the effects on the spine when the pelvis is moved by the hip musculature.
2. Describe the role of the hip during the gait cycle. Include muscle activity, motion needed, and pathological gait patterns when there is muscle weakness or restricted motion.
3. Analyze the type of gait deviations a patient might exhibit after internal fixation of a fracture of the proximal femur, total hip arthroplasty, or hemiarthroplasty of the hip.
4. After total hip arthroplasty or internal fixation of a hip fracture, what are the signs that dislocation of the hip or loss of fracture stabilization has occurred?

● Laboratory Practice

1. Identify and practice the techniques you would use to treat a mobility impairment if the results of your examination included decreased joint play versus restricted flexibility in the hip musculature. Include exercises that could be used in a home exercise program.
2. Demonstrate a progression of exercises to develop control and strength in the gluteus medius muscle after total hip replacement.
3. Develop an exercise routine and progression for an individual with hip muscle weakness who wants to return to work that requires walking, lifting objects that weigh up to 45 lb, and climbing ladders with 45-lb weights.

● Case Studies

1. Mr. C., 57 years of age, is a mail carrier; he has walked his mail route for 32 years and is proud “that he has no heart problems.” Over the past year he has noticed that his hip hurts after sitting for more than 1 hour and that there is a marked increase in pain when first getting up out of a chair and walking. He also has noticed that there is increased discomfort in his hip and knees near the end of each workday. The medical diagnosis is osteoarthritis. Strength testing reveals generally 4/5 on manual muscle tests except the gluteus medius, which is

- 3+/5. There is mild tightness in the hip flexors, including the rectus femoris and tensor fasciae lata. He wants to avoid being a “candidate for total hip replacement surgery.”
- Explain why the patient’s job would perpetuate these symptoms.
 - Outline a plan to manage the symptoms; identify measurable goals and interventions you would use to reach the goals.
 - What can the patient do to protect his hip joints?
2. Ms. J., a 31-year-old mother, recreational tennis player, and bowler, is recovering from multiple femoral fractures that she sustained in an automobile accident 3 months ago. There is radiological healing of all the fracture sites, and she is now allowed full weight bearing and no restrictions in activities. She has significant hip mobility impairments from joint restrictions and muscle weakness.
 - What joint ranges and muscle strength levels are needed for her to return to her functional activities?
 - Outline a plan to manage the symptoms; identify measurable goals and interventions you would use to reach the goals. Using the taxonomy or motor skills described in Chapter 1, develop a series of progressively more challenging motor tasks under varying environmental conditions.
 3. Mr. C. is a 32-year-old firefighter who strained his hamstrings at the ischial tuberosity while pulling a 250-lb individual out of a burning building. It happened 4 days ago. Currently, he is experiencing considerable pain, is unable to sit on hard surfaces (because of pressure as well as flexing the hip), and has pain when arising from or lowering himself into a chair and climbing or descending stairs. Hip flexion is limited to 90° and straight-leg raising to 45°. He tolerates minimal resistance to hip extension or knee flexion. This individual must be able to climb a ladder while wearing his gear (40 lb) and air pack (40 lb) and carrying a 20-lb hand tool; in addition, he must be able to carry a 175-lb individual across his shoulder, drag a heavy body across the floor, climb five flights of stairs wearing full gear, and run 1/2 mile in 5 minutes to be able to return to work.
 - Explain why this patient has impaired function in biomechanical terms.

- Establish goals that reflect treatment of the impairments and desired functional outcomes.
 - Design a program of intervention at each stage of tissue healing.
 - Design a series of exercises that can be used to prepare Mr. C. for return to function once the muscle has healed.
4. A 78-year-old woman who lives at home with her husband has been referred to you for home-based physical therapy. Ten days ago she underwent cemented THA with a posterolateral approach for late-stage post-traumatic arthritis associated with injuries sustained in a horseback riding accident 30 years ago. She has been home from the hospital for 5 days. She is ambulating with a walker on level surfaces, and weight bearing is tolerated. The patient's long-term goals

- are to be able to participate in a community-based fitness program for older adults and resume travel vacations with her husband.
- Continue progressing her exercise program that was initiated in the hospital.
 - Review the precautions she must take for the next 6 to 12 weeks during ADL.
 - Make suggestions on how she or her husband might adapt the home environment to help her adhere to the precautions.
 - To help her meet her long-term goals, design a sequence of progressively more demanding functional activities, integrating the taxonomy of motor tasks (addressed in Chapter 1) and the principles of aerobic conditioning (discussed in Chapter 5).

The knee joint is designed for mobility and stability; it functionally lengthens and shortens the lower extremity to raise and lower the body or to move the foot in space. Along with the hip and ankle, it supports the body when standing, and it is a primary functional unit in walking, climbing, and sitting activities.

As in the other chapters in this section of the text, this chapter is divided into three primary sections. Highlights of the anatomy and function of the knee complex are reviewed in the first section of this chapter, followed by material on the management of disorders and surgeries. The third section includes exercise interventions for the knee region. Chapters 10 through 13 present general information on principles of management. The reader should be familiar with the material in these chapters as well as have a background in examination and evaluation in order to effectively design a therapeutic exercise program to improve knee function in patients with impairments due to injury or pathology or following surgery.

STRUCTURE AND FUNCTION OF THE KNEE

The bones of the knee joint consist of the distal femur with its two condyles, the proximal tibia with its two tibial plateaus, and the large sesamoid bone in the quadriceps tendon, the patella. It is a complex joint both anatomically and biomechanically (Fig. 21.1).²²³ The proximal tibiofibular joint is anatomically close to the knee but is enclosed in a separate joint capsule and functions with the ankle. Therefore, the proximal tibiofibular joint is discussed in Chapter 22.

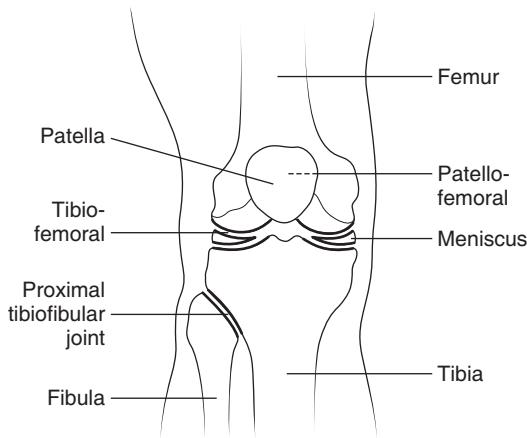

FIGURE 21.1 Bones and joints of the knee and leg.

JOINTS OF THE KNEE COMPLEX

A lax joint capsule encloses two articulations: the tibiofemoral and the patellofemoral joints. Recesses from the capsule form the suprapatellar, subpopliteal, and gastrocnemius bursae. Folds or thickenings in the synovium persist from embryologic tissue in up to 60% of individuals and may become symptomatic with microtrauma or macrotrauma.^{19,107}

Tibiofemoral Joint

Characteristics. The knee joint is a biaxial, modified hinge joint with two interposed menisci supported by ligaments and muscles. Anteroposterior stability is provided by the cruciate ligaments; mediolateral stability is provided by the medial (tibial) and lateral (fibular) collateral ligaments, respectively (Fig. 21.2).^{31,221,223}

- The convex bony partner is composed of two asymmetrical condyles on the distal end of the femur. The medial condyle is longer than the lateral condyle, which contributes to the locking mechanism at the knee.
- The concave bony partner is composed of two tibial plateaus on the proximal tibia with their respective

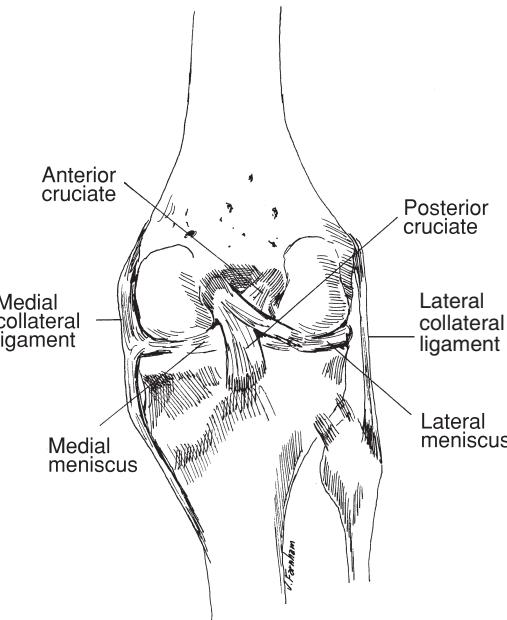

FIGURE 21.2 The medial meniscus is attached to the medial collateral, anterior cruciate, and posterior cruciate ligaments. The lateral meniscus is also attached to the posterior cruciate ligament (the joint capsule has been removed for visualization). (From Snyder-Mackler.²²³ In: Levangie and Norkin, p. 398, with permission.)

fibrocartilaginous menisci. The medial plateau is larger than the lateral plateau.

- The menisci improve the congruency of the articulating surfaces. They are connected to the tibial condyles and capsule by the coronary ligaments, to each other by the transverse ligament, and to the patella via the patellofemoral ligaments.²²³ The medial meniscus is firmly attached to the joint capsule as well as to the medial collateral ligament, anterior and posterior cruciate ligaments, and semimembranosus muscle. The lateral meniscus attaches to the posterior cruciate ligament and the tendon of the popliteus muscle through capsular connections.²²³ Because of the relatively secure attachment of the medial meniscus compared to the lateral meniscus (see Fig. 21.2), it has a greater chance of sustaining a tear when there is a lateral blow to the knee.

Arthrokinematics. Joint mechanics are affected by open- and closed-chain positions of the extremity and are summarized in Box 21.1. Rotation occurs as the knee flexes and extends.

- With motions of the tibia (open kinematic chain), the concave plateaus slide in the same direction as the bone motion. Terminal extension results in the tibia rotating externally on the femur; with flexion, the tibia rotates internally.
- With motions of the femur on a fixated tibia (closed kinematic chain), the convex condyles slide in the direction opposite to the bone motion.

Screw-home mechanism. The rotation that occurs between the femoral condyles and the tibia during the final degrees of extension is called the locking, or screw-home, mechanism. When the tibia is fixed with the foot on the ground (closed kinematic chain), terminal extension results in the femur rotating internally (the medial condyle slides farther posteriorly than the lateral condyle). Concurrently, the hip moves into extension. Tautness in the iliofemoral ligament, which occurs with hip extension, reinforces the medial rotation of the femur. As the knee is unlocked, the femur rotates laterally. Unlocking of the knee occurs indirectly with hip flexion and directly from action of the popliteus muscle. An individual who lacks full hip extension (hip

flexion contracture) cannot stand upright and lock the knee, thus lacking this passive stabilizing function.

Patellofemoral Joint

Characteristics. The patella is a sesamoid bone in the quadriceps tendon. It articulates with the intercondylar (trochlear) groove on the anterior aspect of the distal portion of the femur. Its articulating surface is covered with smooth hyaline cartilage. The patella is embedded in the anterior portion of the joint capsule and is connected to the tibia by the ligamentum patellae. Many bursae surround the patella.²²³

Mechanics. As the knee flexes, the patella enters the intercondylar groove with its inferior margin making first contact and then slides caudally along the groove. With extension, the patella slides superiorly. If patellar movement is restricted, it interferes with the range of knee flexion and may contribute to an extensor lag with active knee extension.²³⁵

PATELLAR FUNCTION

The primary function of the patella is to increase the moment arm of the quadriceps muscle in its function to extend the knee. It also redirects the forces exerted by the quadriceps.

Patellar Alignment

The alignment of the patella in the frontal plane is influenced by the line of pull of the quadriceps muscle group and by its attachment to the tubial tubercle via the patellar tendon. The result of these two forces is a bowstring effect on the patella, causing it to track laterally. One method of describing the bowstring effect is to measure the Q-angle. The *Q-angle* is the angle formed by two intersecting lines: one from the anterior superior iliac spine to the mid-patella, the other from the tubial tubercle through the mid-patella (Fig. 21.3).^{141,223} A normal Q-angle, which tends to be greater in women than men, is 10° to 15°.

BOX 21.1

Summary of Arthrokinematics of the Knee Joint

Physiological Motion	Roll	Slide
<i>Tibial motion—open chain</i>		
Flexion	Posterior and medial rotation	Posterior
Extension	Anterior and lateral rotation	Anterior
<i>Femoral motion—closed chain</i>		
Flexion	Posterior and lateral rotation	Anterior
Extension	Anterior and medial rotation	Posterior

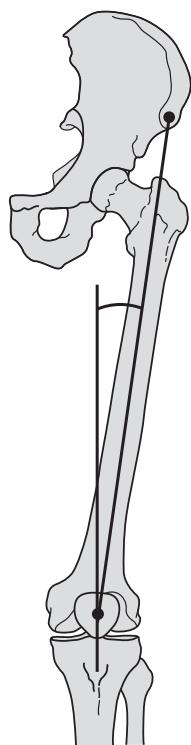

FIGURE 21.3 The Q-angle is the angle formed by the intersection of a line drawn from the center of the patella to the anterosuperior iliac spine and a line drawn from the center of the patella to the tibial tuberosity. These two lines represent the bowstring effect on the patella from the pull of the quadriceps femoris muscle and the patellar tendon. An increased Q-angle is a factor contributing to excessive lateral tracking of the patella. (From McKinnis,¹⁴¹ p. 332, with permission.)

Forces Maintaining Alignment

In addition to the bony restraints of the trochlear groove (femoral sulcus), the patella is stabilized by passive and dynamic (muscular) restraints. The superficial portion of the extensor retinaculum, to which the vastus medialis and vastus lateralis muscles have an attachment, provides dynamic stability in the transverse plane. The medial and lateral patellofemoral ligaments, which attach to the adductor tubercle medially and iliotibial band laterally provide passive restraints to the patella in the transverse plane.²²³ Longitudinally, the medial and lateral patellotibial ligaments and patellar tendon fixate the patella inferiorly against the active pull of the quadriceps muscle superiorly (Fig. 21.4).

Patellar Malalignment and Tracking Problems

Malalignment and tracking problems of the patella may be caused by several factors that may or may not be interrelated.^{81,135}

Increased Q-angle. With an increased Q-angle there may be increased pressure of the lateral facet against the lateral femoral condyle when the knee flexes during weight bearing. Structurally, an increased Q-angle occurs with a wide pelvis, femoral anteversion, coxa vara, genu valgum, and laterally displaced tibial tuberosity. Lower extremity motions in the transverse plane that may increase the Q-angle are external tibial rotation, internal femoral rotation, and a pronated subtalar joint. Functional knee valgus that occurs during dynamic activities also increases the Q-angle.¹⁸⁹

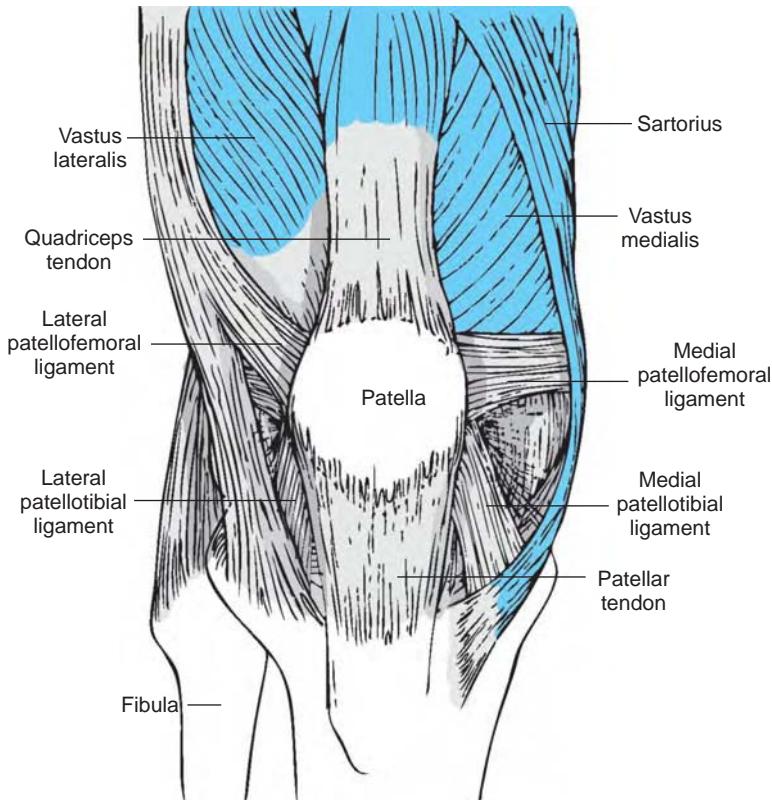

FIGURE 21.4 The extensor retinaculum is reinforced medially by the transversely oriented medial patellofemoral ligament and the longitudinally oriented medial patellotibial ligament. Laterally, the lateral patellofemoral ligament and lateral patellotibial ligament help resist an excessive medial glide of the patella. (From Snyder-Mackler.²²³ In: Levangie and Norkin, p. 401, with permission.)

Muscle and fascial tightness. A tight iliotibial (IT) band and lateral retinaculum prevent medial gliding of the patella. Tight ankle plantarflexors result in pronation of the foot when the ankle dorsiflexes, causing medial torsion of the tibia and functional lateral displacement of the tibial tuberosity in relationship to the patella. Tight rectus femoris and hamstring muscles may affect the mechanics of the knee, leading to compensations.¹³⁵

Lax medial capsular retinaculum or an insufficient VMO muscle. The vastus medialis obliquus (VMO) muscle may be weak from disuse or inhibited because of joint swelling or pain, leading to poor medial stability.²²⁵ Poor timing of its contraction, which alters the ratio of firing between the VMO and vastus lateralis (VL) muscle, may lead to an imbalance of forces.^{201,242} Weakness or poor timing of VMO contractions increase the lateral drifting of the patella.

Hip muscle weakness. Weakness of the hip abductors and external rotators may result in adduction of the femur and valgus at the knee under loaded weight bearing.^{100,189}

Patellar Compression

Patellar contact. The posterior surface of the patella has several facets. It is not completely congruent as it articulates with the trochlear groove on the femur. When the knee is in complete extension (0°), the patella is superior to the trochlear groove. By 15° of flexion the inferior border of the patella begins to articulate with the superior aspect of the groove. As the knee flexes, the patella slides distally in the groove, and more surface area comes in contact. Beyond 60° there is controversy as to whether the contact area continues to increase, level off, or decrease.^{80,81} In addition, as the knee flexes past 90°, the quadriceps tendon comes in contact with the trochlear groove as the patella slides inferiorly.

Compression forces. In full extension, because there is minimal to no contact of the patella with the trochlear groove, there is no compression of the articular surfaces. Furthermore, because the femur and tibia are almost parallel, the line of pull of the quadriceps muscle and patellar tendon causes a very small resultant compressive load. The resultant force of the quadriceps and patellar tendon forces rises as the knee flexes, but there is also greater surface area of the patella in contact with the groove to dissipate this force. The joint reaction force on the articular surface rises rapidly between 30° and 60°. There is controversy as to the extent of joint reaction forces in greater degrees of flexion.

- During squatting, the joint reaction force continues to rise until 90° and then levels off or decreases because the quadriceps tendon begins making contact with the trochlear groove and therefore dissipates some of the force.⁸⁰
- In an open-chain exercise with a free weight on the distal leg, the greatest joint reaction force occurs at around 30°

of flexion.⁸⁰ This is because of the changing moment arm of the resistive force more than the line of pull of the quadriceps and patellar tendons. In an open-chain with variable resistance, the peak stress is at 60° and peak compression at 75°.⁵⁶

- An increased Q-angle causes increased lateral facet pressure as the knee flexes.¹⁸⁹

● MUSCLE FUNCTION

Knee Extensor Muscle Function

The quadriceps femoris muscle group is the only muscle crossing anterior to the axis of the knee and is the prime mover for knee extension. Other muscles that can act to extend the knee require the foot to be fixated, creating a closed chain. In this situation, the hamstrings and the soleus muscles can cause or control knee extension by pulling the tibia posteriorly.

Closed-chain function. During standing and the stance phase of gait, the knee is an intermediate joint in a closed chain. The quadriceps muscle controls the amount of flexion at the knee and also causes knee extension through reverse muscle pull on the femur. In the erect posture, when the knee is locked, the quadriceps need not function when the gravity line falls anterior to the axis of motion. In this case, tension in the hamstring and gastrocnemius tendons supports the posterior capsule.

Patella. The patella improves the moment arm of the extensor force by increasing the distance of the quadriceps tendon from the knee joint axis. Its greatest effect on the leverage of the quadriceps is during extension of the knee from 60° to 30° and rapidly diminishes from 15° to 0° of extension.^{83,223}

Torque. The peak torque of the quadriceps muscle occurs between 70° and 50°.²⁸ The physiological advantage of the quadriceps rapidly decreases during the last 15° of knee extension because of its shortened length. This, combined with its decreased moment arm in the last 15°, requires the muscle to significantly increase its contractile force when large demands are placed on the muscle during terminal extension.⁸³

- During standing, assistance for extension comes from the hamstring and soleus muscles as well as from the mechanical locking mechanism of the knee. In addition, the anterior cruciate ligament and the pull of the hamstring muscle group counter the anterior translation force of the quadriceps muscle.^{63,134}
- During open-chain knee extension exercises in the sitting or supine position, when the resistive force is maximum in terminal extension because of the moment arm of the resistance a relatively strong contraction of the quadriceps muscle is required to overcome the physiological and mechanical disadvantages of the muscle to complete the final 15° of motion.⁸³ However, it is worth mention-

ing that the compressive loads on the patella also decrease in terminal extension because of its superior location with respect to the trochlear groove and the resultant force of the line of pull of the quadriceps and patellar tendon.

- The therapist needs to be aware of the effect of the resistance and where in the range of motion the muscle is being challenged. During open-chain exercises with fixed resistance, when the resistance torque challenges the quadriceps in terminal extension there is little challenge mid-range where the muscle is capable of generating greater tension.

Knee Flexor Muscle Function

The hamstring muscles are the primary knee flexors and also influence rotation of the tibia on the femur. Because they are two-joint muscles, they contract more efficiently when they are simultaneously lengthened over the hip (during hip flexion) as they flex the knee. During closed-chain activities, the hamstring muscles can assist with knee extension by pulling on the tibia.

- The gastrocnemius muscle can also function as a knee flexor, but its prime function at the knee during weight bearing is to support the posterior capsule against hyperextension forces.
- The popliteus muscle supports the posterior capsule and acts to unlock the knee.
- The pes anserinus muscle group (sartorius, gracilis, semitendinosus) provides medial stability to the knee and affects rotation of the tibia in a closed chain.

Dynamic Stability of the Knee

Because of the incongruity of the femoral condyles and tibial plateaus, there is little stability from the bony architecture. The cruciate and collateral ligaments provide significant passive stability in the various ranges of joint motion. Dynamic stability involves motor control of the neuromuscular system to coordinate muscle activity around the joint. The complex feedforward and feedback responses mediated by the central nervous system modulate muscle stiffness and are important for providing dynamic knee stability under varying loads and stresses imposed on the joint structures.²⁵⁴ As summarized in a clinical commentary by Williams,²⁵⁴ clinical and scientific evidence is accumulating to substantiate exercise programs that have the purpose of training dynamic knee stability; that is, to improve control of the knee via neuromuscular responses in order to reduce knee ligament stress and injury during high-intensity activities.

THE KNEE AND GAIT

During the normal gait cycle, the knee goes through a range of 60° (0° extension at initial contact or heel strike

to 60° at the end of initial swing). There is some medial rotation of the femur as the knee extends at initial contact and just prior to heel-off.^{185,223}

Muscle Control of the Knee During Gait

Stability during the gait cycle is efficiently controlled by the normal function of the muscles that attach at the knee.^{172,185}

Quadriceps. The quadriceps muscle controls the amount of knee flexion during initial contact (loading response) and then extends the knee toward mid-stance. It again controls the amount of flexion during pre-swing (heel-off to toe-off) and prevents excessive heel rise during initial swing. With loss of quadriceps function, the patient lurches the trunk anteriorly during initial contact to move the center of gravity anterior to the knee so it is stable or rotates the extremity outward to lock the knee.²²⁸ With fast walking, there may be excessive heel rise during initial swing.

Hamstrings. The hamstring muscles primarily control the forward swing of the leg during terminal swing. Loss of function may result in the knee snapping into extension during this period. The hamstrings also provide posterior support to the knee capsule when the knee is extended during stance. Loss of function results in progressive genu recurvatum.²²⁸

Soleus. The unijoint ankle plantarflexor muscles (primarily the soleus) help control the amount of knee flexion during pre-swing by controlling the forward movement of the tibia. Loss of function results in hyperextension of the knee during pre-swing (also loss of heel rise at the ankle and thus a lag or slight dropping of the pelvis on that side during the pre-swing phase).

Gastrocnemius. The gastrocnemius muscle provides tension posterior to the knee when it is in extension (end of loading response or foot flat and just prior to pre-swing or heel-off). Loss of function results in hyperextension of the knee during these periods as well as loss of plantarflexion during pre-swing or push-off.

Hip and Ankle Impairments

Because the knee is the intermediate joint between the hip and foot, problems in these two areas can interfere with knee function during gait. Examples:

Hip flexion contractures. Inability to extend the hip prevents the knee from extending just before terminal stance (heel-off).

Length/strength imbalances. Most of the muscles functioning to control the hip are two-joint muscles that also cross the knee. With asymmetry of length and strength, unbalanced forces may stress various structures in the knee, giving rise to pain during walking or running. For example, a tight tensor fasciae latae or gluteus maximus

muscle increases stress on the IT band, which could lead to lateral knee pain; or it could affect tracking of the patella and lead to anterior knee pain. Overuse of the hamstring muscle group increases posterior translation forces on the tibia, requiring compensation in the quadriceps femoris muscle and resulting in anterior knee pain (see Chapter 20).

Foot impairments. The position and function of the foot and ankle affect the stresses transmitted to the knee. For example, with pes planus or pes valgus, there is medial rotation of the tibia and an increased bowstring effect on the patella, increasing the lateral tracking forces.

REFERRED PAIN AND NERVE INJURIES

For a detailed description of referred pain patterns and peripheral nerve injuries in the knee region see Chapter 13.

Major Nerves Subject to Injury at the Knee

The sciatic nerve divides into the tibial and common peroneal nerves just proximal to the popliteal fossa. These nerves are relatively well protected deep in the fossa.

- The *common peroneal nerve* (L2-4) becomes superficial where it winds around the fibula just below the fibular head, a common site for injury. Symptoms of sensory loss and muscle weakness are distal to that site.
- The *saphenous nerve* (L2-4) is a sensory nerve that innervates the skin along the medial side of the knee and leg. It may be injured with trauma or surgery in that region.

Common Sources of Referred Pain

Nerve roots and tissues derived from spinal segments L3 refer to the anterior aspect, and those from S1 and S2 refer to the posterior aspect of the knee.³⁸ The hip joint, which is primarily innervated by L3, may refer symptoms to the anterior thigh and knee. Therapeutic exercise for the knee is beneficial only for preventing disuse of the part. Primary treatment must be directed to the source of the irritation.

MANAGEMENT OF KNEE DISORDERS AND SURGERIES

To make sound clinical decisions when treating patients with knee disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting impairments, functional limitations, and possible disabilities. In this section common pathologies and surgical procedures are presented and related to corresponding preferred practice patterns (group

ings of impairments) described in the *Guide to Physical Therapist Practice*² (Table 21.1). Conservative and post-operative management of these conditions is described in this section.

JOINT HYPOMOBILITY: NONOPERATIVE MANAGEMENT

Common Joint Pathologies and Associated Impairments

Osteoarthritis (OA) and rheumatoid arthritis (RA) as well as acute joint trauma can affect knee articulations at the tibiofemoral joint. Decreased flexibility and adhesions develop in the joints and surrounding tissues any time the joint is immobilized for a period of time. Reflex inhibition and resulting weakness of the quadriceps femoris muscle occurs because of joint distention.²²⁵ The etiology of these arthritic and joint symptoms and general management guidelines are described in Chapter 11.

Osteoarthritis (Degenerative Joint Disease)

Osteoarthritis, often referred to as degenerative joint disease (DJD), is the most common disease affecting weight-bearing joints (Fig. 21.5). One-third of individuals over the age of 65 have radiographic evidence of OA.¹² Pain, muscle weakness, and joint limitations affect function and lead to disability. Deformity such as genu varum commonly develops. Factors such as excess weight, joint trauma, developmental deformities, weakness in the quadriceps muscle and abnormal tibial rotation are identified as risk factors for developing OA.¹²

Post-traumatic arthritis in the knee occurs in response to any injury that affects the joint structures but particularly

FIGURE 21.5 Advanced bilateral, medial compartment degenerative joint disease in the knees of a 52-year-old computer programmer/analyst who subsequently underwent right total knee arthroplasty.

TABLE 21.1 Knee Pathologies/Surgical Procedures and Preferred Practice Patterns

PATHOLOGY/SURGICAL PROCEDURE	PREFERRED PRACTICE PATTERN AND ASSOCIATED IMPAIRMENTS ²
<ul style="list-style-type: none"> • Abnormal knee posture (related to hip and foot alignment) • Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis) • Synovitis • Postimmobilization arthritis (stiff knee) • Joint instability, ligament tears • Meniscus lesions • Patellofemoral syndromes (patellar instability, malalignment, plica syndrome, fat pad syndrome, patellar tendonitis, bursitis, chondromalacia) • Apophysitis (Osgood-Schlatter's disease) 	<ul style="list-style-type: none"> • Pattern 4B—Impaired posture • Pattern 4D—Impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
<ul style="list-style-type: none"> • Acute arthritis • Acute tendinitis, bursitis • Acute capsulitis • Acute patellofemoral pain 	<ul style="list-style-type: none"> • Pattern 4E—Impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
<ul style="list-style-type: none"> • Arthroscopic débridement • Articular cartilage repair: microfracture, osteochondral autograft transfer, autologous chondrocyte implantation • Arthroscopic synovectomy • Total knee arthroplasty 	<ul style="list-style-type: none"> • Pattern 4H—Impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
<ul style="list-style-type: none"> • Lateral retinacular release • Extensor mechanism realignment • Arthroscopic or open ligament repair/reconstruction • Meniscectomy or meniscal repair • Repair of ruptured patellar tendon • Osteotomy • Patellectomy 	<ul style="list-style-type: none"> • Pattern 4I—Impaired joint mobility, motor function, muscle performance, and ROM associated with bony or soft tissue surgery
<ul style="list-style-type: none"> • Common peroneal, saphenous nerve injury in the knee region 	<ul style="list-style-type: none"> • Pattern 5F—Impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

following acute ligament and meniscal tears. Joint swelling (effusion) may be immediate, indicating bleeding within the joint, or progressive (more than 4 hours to develop), indicating serous effusion. Acute symptoms include pain, limited motion, and muscle guarding. Trauma, including repetitive microtrauma, is a common cause of degenerative changes in the knee joint.

Rheumatoid Arthritis

Early-stage RA usually manifests in the hands and feet first. With progression of the disease process, the knees also may become involved. The joints become warm and swollen, and limited motion develops. In addition, a genu valgum deformity commonly develops during the advanced stages of this disease.

Postimmobilization Hypomobility

When the knee has been immobilized for several weeks or longer, such as after healing of a fracture or after surgery,

the capsule, muscles, and soft tissue develop contractures, and motion becomes restricted. Adhesions may restrict caudal gliding of the patella, which limits knee flexion, and may cause pain as the patella is compressed against the femur. An extensor lag may occur with active knee extension if the patella does not glide proximally when the quadriceps muscle contracts.¹⁸³ This usually occurs after operative repairs of some knee ligaments, when the knee is immobilized in flexion for a prolonged period.

Common Impairments

- With joint involvement, the pattern of restriction at the knee is usually more loss of flexion than extension.
- When there is effusion (swelling within the joint), the joint assumes a position near 25° of flexion, at which there is the greatest capsular distensibility. Little motion is possible because of the swelling.

- Symptoms of joint involvement, such as distention, stiffness, pain, and reflex quadriceps inhibition, may cause extensor (quadriceps) lag in which the active range of knee extension is less than the passive range available.²²⁶
- Disturbed balance responses also have been reported in patients with arthritis.²⁴⁵

Common Functional Limitations/Disabilities

- With acute symptoms and in advanced stages of degeneration, there is pain during motion, weight bearing, and gait that may interfere with work or routine household and community activities.
- There is limitation of, or difficulty controlling, weight-bearing activities that involve knee flexion, such as sitting down and rising from a chair or a commode, descending or ascending stairs, stooping, or squatting.⁶²
- With end-stage OA, physical activity is markedly curtailed with less participation in leisure activities (e.g., walking, gardening, swimming, athletic activities) and household activities (e.g., dusting, washing floors, cleaning, shopping).²³⁷

Joint Hypomobility: Management—Protection Phase

See Chapter 11 for general guidelines for the management of acute joint lesions and specific guidelines for RA and DJD.

Control Pain and Protect the Joint

Patient education. It is important to teach the patient methods to protect the joint including bed positioning or use of splints in order to avoid deforming contractures, range of motion (ROM) and muscle setting exercises to maintain mobility, and safe functional activities that reduce stresses on the knee.

Functional adaptations. To reduce the amount of knee flexion and patellar compression instruct the patient to minimize stair climbing, use elevated seats on commodes, and avoid deep-seated or low chairs. If necessary during an acute flare of arthritis have the patient use crutches, canes, or a walker to distribute forces through the upper extremities while walking.

Maintain Soft Tissue and Joint Mobility

Passive, active-assistive or active ROM. Use ROM techniques within the limits of pain and available motion. The patient may be able to perform active ROM in the gravity-eliminated, side-lying position, or self-assisted ROM.

Grade I or II tractions or glides. Apply gentle techniques, if tolerated, with the joint in resting position (25° flexion). These techniques are used to inhibit pain as well as maintain joint mobility. Stretching is contraindicated at this stage.

Maintain Muscle Function and Prevent Patellar Adhesions

Setting exercises. Have the patient perform pain-free quadriceps (“quad sets”) and hamstring muscle-setting exercises with the knee in various pain-free positions, quad sets with leg raising, and submaximal closed-chain muscle setting exercises. Muscle setting exercises are described in detail in the last section of this chapter. Quad sets may help maintain mobility of the patella when the tibiofemoral joint is immobilized and therefore are routinely taught following surgery or when the joint is immobilized in a cast.

Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

As the inflammation decreases and the joint tissues are able to tolerate increased stresses, the goals of treatment change to deal with the impairments that interfere with functional activities. The patient is progressed through controlled motion exercises and activities that focus on safely returning to the desired functional outcome.

Educate the Patient

- Inform the patient about his or her condition, what to expect regarding recovery, and how to protect the joints.
- Teach the patient safe exercises to do at home, how to progress them, and how to modify them if symptoms are exacerbated by the disease or from overuse. Exercises that include specifically designed strengthening, stretching, ROM, and use of a stationary bicycle have been shown to improve functional outcomes in patients with OA in a home exercise program.⁴³ It is important to emphasize that maintaining strength in the supporting muscles helps protect and stabilize the joint and that balance exercises help reduce the incidence of falls.
- Instruct the patient to perform active ROM and muscle-setting techniques frequently during the day, especially prior to bearing weight in order to reduce the painful symptoms that occur with initial weight bearing.⁶²
- The patient with OA or RA should be cautioned to alternate activity with rest.

Focus on Evidence

There have been no studies comparing outcomes from home exercise programs versus physical therapy-directed interventions in a clinic setting until recently. In a randomized controlled study of 134 patients with OA of the knees, a clinic treatment group ($n = 66$) underwent supervised exercise, manual therapy, and home exercises for 4 weeks; and a home exercise group ($n = 68$) underwent home exercises only (instructions and a follow-up examination were provided for the same exercises as the clinic group). Outcomes that were measured consisted of the distance walked in 6 minutes and the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC). Both groups improved in the outcome measures at 4 weeks; the clinic

treatment group improved 52% on the WOMAC, whereas the home exercise group improved 26%. Both groups improved 10% on the 6-minute walk distances. At 1 year there was no difference between the groups, and both groups demonstrated improvement over baseline measurements, although it was noted that the clinic treatment group was less likely to be taking medication for the arthritis and were more satisfied with the outcome of their rehabilitation.⁴³

Decrease Pain from Mechanical Stress

Continue use of assistive devices for ambulation, if necessary. The patient may progress to using less assistance or may ambulate for periods without assistance. Continue use of elevated seats on commodes and chairs, if needed, to reduce the mechanical stresses imposed when attempting to stand up.⁶²

Increase Joint Play and Range of Motion

PRECAUTION: Do not increase ROM unless the patient has sufficient strength to control the motion already available. A mobile weight-bearing joint with inadequate muscle control causes impaired stability and makes lower extremity weight-bearing function difficult.

Joint mobilization. When there is loss of joint play and decreased mobility, joint mobilization techniques should be used. Apply grade III sustained or grade IV oscillation techniques to the tibiofemoral and patellofemoral articulations with the joint positioned at the end of its available range before applying the mobilization technique. See Figures 5.49 through 5.54 and their descriptions in Chapter 5. As ROM increases, it is important to emphasize the rotational accessory motions that accompany flexion and extension.¹⁰⁵

- To increase *flexion*, position the tibia in medial rotation and apply the posterior glide against the anterior aspect of the medial tibial plateau.
- To increase *extension*, position the tibia in lateral rotation and apply the anterior glide against the posterior aspect of the lateral tibial plateau.
- Medial and lateral gliding of the tibia on the femur may also be done to regain mobility for flexion and extension.

Stretching techniques. Passive and muscle inhibition stretching techniques are used to increase flexibility in the muscles and extracapsular noncontractile soft tissues that restrict knee motion. Specific techniques are described in the last section of this chapter.

PRECAUTIONS: Techniques that force the knee into flexion by using the tibia as a lever or by using strong quadriceps contractions (during hold-relax maneuver) may exacerbate joint symptoms.

Incorporate the following to minimize joint trauma from stretching.

- Mobilize the patellofemoral and tibiofemoral joints before stretching in order to improve gliding of the joint surfaces during the stretch maneuvers.

- Apply soft tissue or friction massage to loosen adhesions or contractures prior to stretching. Include deep massage around the border of the patella.
- Modify the intensity of contraction when applying muscle inhibition techniques to restricting muscles in order to decrease the effects of joint compression. If hold-relax aggravates anterior knee pain when attempting to increase knee flexion, use agonist contraction to the hamstring muscles to minimize compression from a strong quadriceps muscle contraction.
- Use low intensity, long-duration stretches within the patient's tolerance.

Mobilization with Movement. Mobilization with movement (MWM) may be applied to increase ROM and/or decrease the pain associated with movement by improving joint tracking. Mulligan¹⁵⁴ stated that MWM is more effective with loss of flexion than extension. The principles of MWM are described in Chapter 5.

Lateral or Medial Glides

Patient position and procedure: Supine for extension or prone for flexion. Apply a pain-free medial or lateral glide to the tibial plateau by hand or through the use of a mobilization belt. The direction of glide is often in the direction of the pain (i.e., lateral knee pain responds best to a lateral glide of the tibia and medial knee pain to a medial glide).¹⁵⁴

- While sustaining the mobilization, ask the patient to move to the end of the available pain-free range of flexion or extension.
- Add pain-free overpressure to achieve the benefit of end-range loading.

Internal Tibial Rotation for Flexion—Manual Technique

Patient position and procedure: Supine with the knee flexed to the end of its available pain-free range. Apply internal rotation mobilization to the tibia with manual pressure from one hand on the anteromedial tibial plateau simultaneously with pressure from the other hand on the posterolateral tibial plateau, posterior to the fibular head.

- Sustain the internal rotation mobilization and ask the patient to flex the knee through the use of a mobilization belt looped around the foot. Hold the position at the end of the available pain-free range for several seconds (Fig. 21.6).

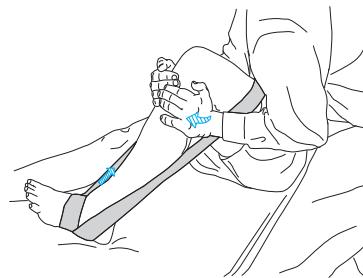

FIGURE 21.6 MWM with internal tibial rotation to increase knee flexion.

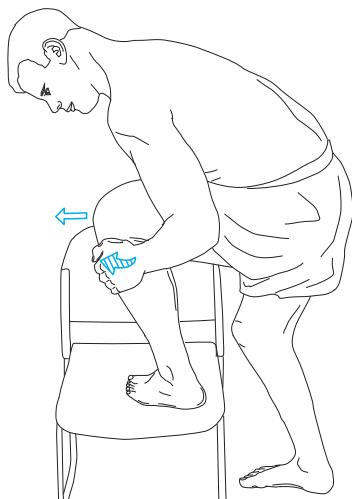

FIGURE 21.7 Self-treatment using MWM with internal tibial rotation to increase knee flexion.

Internal Rotation for Flexion—Self-Treatment

Patient position and procedure: Standing with the foot of the involved leg on a chair and knee flexed. Position the foot such that the tibia is internally rotated. Have the patient apply internal rotation pressure against the anteromedial and posterolateral tibial plateaus and shift the weight forward to flex the knee to the end of the available pain-free range (Fig. 21.7).

Improve Muscle Performance in Supporting Muscles
Exercises identified in this section are described in detail in the last section of this chapter.

Progressive strengthening. Begin with multiple-angle isometrics to both knee flexion and extension, short-arc terminal extension exercises in open- and closed-chain positions, and a moderate progression of repetitions and resistance in wider arcs of motion so long as the motion is pain-free. Exercises intensity should be within the tolerance of the joint and not exacerbate symptoms.

- When doing open-chain exercises, patients experience less pain with faster speeds and lighter resistance than when doing the exercises slowly with heavy resistance.
- Resistance through the mid-range (45° to 90°) tends to exacerbate patellofemoral pain because of the compressive forces on the patella. Apply resistance in arcs of motion that are pain-free on either side of the symptomatic range. This could be done using manual or mechanical resistance in the pain-free ranges.
- Strengthen both hip and ankle musculature using open- and closed-chain activities in order to balance forces throughout the lower extremities and progress the patient toward functional independence. (See Chapters 20 and 22 for hip and ankle exercises.)

Muscular endurance. For muscular endurance, increase repetitions at each resistance level before progressing with greater resistance.

Functional training. Climbing steps, sitting down and rising up from chairs and commodes, and using safe body mechanics to lift objects from the floor are often compromised in individuals with knee arthritis. It is imperative to strengthen the knee musculature using modifications of functional activities, progressing the difficulty as strength improves.

- **Step-up and step-down exercises (forward, backward, lateral).** Begin with blocks or steps 4 to 6 inches in height and progress to the step height the patient requires for home and community mobility. Progress to functional activities such as climbing stairs or ladders, depending on the desired outcome.
- **Wall slides and mini-squats to 90° if tolerated.** Stay within a range that does not exacerbate symptoms or cause crepitus. Practice sitting and sit-to-stand with arm assistance in various chair heights. Determine if chair adaptation is needed for safe function.
- **Partial lunges.** This activity is progressed to include lunging to pick up small objects from the floor. Lunges are an effective way to teach body mechanics for an individual with unilateral knee impairment. Concentrate on trunk control during the motion. Have the patient contract the abdominals to stabilize the pelvis during the lunge activity.
- **Balance activities.** Balance activities are initiated at the level the patient can control. Detailed suggestions are outlined in Chapters 8 and 20.
- **Ambulation.** Decrease use of assistive devices as quadriceps strength improves to a manual muscle test level of 4/5. Practice on a variety of terrains, up and down ramps, and reversing directions, first with assistance and then independently.

Improve Cardiopulmonary Endurance

Develop and improve cardiopulmonary fitness for the individual with joint symptoms by adapting activities to minimize irritating stresses.

- **Swimming, water aerobics, and aquatic exercises** provide an environment for improving muscular and cardiopulmonary function with less joint trauma.
- **Bicycling** is a low-impact form of exercise. Adjust the seat height so the knee goes into complete extension (but not hyperextension) when the pedal is down. On a stationary bike, use low resistance.
- **High impact—with caution.** For some patients, progression to running or jumping rope and other high-impact, faster paced, or more intense activities can be undertaken so long as the joint remains asymptomatic. If joint deformity is present and proper biomechanics cannot be restored, the patient probably cannot progress to these activities.

Focus on Evidence

Two systematic reviews of studies designed to examine evidence of the effects of exercise in the management of hip and knee OA describe support for aerobic exercise and strengthening exercises to reduce pain and disability.^{196,197}

The consensus of expert opinion cited by Roddy¹⁹⁶ is that (1) there are few contraindications and (2) exercise is relatively safe in patients with OA but it should be individualized and patient-centered with consideration for age, co-morbidity, and general mobility. Similarly the Cochrane Database of Systematic Reviews⁶⁶ and the Philadelphia Panel Evidence-Based Clinical Practice Guidelines¹⁸⁶ indicated that there is evidence to support strengthening, stretching, and functional exercises as interventions for the management of knee pain as the result of OA and to improve physical function.

In another study that followed 285 patients with knee OA for 3 years, investigators found that factors that protected the individuals from poor functional outcomes included strength and activity level as well as factors such as mental health, self-efficacy, and social support.²¹⁰

An outcome review⁴⁴ summarized that moderate- or high-intensity exercises for patients with RA have minimal effect on the disease activity but that there is insufficient radiological evidence on the effect in large joints. Long-term moderate- or high-intensity exercises that are individualized to protect radiologically damaged joints improve aerobic capacity, muscle strength, functional ability, and psychological well-being of patients with RA.⁴⁴

JOINT SURGERY AND POSTOPERATIVE MANAGEMENT

A range of surgical options for management of arthritis of the knee is available when joint pain and synovitis cannot be controlled with conservative therapy and appropriate medical management or when destruction of articular surfaces, deformity, or restriction of motion have progressed to the point that functional abilities are significantly impaired.

The surgical procedure selected depends on the patient's signs and symptoms, activity level and age, type of disease, severity of articular damage or joint deformity, and involvement of other joints. *Arthroscopic débridement* and *lavage* are used to remove loose bodies that may be causing swelling and intermittent locking of the knee.^{14,205} A number of procedures to repair damaged articular cartilage have been developed. *Abrasion arthroplasty*, a procedure designed to smooth worn articular surfaces and stimulate growth of replacement cartilage has met with only limited success.^{14,205} More recently developed procedures used to repair small, localized articular cartilage defects of the knee, such as *microfracture*,^{76,207} *osteochondral autograft transplantation/mosaicplasty*,^{8,13,20,86,110} and *autologous chondrocyte implantation*^{36,77,248} appear to hold promise.

Synovectomy may be the procedure of choice for a young patient with unremitting joint effusion, synovial proliferation, and pain as the result of RA or juvenile RA (JRA) but with minimal destruction of articular surfaces.^{29,87,182,205} *Osteotomy* of the distal femur or proximal

tibia (an extra-articular procedure) redistributes weight-bearing forces between the tibia and femur in an attempt to reduce joint pain during weight-bearing activities and delays the need for arthroplasty of the knee for up to 10 years.^{14,29,193,205} In the past, high tibial osteotomy was considered a surgical option for the active patient under 50 to 55 years of age without active systemic disease and significant limitation of motion or joint deformity.¹⁹³ However, because arthroplasty now is being performed in younger patients than was the case a decade or two ago, osteotomy is an infrequently selected surgical option.³³

When erosion of articular surfaces becomes severe and pain is unremitting, *total knee replacement arthroplasty* is the surgical procedure of choice to reduce pain, correct deformity, and improve functional movement.^{98,131,203} Only in highly selective situations is *arthrodesis* (fusion) of the knee used as a salvage procedure to provide a patient with a stable and pain-free knee.

Regardless of the type of surgery selected, the goals of surgery and postoperative management are to (1) reduce pain, (2) correct deformity or instability, and (3) restore lower extremity function. Carefully progressed postoperative rehabilitation is essential for optimal functional outcomes.

Repair of Articular Cartilage Defects

Injuries of the ligaments or menisci of the knee and acute or chronic patellofemoral dysfunction often are associated with damage to an articular surface of the knee. Surgical management of chondral defects has proven challenging because of the limited capacity of articular cartilage to heal.³⁶ However, several surgical procedures introduced during the 1990s are available for repairing small lesions in the symptomatic knee when nonoperative management or arthroscopic débridement and lavage have been unsuccessful.

Procedures include microfracture,^{76,118,207,227} osteochondral autograft transplantation/mosaicplasty,^{8,13,20,86,110} and autologous chondrocyte implantation.^{77,114,118,248} These procedures are designed to stimulate growth of hyaline cartilage for repair of focal defects of articular cartilage and for preventing progressive deterioration of joint cartilage leading to osteoarthritis.^{36,118}

Descriptions of procedures specific to the knee are presented in this section. Regardless of the cartilage procedure selected, each requires the patient's ability and willingness to adhere to a lengthy rehabilitation process.

Indications for Surgery

The primary indication for repair of an articular cartilage defect is a symptomatic knee caused by a small to relatively large focal lesion of the tibiofemoral or patellofemoral joint. Sites typically involved are the weight-bearing portions of the medial or lateral femoral condyles, the trochlear groove, and the articulating facets of the patella.

Selection criteria when choosing the procedure include the size of the chondral lesion (in general, defects greater

than 1 to 2 cm² but no more than 4 cm² are considered suitable for repair), the depth of the lesion, the location of the lesion, the elapsed time since the occurrence of the defect, and the patient's age and intended activity level. Most patients, who undergo articular cartilage repair are young and active.^{36,118}

Procedures

Microfracture. Microfracture is indicated for repair of very small defects usually of the medial or lateral femoral condyle or the posterior aspect of the patella. The procedure is performed arthroscopically and involves the use of a nonmotorized awl to systematically penetrate the subchondral bone and expose the bone marrow. The procedure is designed to stimulate a marrow-based repair response leading to local ingrowth of cartilaginous repair tissue (fibrocartilage) to repair the lesion.^{36,76,118,207,227}

Osteochondral autograft transplantation/mosaicplasty.

For focal lesions involving chondral or subchondral tissue of the weight-bearing surfaces of the knee, osteochondral graft transplantation may be selected. It is an arthroscopic or mini open procedure involving transplantation of *intact* articular cartilage along with some underlying bone, resulting in a bone-to-bone graft.^{8,13,20,86,110} Rather than using a single piece of tissue and creating a similar size osteochondral defect at the donor site, mosaicplasty is used in which multiple, small-diameter osteochondral plugs are harvested and press-fit into the chondral defect.^{8,13,86,110}

Donor sites typically are non-weight-bearing, non-articulating portions of the supracondylar ridge of the lateral femoral articulating surfaces or elsewhere in the knee.⁸

Autologous chondrocyte implantation. This procedure, also referred to as chondrocyte transplantation, is used for full-thickness chondral and osteochondral defects (2 to 4 cm²) of the femoral condyles or patella.^{36,77,114,248} The procedure occurs in two stages. First, healthy articular cartilage is harvested arthroscopically from the patient. Then chondrocytes are extracted from the articular cartilage, cultured for several weeks, and processed in a laboratory to increase the volume of healthy tissue. The second phase is the implantation phase, which currently requires an arthrotomy (open procedure). After the chondral defect sites have been débrided, they are covered with a periosteal patch, typically harvested from the proximal medial tibia. Then millions of autologous chondrocytes are injected under the patch and into the articular defect.

Patient positioning during the first 4 hours after surgery is critical. Patients are positioned so the effect of gravity distributes the chondrocytes evenly along the base of the defect.¹⁹² For example, after a patellofemoral repair, the patient is placed in the prone position.

Maturation of the implanted chondrocytes is a lengthy process. It may take up to 6 months for the graft site to become firm and as long as 9 months for the graft to become as durable as the healthy tissue surrounding the graft.⁷⁷

Osteochondral allograft transplantation. For defects larger than 4 cm², the only option for repair, although used infrequently, is an osteochondral allograft of intact articular cartilage from a cadaveric donor. However, only fresh, intact grafts, which are in limited supply and can be stored for only a few days, can be used. A frozen allograft cannot be used because freezing the graft material kills the articular chondrocytes, leading to graft failure.^{36,118}

Other procedures. If coexisting ligament or meniscus pathology or tibiofemoral or patellofemoral malalignment are identified prior to or concomitant with surgical repair, reconstruction or realignment must be carried out for the articular cartilage repair to be successful. The most common procedures are ACL reconstruction and meniscus repair for tibiofemoral articular defects and lateral retinacular release for patellar defects.^{8,77}

Postoperative Management

A cautiously progressed and closely monitored rehabilitation program after articular cartilage repair procedures is critical for a successful outcome. The components and progression of a rehabilitation program, including exercise, ambulation, and functional activities, must be graded to protect the repair or graft and prevent further articular damage while applying controlled stresses to stimulate the healing process.

The progression of postoperative exercises and functional activities after microfracture, osteochondral autologous transplantation, and autologous chondrocyte implantation has many common elements, yet they vary to some degree. Detailed postoperative protocols for each of these procedures have been published in the literature.^{8,77,110,192} In addition to the type of repair employed, the rehabilitation progression is based on the size, depth, and location of the articular defect, the need for concomitant surgical procedures, and patient-related factors such as age, body mass index, health history, and preoperative activity level.

The goals during rehabilitation after articular cartilage repair are similar to those found for most knee rehabilitation programs presented in this chapter. Protected weight bearing over an extended period of time and early motion are essential after articular cartilage repair to promote maturation and maintain the health of the repaired or implanted cartilage. Special considerations for exercise and weight bearing associated with the various articular cartilage procedures are summarized in Box 21.2.^{8,77,110,192,248}

Synovectomy

Hypertrophic synovitis develops most frequently in patients with RA or JRA.^{29,87,182,205} Resection of proliferated synovium in patients without significant cartilage erosion alleviates pain and stiffness of the knee for a period of time. Although it is unclear if synovectomy alters the course of the underlying disease, it delays the need for arthroplasty in the young patient.

BOX 21.2 Special Considerations and Precautions for Rehabilitation after Articular Cartilage Repair*

- The larger the lesion, the slower/more cautious the progression of rehabilitation.
- Early, but controlled, ROM is advocated to facilitate the healing process and begins immediately or within a day or two after surgery (CPM, passive or assisted exercise).
- Controlled (protected) weight bearing initiated as early as possible is beneficial to the healing process, but adherence to weight-bearing restrictions is critical.
- Duration and degree of weight-bearing restrictions vary with the size of the defect and type and location of the repair.*
- Longer period of protected weight bearing for osteochondral transplantation/mosaicplasty and autologous chondrocyte implantation than after microfracture.
- Longer period of protected weight bearing for a femoral condyle repair (up to 8 to 12 weeks) than for a patellar defect (up to 4 weeks).
- Full weight bearing is delayed for as long as 8 to 12 weeks.
- Protective bracing may be used postoperatively.
- Typically locked in extension, except during exercise.
- Worn during weight bearing activities 4 to 6 weeks.
- Worn during sleep for up to 4 weeks.
- An unloading brace may be used after repair of a femoral condyle defect to shift the weight away from the repair during the period of protected weight bearing.

*Considerations and precautions vary with the size, depth, and location of the articular defect, type of surgical repair and concomitant procedures, and patient-related factors (age, body mass index, health history, preoperative activity level).

Indications for Surgery

The following are frequently cited indications for synovectomy of the knee.^{29,87,182,205}

- Chronic, proliferative synovitis, joint pain, restricted joint mobility lasting 6 months or longer secondary to unremitting but early-stage RA or JRA that cannot be controlled by medical management
- Synovial hypertrophy and joint pain secondary to recurrent hemarthrosis as the result of hemophilia
- Intact or minimally eroded articular surfaces

Procedures

Arthroscopic synovectomy involves the use of multiple portals for access to and endoscopic removal of as much synovium as possible from all compartments of the knee.^{87,182,205} A partial meniscectomy often is performed during synovectomy because chronically inflamed synovium can invade a portion of a meniscus leading to a tear.¹⁹³

An arthroscopic approach to synovectomy is routinely preferred over an open approach. *Open synovectomy* necessitates arthrotomy of the knee through a longitudinal medial and/or lateral parapatellar incision(s) of the capsule and,

therefore, causes greater postoperative morbidity and a lengthier recovery. It is also more difficult to preserve the menisci with an open approach than an arthroscopic approach.⁸⁷ However, an open approach may be selected by the surgeon if synovectomy is performed in conjunction with other open procedures.

Postoperative Management

Postoperative management after arthroscopic synovectomy, summarized in Table 21.2, is progressed based on the patient's signs and symptoms rather than strict adherence to timelines.¹⁶⁷ Exercises and weight-bearing activities are progressed relatively rapidly after arthroscopic synovectomy. A patient often achieves nearly full ROM of the operated knee and is able to ambulate without assistive devices as early as 10 to 14 days postoperatively depending on involvement of unoperated joints. Nevertheless, return to a full level of functional activity should occur gradually with some degree of protection continuing until joint swelling, limitation of active and passive knee ROM, and muscle weakness are resolved.

Immobilization and Weight Bearing

The knee is immobilized for 24 to 48 hours in a compression dressing and a posterior splint that holds the knee in extension. During that time the leg is elevated to control postoperative edema. Ambulation with crutches begins the day of surgery, with weight bearing as tolerated. The patient should wear the posterior splint during ambulation until full, active knee extension has been achieved.

Exercise

The choices and progression of exercises are based not only on the status of the operated knee but also on the extent of involvement of other joints of the upper or lower extremities affected by chronic arthritis. The goals and exercise interventions commonly included in successive phases of postoperative rehabilitation are described in the following sections.

Exercise: Maximum Protection Phase

Immediately after surgery and for the next 2 to 3 weeks, early movement must be balanced with protection of the operated knee. Attention to wound care is particularly important because of the systemic nature of inflammatory arthritis. Regaining full, active knee extension is essential for ambulation without crutches or a cane. The goals and interventions implemented during the first phase of rehabilitation include the following.^{87,205}

- **Control pain and peripheral edema and decrease the risk of deep vein thrombosis.**
 - Elevation of the lower extremity and application of cold to the operated knee.
 - Active ankle pumping exercises.
- **Regain or maintain neuromuscular control of hip and knee musculature on the operated side.**
 - Quadriceps and hamstring setting exercises performed frequently during the day
 - Straight-leg raising exercises (SLRs) in the supine, prone, and side-lying positions.

TABLE 21.2 Arthroscopic Synovectomy—Interventions for Each Phase of Rehabilitation

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–2	Moderate to Minimum Protection Phases: Weeks 3–6	Return to Activity Phase: Week 6
Patient presentation	<ul style="list-style-type: none"> Patient enters rehabilitation within 2 days Postoperative compression dressing Minimal postoperative pain ROM minimally limited Weight bearing as tolerated 	<ul style="list-style-type: none"> Minimum gain Full weight bearing Nearly full ROM Joint effusion controlled 	<ul style="list-style-type: none"> Muscle function: 70% of noninvolved side No symptoms of pain or swelling during the previous phase
Key examination procedures	<ul style="list-style-type: none"> Pain assessment: 1–10 scale Monitor for hemarthrosis ROM Patellar mobility Muscle control Soft tissue palpitation 	<ul style="list-style-type: none"> Pain assessment Joint effusion—girth ROM Patellar mobility Muscle strength Gait analysis 	<ul style="list-style-type: none"> Pain assessment Muscle strength Patellar alignment/stability Functional strength
Goals	<ul style="list-style-type: none"> Control postoperative swelling Minimize pain ROM: 0°–115° 3/5 to 4/5 muscle strength Ambulate without assistance unless weight bearing is delayed Establish home exercise program 	<ul style="list-style-type: none"> Control swelling Full ROM Full weight bearing 4/5 to 5/5 strength Improve cardiopulmonary fitness Improve balance Unrestricted ADL Adherence to home program 	<ul style="list-style-type: none"> Transition to maintenance program for self-management and prevention Reinforce lifelong joint protection
Interventions	<ul style="list-style-type: none"> Compressive wrap to control effusion Pain modulation modalities (cryotherapy) Ankle pumps to prevent peripheral edema A-AROM and AROM Patellar mobilization Muscle setting: quadriceps, hamstrings and adductors (may augment with E-stim) SLRs—four positions (assisted to unassisted) Flexibility program: hamstrings, plantarflexors, IT band Trunk/pelvis strengthening 	<ul style="list-style-type: none"> LE flexibility program Closed-chain strengthening Limited-range PRE Tibiofemoral joint and patellar mobilization, if needed Proprioceptive training Stabilization exercises Gait training Protected aerobic exercise: swimming or walking program 	<ul style="list-style-type: none"> Continue previous phase activities and advance as appropriate Implement exercise specific to functional tasks

● **Regain ROM of the knee.**

- Active-assistive knee flexion and extension exercises within the pain-free ROM.
- Gentle superior and inferior patellar mobilization techniques as swelling decreases.
- Gravity-assisted knee extension with a rolled towel under the ankle and the posterior aspect of the knee unsupported.
- Continuous passive motion (CPM), if requested by the surgeon.

Exercise: Moderate, Minimum Protection and Return to Function Phases

As joint swelling and postoperative pain subside, emphasis is placed on re-establishing functional control of the operated knee necessary for independence during daily living activities. Goals and interventions for the intermediate and final phases of rehabilitation after arthroscopic synovectomy, noted in Table 21.2, are consistent with those for non-operative management of joint dysfunction described in the previous section of this chapter.

Outcomes

Synovectomy has been shown to be of benefit in alleviating chronic synovitis and joint pain and, in most cases, improving ROM and postponing deterioration of the involved joint.²⁰⁵ After recovery from surgery, joint pain and swelling are reduced in approximately 90% to 95% of patients.⁸⁷ Long-term results of arthroscopic and open approaches are reported to be comparable. A review of several studies indicated that at 2.0 to 2.5 years after arthroscopic synovectomy 78% to 90% of patients continued to report a reduction of symptoms and general satisfaction with the procedure. However, by 4 to 5 years, positive outcomes after both arthroscopic and open procedures tended to deteriorate to approximately 60% to 70% in the presence of recurrent synovitis.⁸⁷ Progression of inflammatory joint disease, as reflected by radiographic changes, is common several years after synovectomy. Therefore, there is little evidence to support the claim that synovectomy can reverse the disease process.^{29,87,205}

Total Knee Arthroplasty

Total knee arthroplasty (TKA), also called total knee replacement, is a widely performed procedure for advanced arthritis of the knee, primarily in older patients (≥ 70 years of age) with osteoarthritis. However, during the decade between 1990 and 2000, the proportion of younger patients undergoing TKA increased significantly. During this period the proportion of knee replacements performed in the 40- to 49-year-old age group increased by 95.2% and in the 50- to 59-year-old age group by 53.7%. This indicates the criteria for TKA, traditionally reserved for the patient over 65 years of age, are broadening.¹⁰¹

The primary goals of TKA are to relieve pain and improve a patient's physical function and quality of life.^{149,203}

Indications for Surgery

The following are common indications for TKA.^{98,131,203,205}

- Severe joint pain with weight bearing or motion that compromises functional abilities
- Extensive destruction of articular cartilage of the knee secondary to advanced arthritis
- Marked deformity of the knee such as genu varum or valgum
- Gross instability or limitation of motion
- Failure of nonoperative management or a previous surgical procedure

Procedure

Background

Prosthetic replacement of one or more surfaces of the knee joint began to develop during the 1960s. Initially, only the tibial plateau was replaced (hemiarthroplasty). This was followed by the first generation of TKA, which involved a noncemented, double-stemmed, hinged, metal prosthesis that replaced the articulating surfaces of the distal femur and proximal tibia. This early design had a high failure rate

because of progressive component loosening.^{98,131,203} The next major step was the development of an unconstrained, metal-to-plastic system that replaced the entire articular surfaces of the tibia and femur or just the medial or lateral compartment of the knee. The implants were held in place with acrylic cement. Completely unconstrained TKA also was associated with early failure because of a high incidence of instability or dislocation.^{98,131,203} To address these problems, semiconstrained, two-component designs evolved. For the patient with severe anterior knee pain resulting from advanced patellofemoral deterioration, a three-component, total condylar design that included resurfacing the patellofemoral joint was developed.

These early designs were forerunners of current-day designs of TKA and unicompartmental knee arthroplasty (UKA).^{98,131,156,203,236} A therapist's knowledge of the different types of TKA and UKA used today enhances communication between the therapist and surgeon and provides a foundation for decisions made during rehabilitation.

Types of knee arthroplasty. Contemporary knee replacement procedures can be divided into several categories based on component design, surgical approach, and type of fixation (Box 21.3).^{99,131,153,203} One category is based on

BOX 21.3 Total Knee Arthroplasty—Design, Surgical Approach, Fixation

Number of Compartments Replaced

- **Unicompartmental:** only medial or lateral joint surfaces replaced
- **Bicompartmental:** entire femoral and tibial surfaces replaced
- **Tricompartmental:** femoral, tibial, and patellar surfaces replaced

Implant Design

- Degree of constraint
 - **Unconstrained:** no inherent stability in the implant design; used primarily with unicompartmental arthroplasty
 - **Semiconstrained:** provides some degree of stability with little compromise of mobility; most common design used for total knee arthroplasty
 - **Fully constrained:** significant congruency of components; most inherent stability but considerable limitation of motion
- Fixed-bearing or mobile-bearing design
- Cruciate-retaining or cruciate-excising/substituting

Surgical Approach

- Standard/traditional or minimally invasive
- Quadriceps-splitting or quadriceps-sparing

Implant Fixation

- Cemented
- Uncemented
- Hybrid

the number of components implanted or articulating surfaces replaced. Another is based on the degree of constraint (i.e., the amount of inherent congruity/stability in the design). Most TKA procedures today involve a two-component (bicompartamental), semiconstrained prosthetic system to replace the proximal tibia and distal femur (Fig. 21.8). These systems typically are composed of a modular or nonmodular femoral component with a metal articulating surface and a single all-polyethylene or metal-backed modular or nonmodular tibial component with a polyethylene articulating surface.^{99,131,203}

Occasionally, a tricompartmental design, which also resurfaces the posterior aspect of the patella with a polyethylene component, is selected if the patellofemoral joint is symptomatic.^{98,131,203} For the younger patient (< 55 years of age) with advanced disease of only the medial or lateral aspect of the knee joint, a unicompartmental design often is selected to replace just one tibial and one femoral condyle.^{156,177,203,236}

Intact medial and lateral collateral ligaments are necessary prerequisites for semiconstrained and unconstrained TKA.^{98,131,203} Fully constrained designs, now used infrequently, are reserved for the low-demand patient who has marked instability of the knee, extensive bone loss, or severe deformity or who has had previous TKA revisions.^{98,131} Contemporary fully constrained designs are not hinged but have inherent medial-lateral (ML) and anterior-posterior (AP) stability and some degree of rotation of the tibia on the femur to lessen the problem of progressive loosening of the prosthetic components over time.^{98,131}

TKA designs also are classified as mobile-bearing or fixed-bearing. The most recent development in the evolution of TKA is introduction of the mobile-bearing, bicompartamental prosthetic knee. A mobile-bearing knee has a rotating platform inserted between the femoral and tibial components whose top surface is congruent with the femoral implant (round-on-round articulation) but whose undersurface is flat for rotation and sliding of the tibial component (flat-on-flat articulation).^{32,153,203} A fixed-bearing knee does not have such an insert.^{46,203} The purpose of the mobile-bearing insert is to decrease long-term wear of the polyethylene tibial component. A mobile-bearing knee design is recommended most often for the active patient, under 55 to 65 years of age.²⁰³

Another way to classify TKA design is based on the status of the posterior cruciate ligament (PCL). Designs are described as cruciate-retaining or cruciate-excising/substituting.^{98,131,173,176,203} Although the ACL is routinely excised during knee replacement, except with UKA, the PCL can be preserved or excised. If the PCL is intact to provide posterior stability to the knee, one of several cruciate-retaining designs that require less congruity and allow some degree of AP glide can be used. If the PCL is irreparably deficient, a cruciate-substituting prosthesis is selected. This type of design has inherent posterior stability from the congruity of the components, a posterior prominence in the tibial component, or a cam-post mechanism built into the design. Cruciate-retaining and cruciate-

FIGURE 21.8 Posterior cruciate-retaining total knee arthroplasty of the right knee with cemented fixation. (A) Anteroposterior view. (B) Lateral view. Preoperative ROM is 0° to 125°; ROM 1 month after surgery is 0° to 120°.

substituting designs can have a fixed-bearing or mobile-bearing design.²⁰³

Surgical approach. TKA and UKA procedures are also described in terms of the surgical approach employed.^{21,34,156,203} Since the inception of knee arthroplasty, an open approach requiring a relatively long anterior incision traditionally has been employed to provide sufficient exposure of the knee joint during the procedure. A recent advance is the development of *minimally invasive* knee arthroplasty.^{21,156} Although minimally invasive, as with traditional joint arthroplasty it is an open procedure. However, minimally invasive TKA involves a smaller incision and less soft tissue disruption to reduce postoperative pain and increase the rate of postoperative recovery. Standard (traditional) and minimally invasive surgical approaches are described later in this section.

Fixation. The method of fixation—cemented, uncemented, or “hybrid”—is another way to classify TKA procedures. That is, implants are held in place with acrylic cement, bone ingrowth (uncemented), or a combination of these two methods.^{131,175,191,247} Initially, almost all total knee replacements relied on cemented fixation. In fact, cemented fixation revolutionized knee arthroplasty.^{98,191} However, a long-term complication associated with early designs of cemented prostheses was biomechanical loosening, primarily of the tibial component at the bone-cement interface. Young, active patients were believed to be at highest risk for component loosening.²⁴⁷

To address the problem of loosening, cementless (biological) fixation relying on rapid growth of bone into the surfaces of a porous-coated or beaded prosthesis was introduced and recommended primarily for the young, active patient.^{98,131,175,203,247} In addition, the use of a hydroxyapatite coating on the prosthesis has been advocated to enhance the ingrowth of bone.²⁰⁵ However, long-term follow-up demonstrated that although the femoral component reliably achieved fixation to bone tibial component loosening occurred at an even higher rate with all-cementless fixation compared with cemented fixation.^{175,247} This finding gave rise to the “hybrid” TKA, which combines

cemented fixation of the tibial component and cementless fixation of the femoral component.

Currently, all-cemented fixation is used most often and all-cementless used least often. A surgeon’s decision whether to employ hybrid fixation is based on the patient’s age, bone quality, expected activity level, and the tightness of fit of the femoral component achieved during surgery.²⁰³ Design modifications to augment fixation of the tibial component (e.g., with pegs or screws) continue, although the long-term value of these design changes has yet to be determined.^{98,257}

In summary, research continues on the biomechanics of knee arthroplasty, modifications of designs, development of better methods of fixation and new materials with better wear qualities, as well as improved surgical techniques and use of sophisticated instrumentation for alignment and placement of prosthetic components. Ongoing developments in all of these areas will continue to contribute to the success of current-day and improvement of future TKA procedures.^{203,257}

Operative Overview

One of several variations of standard or minimally invasive approaches along the anteromedial aspect of the knee can be used. Key features of these two types of approaches are compared in Table 21.3.^{21,34,156,203} A quadriceps-splitting or a quadriceps-sparing approach is used to reach the capsule for an arthrotomy. The knee is flexed; and osteophytes, menisci, and the ACL are resected. If a posterior cruciate-substituting prosthesis is to be implanted, the PCL is also excised.

A series of surgical techniques are performed prior to inserting the implants.^{99,203} Small portions of the distal femur and proximal tibia are removed and prepared for the implants. If a patellar implant is indicated, the patellar surface also is prepared and the prosthesis inserted. After trial components are inserted, soft tissue tension, collateral ligament balance, ROM, and patellar tracking are checked. The lateral retinaculum may be released to improve patellar tracking.^{111,203} Permanent components are inserted, and the capsule and other soft tissues are repaired. The area

TABLE 21.3 Features of Standard and Minimally Invasive Surgical Approaches for Total Knee Arthroplasty

Standard Approach	Minimally Invasive Approach
<ul style="list-style-type: none"> Anteromedial parapatellar vertical or curved incision from the distal aspect of the femoral shaft, running medial of the patella to just medial of the tibial tubercle, ranging from 8 to 12 cm²¹ or 13 to 15 cm²⁰⁴ in length Necessary soft tissue releases prior to eversion of the patella Anterior capsule release Dislocation of the tibiofemoral joint prior to bone cuts and implantation of components 	<ul style="list-style-type: none"> Reduced length of anteromedial skin incision 6–9 cm in length²¹ No patellar eversion Anterior capsule release No tibiofemoral dislocation In situ bone cuts In situ implantation of components

is thoroughly irrigated, and the wound is closed with the knee extended or in 90° of flexion⁹⁶ and with a small suction drain in place. A sterile dressing is placed over the incision, and the area is covered from foot to thigh with a compression wrap.

Complications

Overall, the incidence of complications after TKA is low. Intraoperative complications during knee arthroplasty, such as intercondylar fracture or damage to a peripheral nerve (e.g., the peroneal nerve), are uncommon. Because minimally invasive TKA is considered more technically challenging than traditional TKA, early reports suggest that the rate of intraoperative complications, such as fracture or malpositioning of an implant, is higher with a minimally invasive than a standard approach.²¹

Early and late postoperative complications include infection, joint instability, polyethylene wear, and component loosening. As with arthroplasty of other joints, there is a risk of wound-healing problems and deep vein thrombosis (DVT) during the first few months after surgery. Although the incidence of deep periprosthetic infection is low, it is the most common reason for early failure and the need for revision arthroplasty. In contrast, polyethylene wear of the patellar and tibial components is the most common late complication requiring revision.^{40,155} The incidence of biomechanical loosening has been reduced significantly with the newer prosthetic designs and improved surgical techniques.^{155,204} If mechanical loosening develops over time, it occurs most often at the tibial component and more often with cementless or hybrid TKAs than fully cemented replacements.^{175,205}

Other postoperative complications that can compromise a patient's functional recovery include limited knee flexion, joint instability leading to subluxation,^{40,203} and patellar instability or tracking problems leading to impaired function of the extensor mechanism (most often an extensor lag).^{111,203}

Postoperative Management

Goals and interventions during progressive phases of postoperative rehabilitation after TKA are summarized in Table 21.4. Guidelines are similar for management after UKA. Interventions also may include preoperative patient education on an individual or group basis.²⁰⁵ After surgery, patients routinely receive gait training and exercise instruction while hospitalized and in a subacute rehabilitation facility. Many patients also receive home-based or outpatient therapy after discharge from inpatient care.

A patient is advanced from one phase of rehabilitation to the next based on an evaluation of their signs and symptoms and responses to selected interventions rather than at designated time periods.¹⁶⁷ Accordingly, the timelines noted in Table 21.4 and described in the following sections are intended to serve only as general guidelines.

NOTE: The postoperative guidelines in Table 21.4 and the following sections reflect recommendations for patients who have undergone *primary* TKA in which a *standard* surgical

approach was used. The suggested timelines for the progression of exercises and weight bearing tend to be more rapid after UKA than TKA and minimally invasive compared with traditional arthroplasty but slower after complex revision arthroplasty versus primary arthroplasty.

Immobilization and Early Motion

Typically, after primary TKA the knee is immobilized in a bulky compression dressing for a day, or sometimes continuous passive motion (CPM) is initiated in the recovery room or within a day after surgery. After complicated revision arthroplasty, an extended period of immobilization may be required. The position of immobilization after primary TKA usually is extension.²⁰³ Although atypical, an alternative approach is to immobilize the knee in a 90° flexion splint immediately after surgery and for brief intervals during the next day or two to achieve knee flexion as soon as possible while maintaining knee extension with exercises.⁹³

During the initial postoperative period, it is advisable to have a patient wear a posterior extension splint during ambulation until quadriceps control is re-established. A extension splint also is indicated at night for a patient who is having difficulty achieving full knee extension after surgery or who had a significant preoperative knee flexion contracture.^{33,203}

During the 1980s and 1990s CPM was used routinely during a patient's hospital stay after TKA.^{51,79} At that time a number of studies describing the benefits of CPM, such as decreased need for postoperative pain medication, decreased incidence of deep vein thrombosis, and increased or more rapid recovery of ROM, were reported in the literature.^{103,120,140} However, in some of the investigations that reported greater ROM with CPM, the knees of patients in the control groups, who did not undergo CPM, were immobilized for several days to a week after surgery.^{103,140}

Customary practice for the past decade or more has been to initiate early postoperative exercise except in some instances of complex revision arthroplasty.⁵⁵ To evaluate postoperative CPM in the context of current practice, several randomized, controlled studies have been conducted comparing the effects of early postoperative exercise with and without the use of CPM after TKA.^{9,35,42,112,122} The results of these studies have demonstrated that although the addition of CPM in the recovery room or within a day after surgery increased the rate of return of knee flexion during the early postoperative period in one study³⁵ it provided no significant long-term benefits as to gains in ROM and functional mobility.^{9,35,42,112,122}

Although CPM continues to be used at the surgeon's discretion, the literature currently reflects that it is either no longer recommended after primary TKA^{42,112,175} or, if used, is recommended as an adjunct to, not a replacement for, a postoperative exercise program.^{9,35,42,122,203}

Weight-Bearing Considerations

The extent to which weight bearing is allowable after primary TKA depends on the type of prosthesis implanted,

TABLE 21.4 Total Knee Arthroplasty—Interventions for Each Phase of Rehabilitation

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–4	Moderate Protection Phases: Weeks 4–8	Minimum Protection/Return to Function Phases: Beyond Week 8

the type of fixation used, the patient's age, size, and bone quality, and whether a knee immobilizer is worn during ambulation or transfers. With *cemented fixation*, weight bearing typically is permitted as tolerated immediately after surgery using crutches or a walker. During the first few days after surgery, use of a knee immobilizer may be required. The patient progresses to full weight bearing over 6 weeks.¹⁹¹

With *biological/cementless fixation*, recommendations for weight bearing vary from permitting only touch-down

weight bearing for 4 to 8 weeks while using crutches or a walker¹⁷⁵ to weight bearing as tolerated within a few days after surgery while using crutches or a walker.^{33,203,205}

Cane use is indicated as a patient progresses from partial to full weight bearing. Ambulation without an assistive device, particularly during outdoor walking, is not advisable until the patient has attained full or nearly full active knee extension and adequate strength of the quadriceps and hip musculature to control the operated lower extremity.^{33,131,175,205}

BOX 21.4 Exercise Precautions Following TKA

- Postpone straight-leg raises (SLRs) in side-lying positions for 2 weeks after cemented arthroplasty and for 4 to 6 weeks after cementless/hybrid arthroplasty to avoid varus and valgus stresses to the operated knee.
- Monitor the integrity of the surgical incision during knee flexion exercises. Watch for signs of excessive tension on the wound, such as drainage or skin blanching.
- Check with the surgeon to determine when it is permissible to initiate exercises against low-intensity resistance. It may be as early as 2 weeks or as late as 3 months postoperatively.²⁰
- Tibiofemoral joint mobilization techniques to increase knee flexion or extension may or may not be appropriate, depending on the design of the prosthetic components. It is advisable to discuss the use of these techniques with the surgeon before initiating them.
- Postpone unsupported or unassisted weight-bearing activities until strength in the quadriceps and hamstrings is sufficient to stabilize the knee.

Exercise

Guidelines for exercise after TKA have been reported in the literature since the mid-1970s.^{130,244} Goals and exercises for progressive phases of postoperative rehabilitation after current-day TKA, noted in Table 21.4, are discussed in the following sections.^{33,51,55,205} Precautions for exercise during rehabilitation are summarized in Box 21.4.

Many of the exercises described for the early phase of rehabilitation were reported in a consensus document developed by physical therapists on the management of patients during the period of hospitalization after TKA.⁵⁵ Prior to discharge from inpatient rehabilitation, a home exercise program serves as the foundation for the remainder of the rehabilitation process, with some patients also undergoing home-based or outpatient rehabilitation for a limited number of visits.

Exercise: Maximum Protection Phase

The focus of management during the first phase of rehabilitation, which extends for about 4 weeks, is to control pain and swelling (with cold and compression), achieve independent ambulation and transfers while using a walker or crutches, prevent early postoperative medical complications, such as pneumonia and deep vein thrombosis, and minimize the adverse effects of postoperative immobilization. The goal is to attain 90° of knee flexion and full knee extension by the end of this first phase of rehabilitation. However, full knee extension may not be possible until joint swelling subsides.

It is well established that pain and joint swelling limit the function of the quadriceps.⁴⁵ In addition, there is a high correlation between quadriceps muscle weakness and impaired functional abilities during the initial period of recovery after TKA.¹⁴⁷ Regaining quadriceps muscle strength, particularly in terminal extension, as

early as possible after TKA is essential for functional control of the knee during ambulation and negotiating stairs. In addition to early postoperative exercise, neuromuscular electrical stimulation or biofeedback is recommended.

Focus on Evidence

A study by Mizner and co-investigators¹⁴⁸ measured the voluntary activation and force-producing capacity of the quadriceps femoris muscle group in 52 patients (mean age 64.9 years, range 49 to 78 years) 3 to 4 weeks after unilateral, cemented primary TKA for OA and in 52 healthy individuals (mean age 72.2 years, range 64 to 85 years) without knee pathology. All patients in the TKA group had participated in a standard exercise program following surgery. Force production (maximum voluntary isometric contraction) and volitional activation of the quadriceps muscle group of the operated limb were, respectively, 64% and 26% less in the TKA group than in the healthy group. There was a weak relationship ($r^2 = 0.17$) between these results and postoperative knee pain. There were no significant differences in quadriceps muscle force production and volitional activation of the noninvolved knees in the TKA group compared with the healthy group. Based on the results of their study, the investigators recommended the use of neuromuscular electrical muscle stimulation or biofeedback as an adjunct to an individualized postoperative exercise program to augment quadriceps muscle force production after TKA.

Results of a prospective, randomized, controlled study conducted by Avramidis and colleagues⁶ support the use of neuromuscular electrical stimulation in addition to a postoperative exercise program after TKA. Thirty patients scheduled to undergo primary TKA were randomly assigned to two groups (15 patients per group). Postoperatively, patients in both groups underwent an individualized program of exercise and gait training. In addition, the treatment group received electrical stimulation to the vastus medialis muscle 4 hours a day for 6 weeks beginning on postoperative day 2. Patients in the electrical stimulation group demonstrated a significantly faster walking speed than those in the control group at 6 weeks and 12 weeks postoperatively.

The following goals and exercise interventions are included in the first phase of rehabilitation after TKA.^{33,51,55,102,205}

Prevent vascular and pulmonary complications.

- Ankle pumping exercises with the leg elevated immediately after surgery to prevent a DVT or pulmonary embolism
- Deep breathing exercises

Prevent reflex inhibition or loss of strength of knee and hip musculature.

- Muscle-setting exercises of the quadriceps (preferably coupled with neuromuscular electrical stimulation), hamstrings, and hip extensors and adductors.

- Assisted progression to active SLRs in supine and prone positions the first day or two after surgery, postponing SLRs in side-lying positions for 2 weeks after cemented TKA and for 4 to 6 weeks after cementless/hybrid replacement to avoid varus or valgus stresses to the operated knee.
- Active assisted ROM (A-AROM) progressing to assisted ROM (AROM) of the knee while seated and standing for gravity-resisted knee extension and flexion, respectively.
- As weight bearing on the operated lower extremity permits, wall slides in a standing position, mini-squats, and partial lunges to develop control of the knee extensors and reduce the risk of an extensor lag.

Regain knee ROM.

- Heel-slides in a supine position or while seated with the foot on the floor to increase knee flexion.
- Neuromuscular facilitation and inhibition technique, such as the agonist-contraction technique (described in Chapter 4), to decrease muscle guarding, particularly in the quadriceps, and increase knee flexion.
- Gravity-assisted knee flexion by having the patient sit and dangle the lower leg over the side of a bed.
- Gravity-assisted knee extension in the supine position by periodically placing a rolled towel under the ankle and leaving the knee unsupported or in a seated position with the heel on the floor and pressing downward just above the knee with both hands.
- Gentle inferior and superior patellar gliding techniques to prevent restricted mobility.

PRECAUTION: Avoid placing a pillow under the knee while lying supine or while seated with the operated leg elevated to reduce the risk of developing a knee flexion contracture.

Exercise: Moderate Protection Phase

The emphasis of the moderate protection phase of rehabilitation, which begins at about 4 weeks and extends to 8 to 12 weeks postoperatively, is to achieve approximately 110° knee flexion and active knee extension to 0° and gradually to regain lower extremity strength, muscular endurance, and balance. By 4 to 6 weeks postoperatively if nearly full knee extension has been achieved and the strength of the quadriceps is sufficient, most patients transition to using a cane during ambulation activities. This makes it possible to focus on improving the patient's gait pattern and the speed and duration of walking.

The goals and exercise interventions for this phase of rehabilitation are the following.^{33,51,55,102,147,205}

Increase strength and muscular endurance of knee and hip.

- Multiple-angle isometrics and low-intensity dynamic resistance exercises of the quadriceps and hamstrings against a light grade of elastic resistance or a cuff weight around the ankle. Perform in a variety of positions to strengthen knee and hip musculature.

- Resisted SLRs in various positions to increase the strength of hip musculature, with emphasis on the hip extensors and abductors.
- As weight bearing allows, continue or begin closed-chain exercises including wall slides, mini-squats, and partial lunges. Add forward and backward, progressing to lateral step-ups and step-downs (initially using a low block or stool and progressing the height of the block) and scooting forward and backward on a wheeled stool to improve functional control of the knee.
- Stationary cycling with the seat positioned as high as possible to emphasize knee extension.

Continue to increase knee ROM.

- Low-intensity self-stretching using a prolonged stretch or hold-relax exercises to increase knee flexion and extension if limitation persists. Flexibility of the hip flexors, hamstrings, and calf muscles also may need to be increased for standing and ambulation activities.
- Stationary cycling with seat lowered to increase knee flexion.
- Grade III inferior or superior patellar mobilization techniques to increase knee flexion or extension, respectively, if insufficient patellar mobility is restricting ROM.

Improve standing balance.

- Proprioceptive and balance training progressing from bilateral to unilateral stance on stable surface, then to balance activities on an unstable surface.
- Functional reaching activities while standing, stooping.
- Heel-toe walking; ambulation on a variety of surfaces and inclines.
- Stepping over small objects.

Exercise: Minimum Protection and Return to Function Phases

From the 8th to 12th week and beyond after surgery, the emphasis of rehabilitation is on task-specific strengthening exercises, proprioceptive training, and cardiopulmonary conditioning so the patient develops the strength, balance, and endurance needed to return to a full level of functional activities. However, patients often are discharged from supervised therapy 2 to 3 months postoperatively after attaining functional ROM of the knee and the ability to ambulate independently with an assistive device despite persistent strength deficits and functional limitations. These deficits have been shown to persist for a year or more after surgery.²⁴⁷

It is likely that some patients, especially those living in the community, could benefit from an intensive exercise program during the late phases of rehabilitation to perform demanding physical activities more efficiently, such as ascending and descending stairs and returning to selected recreational activities.

Focus on Evidence

Moffet et al.¹⁴⁹ conducted a single-blind, randomized controlled study to determine the effectiveness of an intensive, supervised functional training program initiated 2 months after primary TKA for OA. Patients in the experimental

group ($n = 38$) participated in facility-based, twice weekly, 60- to 90-minute exercise sessions consisting of hip and knee strengthening exercises, task-specific functional exercises, and aerobic conditioning exercises. These exercises were preceded by a warm-up and followed by a cool-down period. The full cohort of exercises was phased in gradually during the first 2 weeks of the program. Patients also received a home program to be followed on the days they did not participate in the supervised program. Patients in the control group ($n = 39$) participated in a home exercise program for 6 weeks with periodic home visits by a therapist. No exercise-related adverse events occurred during the study.

Patients were evaluated by means of the 6-minute walk test and two functional outcome and quality-of-life (QOL) measures prior to beginning the exercise program (baseline measurement at 2 months after surgery), at the conclusion of the 6-week exercise program, and at 6 and 12 months postoperatively. The two groups were comparable at baseline. At the conclusion of the intervention and at the 6- and 12-month follow-ups, patients in the intensive exercise group walked significantly longer distances during the 6-minute walk test than did those in the control group. Functional abilities and QOL measures also were significantly better for the intensive exercise group than the control group immediately after the 6-week program and at 6 months postoperatively. At 1 year after surgery there were no significant differences in function or QOL measures between the two groups.

The investigators concluded that an intensive, functionally oriented exercise program initiated 2 months after primary TKA was safe and effective for improving physical function and quality of life.

With the trend toward an increasing number of young (< 60 years of age) and active patients undergoing TKA,¹⁰¹ patient education is essential to help patients understand the detrimental effects of repetitive, high-impact activities (work-related, fitness-related, recreational) on the prosthetic implants and learn how to select activities that promote fitness but are least likely to reduce the longevity of the prosthetic knee.^{88,113,138} Accordingly, patients are advised to participate in low-impact physical activities after TKA to reduce the risk of component wear and mechanical loosening over time and the premature need for revision arthroplasty.

For the patient who wishes to participate in athletic activities after TKA, there are a number of considerations. Factors that influence participation include the level of demand (intensity and load) of an athletic activity, a patient's body weight, overall level of fitness, and pre-operative experience with the activity, and the technical quality of the knee replacement and related soft tissue balancing or reconstruction.^{88,113}

Physical activities for fitness and recreation that are highly recommended, recommended with caution, or not recommended after TKA are noted in Box 21.5.^{88,113,138}

BOX 21.5 Recommendations for Participation in Physical Activities Following TKA

Highly Recommended*

- Stationary cycling
- Swimming, water aerobics
- Walking
- Golf (preferably with golf cart)
- Ballroom or square dancing
- Table tennis

Recommended If Experienced Before TKA**

- Road cycling
- Speed/power walking
- Low-impact aerobics
- Cross-country skiing (machine or outdoor)
- Table tennis
- Doubles tennis
- Rowing
- Bowling, canoeing

Not Recommended***

- Jogging, running
- Basketball
- Volleyball
- Singles tennis
- Baseball, softball
- High-impact aerobics
- Stair-climbing machine
- Handball, racquetball, squash
- Football, soccer
- Gymnastics, tumbling
- Water-skiing

*Low impact, low load; appropriate at moderate- or high-intensity on a regular basis for aerobic fitness.

**Moderate impact; appropriate on a recreational basis if performed at low or moderate intensity.

***High impact, high load; peak load occurs during knee flexion.

Outcomes

Extensive research has been published in the orthopedic literature on patient-related outcomes after knee arthroplasty and the survivorship associated with a wide variety of prosthetic designs, surgical techniques, methods of fixation, and types of materials that have evolved over the past three to four decades.^{98,99,203,257} Because of this variability, it is difficult to draw general conclusions.²⁰⁴ What can be said, however, is that knee arthroplasty is a successful procedure for patients with advanced joint disease, although the ideal total knee replacement that replicates the normal biomechanics of the knee has yet to be developed. The effects of minimally invasive TKA and UKA on long-term patient-related outcomes and the longevity of implants have yet to be determined.

Patient-related outcomes after knee arthroplasty that have the most influence on patient satisfaction are relief of pain and an improved ability to perform necessary and desired functional activities for an extended number

of years. Approximately 90% of patients who undergo primary TKA can expect 10 to 20 years of satisfactory function before revision arthroplasty may need to be considered.²⁰³ For example, Dixon and colleagues⁴⁶ reported a 92.6% survival rate of modular, fixed-bearing TKA in patients followed for a minimum of 15 years.

Parameters typically measured to determine the success of knee replacement surgery are the level of pain, overall QOL, knee ROM, strength of the knee musculature, and a patient's ability to perform functional activities safely and with ease.

Pain relief. Almost all patients who undergo knee arthroplasty report a significant reduction of pain during knee motion and weight bearing, with most patients reporting good to excellent pain relief.^{59,203,204,220,243}

ROM. Improvements in knee ROM are not as predictable as relief of pain. Stiffness often persists after the initial recovery from surgery has occurred.⁵⁹ However, it also has been reported that ROM may continue to improve up to 12 to 24 months postoperatively.²²⁰ Factors that influence postoperative ROM include preoperative ROM, the underlying disease, postoperative pain, and whether a primary or a revision arthroplasty was performed. Complications such as component malpositioning, inadequate soft tissue balancing or reconstruction, infection, and mechanical loosening of an implant can adversely affect postoperative ROM.^{179,217}

Patients with restricted ROM preoperatively usually continue to have limited knee flexion, extension, or both postoperatively despite an aggressive postoperative exercise program.^{217,220} In fact, the most important predictor of long-term postoperative knee ROM is preoperative ROM.^{119,202,217} For example, in a study of 358 patients who underwent primary TKA for OA, total ROM of the knee was 110° preoperatively and 113° postoperatively due to a reduction in the average knee flexion contracture from 12° to 9°.²⁰² The results of two other studies found that despite patients' participation in an outpatient or home-based postoperative rehabilitation program, there was no significant change in preoperative or postoperative knee ROM at 6 months¹⁴⁷ or at 12 months after surgery.¹⁹⁰

Differences in prosthetic design, such as mobile-bearing versus fixed-bearing^{32,133,203} or PCL-retaining versus PCL-substituting designs,^{173,176,203} and the method of fixation^{175,203} do not appear to affect ROM outcomes after primary TKA. A comparison of five designs of posterior cruciate-substituting implants, for example, showed no significant differences in the extent of improvement of knee ROM among designs.²⁰²

Limited knee ROM has a substantial impact on postoperative function, particularly if knee flexion is less than 90° and knee extension is limited by more than 10° to 15°.²⁰³ With less than 90° to 100° of knee flexion, it is difficult to negotiate stairs; and having less than 105° makes it difficult to stand up from a standard height chair without using arm support.²⁰³ In contrast, lack of full

knee extension because of contracture or an extensor lag is thought to be a source of a patient's perception of knee pain or instability during ambulation activities particularly when ascending and descending stairs.^{111,203}

Strength and endurance. It takes a minimum of 3 to 6 months after surgery for a patient to regain strength in the quadriceps and hamstrings to a preoperative level.^{111,147,220} Quadriceps weakness tends to persist longer after knee arthroplasty than does knee flexor weakness.²²⁰

Studies of patients after unilateral TKA with a conventional surgical approach have demonstrated that quadriceps strength in the operated leg correlates highly with performance on tests of functional abilities during the first 6 months after surgery.¹⁴⁷ Quadriceps strength also is significantly less than in similarly aged healthy individuals 6 months to a year after surgery^{59,147,243} and the noninvolved leg 1 to 2 years postoperatively.^{199,218} It has been suggested that eversion of the patella during a conventional surgical approach may contribute to impaired function of the quadriceps mechanism after surgery.^{124,218} Given the number of studies that identified significant quadriceps weakness after TKA and the high correlation between quadriceps strength and functional performance, there is substantial evidence to support the importance of quadriceps strengthening exercises in postoperative rehabilitation programs to optimize function after TKA.

Physical function and activity level. Relief of pain as the result of TKA significantly improves a patient's QOL and ability to perform functional activities. In general, when comparing preoperative with postoperative function, patients with high preoperative scores on functional measures achieved a higher level of function postoperatively than patients with low preoperative functional scores.⁶⁵ An insufficient number of studies have been conducted directly comparing the effects of various prosthetic designs (e.g., cruciate-retaining versus cruciate-substituting and mobile-bearing versus fixed-bearing designs) on knee control during functional activities (e.g., walking or negotiating stairs) to draw conclusions.

A systematic review of the literature by Ethgen and colleagues⁵⁷ revealed that a patient's postoperative level of function and QOL, as measured by self-report questionnaires, typically begins to surpass the preoperative level at approximately 3 months, with most improvement in function occurring by 6 months, although additional improvements may occur for a year or more postoperatively.^{220,243}

A survey by Weiss et al.²⁴⁶ of 176 patients (mean age 70.5 years) 1 year or more after TKA identified patients' level of participation in activities of graduated difficulty and determined which activities were most important to patients. The survey also identified activities that were difficult after TKA. The results of the survey indicated that in addition to basic activities of daily living (ADL)—walking, stair-climbing, personal care—patients performed a wide range of therapeutic and recreational

activities after TKA. The activities in which the highest percentage of patients participated were stretching exercises (73%), leg-strengthening exercises (70%), gardening (57%), and stationary cycling (51%). These same activities were rated as important by patients. Functions that were the most difficult and most often caused knee pain were squatting (75%) and kneeling (70%).

Bradbury and colleagues²³ studied the pre- and post-operative sports participation of 160 patients who had undergone TKA 5 years earlier. Preoperatively, there were no significant differences in knee ROM, walking abilities, and radiographs in the patients who did and did not participate in sports activities. Postoperatively, the investigators found that 51 (65%) of the 79 patients (mean age 73 at the 5-year follow-up) who had regularly (at least twice a week) participated in sports activities during the year prior to surgery were participating in some type of sport at the 5-year follow-up. Patients were more likely to return to low-impact rather than high-impact activities. Of the patients who did not regularly participate in a sport before surgery, none took up a sport postoperatively.

Despite an overall positive impact of TKA on physical function, long-term studies indicate that functional abilities typically remain below norms for age-matched populations.^{59,65} A follow-up study of 276 community-dwelling patients 6 months after primary TKA revealed that overall physical function improved significantly for all patients, although 60% reported moderate to extreme difficulty descending stairs and 64% continued to have a similar degree of difficulty with heavy household tasks.¹⁰⁴

Results of another study indicated that 1 year after TKA, despite a relative absence of pain and some improvement in functional abilities, significant deficits in strength and function were apparent when compared with the abilities of age-matched, healthy individuals.²⁴³ The post-TKA patients had less strength of the knee musculature, slower walking and stair-climbing speeds, and a higher perceived level of exertion during activities than healthy individuals. The authors pointed out that the post-TKA patients as a group were heavier than the control group and suggested that general physical deconditioning may have contributed to the postoperative group's functional limitations. This study emphasizes the need for inclusion of a low-impact aerobic conditioning program during rehabilitation after TKA.

PATELLOFEMORAL DYSFUNCTION: NONOPERATIVE MANAGEMENT

Related Patellofemoral Pathologies

Historically, the differential diagnosis of patellofemoral pathologies has been plagued with confusion, largely related to the use of broadly inclusive terminology such as chondromalacia patellae and patellofemoral pain syndrome. In an attempt to more clearly identify the anatomical struc-

tures involved and the biomechanical changes leading to dysfunction, several classification systems have been proposed. These classifications include guidelines for intervention based on impairments and functional limitations.^{96,252}

Patellofemoral Instability

Instability includes subluxation or dislocation of a single or recurrent episode. There may be an abnormal Q-angle, dysplastic trochlea (shallow groove or flat lateral femoral condyle), patella alta, tight lateral retinaculum, and inadequate medial stabilizers (VMO). There may be associated fractures. Usually the instability is in a lateral direction. The dislocation may derive from direct trauma to the patella or from a forceful quadriceps contraction while the foot is planted and the femur is externally rotating while the knee is flexed. Recurrent dislocation is usually an indication for surgery to redirect the forces through the patella.

Patellofemoral Pain with Malalignment or Biomechanical Dysfunction

Patellofemoral pain due to malalignment or a biomechanical dysfunction includes impairments that cause an increased functional Q-angle such as femoral anteversion, external tibial torsion, genu valgum, or foot hyperpronation. There may be a tight lateral retinaculum, weak VMO, patella alta, patella baja, or dysplastic femoral trochlea. There is usually abnormal patellar tracking, and there may be discordant firing of the quadriceps muscle.⁹⁶

Patellofemoral Pain Without Malalignment

Patellofemoral pain without malalignment includes many subcategories of lesions that cause anterior knee pain.

Soft tissue lesions. Soft tissue lesions include plica syndrome, fat pad syndrome, tendinitis, iliotibial band friction syndrome, and bursitis.

- **Plica syndrome** describes a condition related to irritation of remnants of embryological synovial tissue around the patella. With chronic irritation, the tissue becomes an inelastic, fibrotic band that is tender during palpation. When acute, the tissue is painful during palpation. The band is usually palpable medial to the patella, although there are variations in its location.^{19,107}
- **Fat pad syndrome** involves irritation of the infrapatellar fat pad from trauma or overuse.
- **Tendinitis** of the patellar or quadriceps tendons often occurs from overuse as the result of repetitive jumping. Tenderness occurs along the attachment of the tendon to the patella.
- **Iliotibial (IT) band friction syndrome** is irritation of the IT band as it passes over the lateral femoral condyle. Contributing factors could be tight tensor fasciae latae or tight gluteus maximus (see discussion in Chapter 20). Because the IT band attaches to the patella and lateral retinaculum, it may cause anterior knee pain.
- **Prepatellar bursitis**, also known as housemaid's knee results from prolonged kneeling or recurrent minor trauma to the anterior knee. When inflamed there may be restricted motion due to the swelling and pain caused by direct pressure or pressure from the patellar tendon.

Tight medial and lateral retinacula or patellar pressure syndrome. There is increased contact pressure of the patella in the trochlear groove.

Osteochondritis dissecans of the patella or femoral trochlea. Osteochondral lesions result in pain on the retro surface of the patella that is worse during squatting, stooping, ambulation, and descending steps. The knee may give way or may lock. There may be loose bodies within the joint.

Traumatic patellar chondromalacia. With chondromalacia there is softening and fissuring of the cartilaginous surface of the patella, which is diagnosed with arthroscopy or arthrography.⁹⁶ It may eventually predispose the joint to degenerative arthritis or basal degeneration of the middle and deep zones of the cartilage.⁷⁸ Causes of the degeneration may include trauma, surgery, prolonged or repeated stress, or lack of normal stress such as during periods of immobilization.¹⁷⁴

Patellofemoral osteoarthritis. Osteoarthritis may be idiopathic or posttraumatic and is diagnosed by radiographic changes consistent with degeneration.

Apophysitis. Osgood-Schlatter's disease (traction apophysitis of the tibial tuberosity) and Sinding-Larsen-Johansson syndrome (traction apophysitis on the inferior pole of the patella) occur during adolescence owing to overuse during rapid growth. They are self-limiting conditions.

Symptomatic bipartite patella. Most bipartite patellae (due to patellar ossification variants) are asymptomatic, but trauma may disrupt the chondro-osseous junction leading to symptoms.⁹⁶

Trauma. Trauma includes tendon rupture, fracture, contusion, and articular cartilage damage that results in inflammation, swelling, limited motion, and pain with dysfunction whenever contracting the quadriceps, such as during stair climbing, squatting, and resisted knee extension.

Etiology of Symptoms

The cause of anterior knee pain may be direct trauma, overuse, faulty patellar tracking from malalignment due to anatomical variations or soft tissue length and strength imbalances, degeneration, or a combination of these factors.^{27,47,135,189,201,215,242,256} An attempt should be made to determine the causative factors based on the patient's history and a comprehensive and sequential examination.

Common Impairments and Functional Limitations/Disabilities

Impairments that may be associated with patellofemoral dysfunction include the following.^{27,47,100,116,135,189,201,215,242,256}

- Weakness, inhibition, or poor recruitment or timing of firing of the VMO
- Overstretched medial retinaculum

- Restricted lateral retinaculum, IT band, or fascial structures around the patella
- Decreased medial gliding or medial tipping of the patella
- Pronated foot
- Pain in the retropatellar region
- Tight gastrocnemius soleus, hamstring, or rectus femoris muscles
- Irritated patellar tendon or subpatellar fat pads
- Patellar crepitus, swelling, or locking
- Weakness in the hip abductor or external rotator musculature

Limitations associated with the impairments include the following.

- Pain or poor knee control when descending or ascending stairs
- Pain with walking, jumping, or running interfering during ADL, instrumental ADL (IADL), work, and community, recreational, or sport activities
- Pain and stiffness with prolonged flexed knee postures, such as sitting or squatting

Patellofemoral Symptoms: Management—Protection Phase

When symptoms are acute, treat them as any acute joint problem—with modalities, rest, gentle motion, and muscle-setting exercises in pain-free positions. Pain and joint effusion inhibit the quadriceps,²³¹ so it is imperative to reduce irritating forces. Splinting the patella with a brace or tape may unload the joint and relieve the irritating stress.¹⁰⁷

Patellofemoral Symptoms: Management—Controlled Motion and Return to Function Phases

When signs of inflammation are no longer present, management is directed toward correcting or modifying the biomechanical forces that may be contributing to the impairment. Because no one factor or combination of factors has been identified as the direct cause or effect of patellofemoral pain symptoms, it is imperative to develop interventions that address the patient's specific impairments.¹⁸⁹

Educate the Patient

Patient advice. Because end-range stress and prolonged postures tend to exacerbate symptoms, the following information should be provided.

- Until the knee is symptom-free, avoid positions and activities that provoke the symptoms.
- Minimize or avoid stair climbing and descending until the hip and knee muscles are strengthened to a level at which they can control knee function without symptoms.
- Do not sit with the knees flexed excessively for prolonged periods. During sitting, periodically perform ROM to the knee to relieve stasis.

Home exercise program. Use a home exercise program to reinforce training. Prior to discharge provide instructions for safe progression of the exercises.

Increase Flexibility of Restricting Tissues

Identify any structures that could be contributing to faulty mechanics and establish a stretching program. The gastrocnemius, soleus, quadriceps, and hamstring muscles have been identified as specific muscles with decreased flexibility in individuals with patellofemoral dysfunction.¹⁸⁷ In addition to self-stretching techniques described in the exercise section of this chapter, techniques to stretch the two-joint muscles that cross the hip and knee are described in Chapter 20, and those that cross the knee and ankle are described in Chapter 22.

Because restrictions related to insertion of the IT band and the lateral retinaculum may contribute to decreased patellar mobility and faulty patellar tracking in some patients with patellofemoral pain syndrome, specific techniques to address these impairments are described in this section.

Patellar mobilization—medial glide. Position the patient side-lying. Stabilize the femoral condyles with one hand under the femur and glide the patella medially with the base of the other hand (Fig. 21.9).^{81,136} There is usually greater mobility with the knee near extension; progress by positioning the knee in greater flexion prior to performing the medial glide.

Medial tipping of the patella. Position the patient supine. Place the thenar eminence at the base of the hand over the medial aspect of the patella. Direct posterior force tips the patella medially. While the patella is held in this position, friction massage can be applied with the other hand along the lateral border (Fig. 21.10). Teach the patient to self-stretch in this manner.

Patellar taping. Use tape to realign the patella and apply a prolonged stretch as well as maintain alignment of the patella for nonstressful training.^{81,135,136}

Self-stretching—insertion of IT band. Position the patient side-lying with a belt or sheet strapped around the ankle and the other end placed over the shoulder and held in the hand. The hip is positioned in extension,

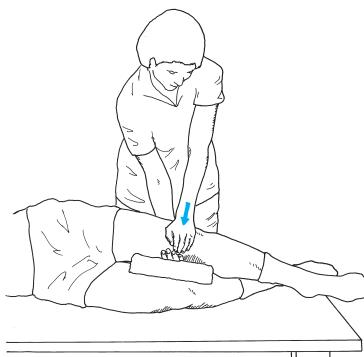

FIGURE 21.9 Medial glide of the patella.

FIGURE 21.10 Medial tipping of the patella with friction massage along the lateral border.

adduction, and slight lateral rotation and the knee in flexion.

- Instruct the patient to first flex the knee and abduct the hip; then extend the hip (this ensures that the IT band is over the greater trochanter).
- The femur is then adducted with slight lateral rotation until tension is felt in the IT band along the lateral knee.
- The patient stabilizes himself/herself in this position by holding onto the strap. If tolerated, a 2- to 5-lb weight is placed distally over the lateral thigh for added stretch, and the position is maintained for 20 to 30 minutes (Fig. 21.11).

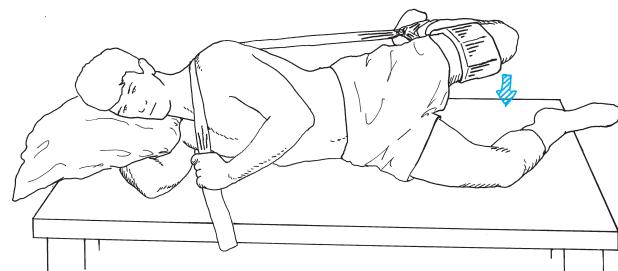

FIGURE 21.11 Self-stretch to the insertion of IT band.

Improve Muscle Performance for Functional Control

Because many possible diagnoses fall under the category of patellofemoral pain syndromes, various biomechanical influences may be the precipitating or perpetuating cause of the symptoms. Not all patients benefit from the same exercises. Research studies have not identified interventions that have led to consistent results.¹⁸⁹ It is imperative that the therapist design an exercise program that addresses the specific impairments of each patient, considering factors such as trunk, hip, and foot strength and alignment.^{100,132,189} Exercises for impairments in these regions are described in Chapters 16, 20, and 22, respectively.

Non-Weight-Bearing (Open-Chain) Exercises

NOTE: There is controversy regarding compressive forces and stress in the patellofemoral joint with open-chain exercises.^{56,80} The type of resistance (constant, variable, or isokinetic) places different demands on the quadriceps muscle in

terms of maximum effort at various ranges. The resultant force from the quadriceps tendon and patellar tendon and the patellar contact area also vary through the ROM. Therefore, the stress to the articulating surface of the patella varies. There is little or no contact of the patella with the trochlear groove from 0° to 15° of flexion,⁵⁶ so pain felt in that range could derive from irritation of the patellar fat pads or synovial tissue. Greatest patellar stress is at 60° and compression loads at 75°, so pain may be provoked in these ranges when maximum torque from the resistance force is applied in these ranges.⁵⁶ Where the pathology is located affects where in the range the patient feels pain.⁸⁰ It is recommended that when examining the patient the range where pain is felt is noted and resistance loads that cause pain in that range be avoided.

Vastus medialis obliquus emphasis. Although it is not possible to isolate contraction of the VMO, it is accepted that the line of pull of this component of the quadriceps muscle influences the tracking of the patella, and thus effort is directed toward developing awareness of the VMO contraction during quadriceps muscle activity. Use tactile cues over the muscle belly, electrical stimulation, or biofeedback to reinforce the VMO contraction during open- and closed-chain extension exercises.

Quadriceps setting (quad sets) in pain-free positions. Have the patient set the quads with the knee in various positions while focusing on tension development in the VMO. Because the site of irritation varies among patients, identify pain-free positions for each patient to ensure non-destructive loading.^{56,80}

Quad sets with straight-leg raising. Because many fibers of the VMO originate on the adductor tendons and medial intramuscular septum, some popular exercise programs suggest that by laterally rotating the femur while performing SLR exercises the adductors contract and provide a firm base for the VMO.^{4,47,135} However, electromyography (EMG) studies do not support the claim of increased activity in the VMO.¹⁰⁶

Progression of resisted isometrics. When the patient tolerates it, isometric resistance to knee extension may be utilized in pain-free positions.

Focus on Evidence

To determine if there is preferential recruitment of the VMO over the VL, five knee extension exercises in symptomatic and control subjects were studied during various combinations of adduction and medial rotation of the tibia.¹¹⁶ Investigators found that the VMO/VL ratio was greatest when there was simultaneous resistance to medial tibial rotation and knee extension. The test was conducted with the knee at 70° of flexion and the tibia laterally rotated. The ratio with resisted adduction in extension was less than with resisted extension alone. This study did not evaluate the effects of exercise on pain or improved function.

Short-arc terminal extension. Begin with the patient supine and knee flexed around 20° (see Fig. 21.17). If tolerated and the motion is not painful, light resistance is added at the ankle. Strengthening in terminal extension trains the muscle to function where it is least efficient because of its shortened position and where there is minimal patellar compression because it is superior to the femoral groove. This action is needed when lifting the leg into bed and moving the covers, as well as when lifting the leg into a car.

PRECAUTION: If there is irritation of the synovial lining of the suprapatellar pouch or bursa, terminal knee extension may be painful and should be avoided until the pain subsides.

Weight-Bearing (Closed-Chain) Exercises

See the last section of this chapter for detailed descriptions of various weight-bearing exercises.

- If weight bearing is painful, begin with partial weight-bearing exercises. Progress to standing exercises as tolerated.
- To improve strength and muscular endurance, the patient should perform the repetitions of the appropriate exercise until symptoms or loss of control just begins. It is important to not push beyond that point in order to avoid faulty mechanics or loss of control.
- Mini-squats, which may be useful for improving patellar tracking, are introduced early in the exercise program when weight bearing and partial squatting are tolerated and do not provoke symptoms.

NOTE: A recent study suggests that mini-squats are effective in causing a greater VMO/VL ratio than a maximum voluntary isometric quadriceps contraction.⁹⁷

- Observe the lower extremity positioning as the patient squats or descends steps; it is important for the knee to maintain alignment over the foot and not go into increased valgus.¹⁸⁹ Valgus alignment may be indicative of weak hip abductor musculature, which should be addressed with strengthening exercises to develop dynamic control.

PRECAUTION: Because there are higher patellar compressive loads when the knee is flexed beyond 60° during weight bearing, exercises and activities with the knee flexed beyond this angle may provoke symptoms. Use caution when the patient is ready to progress beyond 60°. Have the patient carefully monitor symptoms and stop the exercise if symptoms develop.

Functional Activities

Exercises are progressed as described in the exercise section of this chapter so long as the patient is able to maintain control and not exacerbate the symptoms. Use activity-specific drills to prepare the patient to return to the desired activity.

Modify Biomechanical Stresses

If the patient has foot pronation, a foot orthosis may relieve the stresses at the knee.^{53,84} Assess lower extremity mechanics, and modify any faulty patterns.

Focus on Evidence

A systematic review of the literature focusing on quality randomized controlled studies for patellofemoral pain syndrome revealed that interventions most effective for reducing pain and improving function were acupuncture, quadriceps strengthening, and combinations of interventions that include quadriceps strengthening with patellar taping and use of biofeedback.¹⁸ The effectiveness of a patellar brace was not refuted or supported, nor was the use of manual therapy techniques such as stretching and manipulation. No particular exercise approach was superior to another for improving pain and function, although exercise interventions in general have been shown to improve symptoms sooner than in control groups. The authors emphasized the importance of developing effective methods for classifying patients and gearing interventions to each patient's impairments.¹⁸

BOX 21.6 Surgical Options for Patellofemoral Dysfunction

- Lateral retinacular release, including release of the lateral patellofemoral and patellotibial ligaments
- Repair, imbrication, or reconstruction of the medial patellofemoral ligament
- Proximal realignment of the extensor mechanism (medialization or advancement and medialization of the VMO)
- Distal realignment of the extensor mechanism (anteromedialization of the tibial tubercle and insertion of the patellar tendon)
- Arthroscopic débridement
- Repair of patellofemoral articular cartilage lesions (microfracture, osteochondral autograft transfer/mosaicplasty, autologous chondrocyte implantation)
- Abrasion arthroplasty/chondroplasty of the posterior surface of the patella (used less frequently with the advent of surgeries to repair articular cartilage)
- Interposition trochleoplasty for trochlear dysplasia
- Replacement arthroplasty of the posterior surface of the patella or patellectomy (salvage procedures for advanced degeneration of the articular surface)

PATELLOFEMORAL AND EXTENSOR MECHANISM DYSFUNCTION: SURGICAL AND POSTOPERATIVE MANAGEMENT

Any number of factors, noted in the previous section, can contribute to chronic patellofemoral pain and crepitus, degeneration of the articular surface of the patella, or recurrent instability of the patella. When conservative (nonoperative) management of patellofemoral dysfunction fails, surgery may be indicated.

Surgical intervention can be used to alter the alignment of the patellofemoral joint, correct imbalances of static stabilizers (see Fig. 21.4) of the patella and knee, decrease an abnormal Q-angle (see Fig. 21.3 for depiction of Q-angle measurement), improve tracking of the patella, and débride or repair the articular surface of the patella. However, before a surgical procedure is selected, the etiology of symptoms and identification of contributing factors must be determined by a thorough physical examination and radiographic and arthroscopic evaluation.

Categories of surgical options for patellofemoral dysfunction are noted in Box 21.6.^{72,73,95,144,145,180,188} Numerous variations of procedures fall under each of these categories. Often a combination of procedures is necessary.^{73,158} Of the procedures noted, lateral retinacular release is the procedure performed most often for patellofemoral pain. In contrast, only in rare instances is a patellofemoral joint replacement (as an alternative to TKA) or patellectomy performed for chronic patellofemoral pain and dysfunction. If used, these

procedures are reserved as salvage procedures for patients with end-stage articular degeneration and collapse of the joint space.^{73,145,180}

The goals and interventions for rehabilitation after surgeries for patellofemoral and extensor mechanism dysfunction are directed toward restoring and improving the function of the entire lower extremity and trunk, not just the knee, and are derived from resources dealing with postoperative and nonoperative management.^{10,67,126,132,189} Depending on the phase of rehabilitation, the goals and interventions discussed in the previous section on nonoperative management of patellofemoral dysfunction are applicable to postoperative management.

The goals of postoperative rehabilitation are to: (1) control pain and swelling; (2) prevent or reduce the adverse effects of immobilization (3) restore postoperative knee ROM quickly and safely; (4) maximize the function of the extensor mechanism, especially the VMO, to restore full active knee extension and prevent an extensor lag; (5) remediate deficits in the length and strength of the hip and ankle to develop stability and flexibility proximal and distal to the knee; and (6) educate the patient and possibly alter the lifestyle to prevent recurrence of patellofemoral pain or instability.

A number of factors influence the rate of progression of postoperative rehabilitation. These factors include the patient's age, general health, and severity of symptoms prior to the surgical procedure, the presence of other pathology, the desired functional outcomes, and the patient's adherence to the prescribed home exercise program and motivation to return to functional activities.

Lateral Retinacular Release

Depending on the underlying pathologies, lateral retinacular release (LRR) may be performed in isolation or in conjunction with other procedures, such as proximal or distal realignment of the extensor mechanism, imbrication of the medial structures, joint débridement, articular cartilage repair, chondroplasty, or synovectomy.

Indications for Surgery

Although opinion varies, the following are often cited as indications for LRR.^{67,70,73,75,145,188} Chronic patellofemoral pain and functional limitations without improvement in symptoms after 6 months of conservative (nonoperative) management including exercise, taping, bracing, anti-inflammatory medication, and modification of daily activities.

- Restricting and often tender lateral retinaculum with documented rotational malalignment of the patella, specifically a lateral patellar tilt (without subluxation), and resulting lateral compression syndrome.^{70,73,145,188}
- Minimal or no evidence of patellofemoral chondrosis or abnormal Q-angle.
- In conjunction with other surgical procedures performed to correct instability (subluxation or dislocation) of the patella, inadequate dynamic medial stabilizers, increased Q-angle, and inadequate size/shape of the trochlear groove.

Procedures

Background and Operative Overview

The LRR is designed to reduce an identified lateral tilt of the patella, alleviate excessive compressive forces on the lateral facet of the patella, and consequently reduce pain and the risk of lateral subluxation of the patella.^{73,188} Typically, LRR is performed arthroscopically through several parapatellar portals, but it also may be performed through an open approach that involves a longitudinal parapatellar incision immediately lateral to the patella when done concomitantly with other open procedures.^{67,70,73,75,145,180,188}

The procedure “releases” the lateral structures supporting the patellofemoral joint, specifically the superficial and deep portions of the lateral retinaculum and the lateral patellofemoral and patellotibial ligaments by means of an incision extending from the superior lateral pole of the patella to just lateral and inferior to the patellar tendon. Any loose chondral flaps are removed.¹⁴⁵ The location of the incision is such that the superior lateral and inferior lateral geniculate arteries are cut and must be cauterized immediately and tied. However, the release leaves the tendinous portion of the vastus lateralis (VL) muscle intact so as not to compromise the function of the quadriceps.

Electrocautery¹⁵⁸ and, most recently, radiofrequency ablation⁷⁵ are alternatives to surgically incising the retinaculum. The advantages of these methods for releasing the lateral structures is less bleeding and subsequent hemarthrosis.

After the release has been completed, patellar tracking is assessed. The wounds are closed and covered with a sterile dressing, and a compression dressing is placed around the knee.

Complications

Several complications may occur with LRR.^{75,126,188} The most common complication associated with LRR is hemarthrosis if the geniculate artery is not adequately cauterized during surgery. Thermal injury to overlying skin can occur with radiofrequency ablation or electrocautery.⁷⁵ As with any surgery, there is always the risk of the patient developing a DVT. A superficial infection also can occur, but intra-articular infection is rare.

Other complications include postoperative arthrofibrosis or medial patellar subluxation as the result of the release extending too far proximally, causing weakness of the VL muscle. In rare instances rupture of the quadriceps tendon or complex regional pain syndrome (reflex sympathetic dystrophy) may occur.³⁷ Any of these complications can affect postoperative rehabilitation and compromise the outcome.

Postoperative Management

Postoperative management of LRR is a fairly straightforward intervention process that progresses quite rapidly, especially after arthroscopic LRR because of less postoperative tissue morbidity.^{10,70,75,126} The patient is progressed through the phases of rehabilitation based on signs and symptoms and the attainment of phase-specific goals.¹⁶⁷ Management of each phase of rehabilitation following arthroscopic LRR is summarized in Table 21.5.

Immobilization and Weight-Bearing Considerations

The knee is immobilized postoperatively in full extension with a compression dressing and patella-stabilizing orthosis or posterior splint.^{10,75,126} A Cryo-Cuff®, which combines cold and compression, or another form of cryotherapy is applied to minimize the postoperative joint effusion often associated with hemarthrosis. The patient is permitted to ambulate, weight bearing as tolerated with crutches, immediately after surgery. When control of the quadriceps is sufficient to hold the knee in full extension, use of the knee immobilizer and assistive devices for ambulation may be discontinued.

Exercise: Maximum Protection Phase

Emphasis during the maximum protection phase after arthroscopic LRR, which extends approximately 2 weeks postoperatively, is prevention of complications, such as a DVT, control of pain and joint swelling, restoration of quadriceps function, and regaining ROM. Maintaining adequate patellar mobility to prevent formation of adhesions that could position the patella in the same alignment that was evident preoperatively or even in a more lateral position is also a priority. By the end of this first phase of rehabilitation, as swelling subsides and tissues heal, the goal is to achieve 115° of knee flexion to full extension.

TABLE 21.5 Lateral Retinacular Release—Interventions for Each Phase of Rehabilitation

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–2	Moderate Protection Phase: Weeks 3–4	Minimum Protection Phase: Weeks 5–6	Return to Function Phase: Beyond Week 6

Adapted from: Magine et al.,¹²⁶ page 327, with permission.

Exercises are initiated the day of surgery, even after an open release, and include setting exercises of the knee and hip musculature and assisted ROM. These exercises, summarized in Table 21.5, are similar to those for nonoperative management of patellofemoral dysfunction during the acute stage of tissue healing (detailed in the previous section of this chapter). All exercises are progressed within the patient's comfort level. Exercises to develop control of the quadriceps can be performed in non-weight-bearing and protected weight-bearing positions. As noted in Table 21.5, the use of a felt pad wedge placed under the compression dressing along the lateral border of the patella,¹²⁶ which applies a slight medial glide, or the use of McConnell taping^{81,135} to maintain patellar alignment and unload the lateral soft tissue structures may enable the patient to perform knee exercises more comfortably.

Although grades I and II patellar mobilization procedures should be initiated during the early postoperative period to maintain patellar gliding and to prevent patellofemoral adhesions, these glides should be performed within the patient's pain parameters.¹²⁶ With proper instruction the patient can be taught to carry out patellar mobilization techniques at home and should do so regularly throughout the day.

Exercise: Moderate Protection Phase

The moderate protection phase after arthroscopic LRR, which begins by the third postoperative week, places emphasis on attaining full active ROM of the knee as well as the hip and ankle. Interventions are aimed at developing muscular strength and endurance of the entire lower extremity and the trunk, as well as re-establishing balance as pain and joint effusion reach a minimal level. Closed-chain and open-chain exercises, performed while maintaining appropriate alignment, are progressed for knee, hip, and ankle musculature at levels of intensity and positions in the ROM that do not evoke pain. In addition to quadriceps training, emphasis is placed on improving the function of the hip abductors, extensors, and external rotators.¹³² If the patient is having difficulty re-establishing active control of the quadriceps, electrical stimulation or biofeedback is beneficial. Aerobic conditioning on a stationary bicycle to re-establish cardiopulmonary fitness also is begun during this phase.

Flexibility exercises for the lower extremity should continue, with particular emphasis placed on stretching the gastrocnemius, soleus, and hamstring muscles, which have been shown to be tight in patients with patellofemoral dysfunction.¹⁸⁷ Stretching the IT band also may be necessary. If restricted, the IT band can contribute to excessive compression over the lateral femoral condyle and lateral border of the patella during knee motion.

Available motion and strength are incorporated into progressive functional activities. Any number of exercises (described in the final section of this chapter) and individually designed exercises can be incorporated and progressed in a patient's rehabilitation program so long as the selected exercises do not cause a recurrence of patellofemoral symptoms.

Exercise: Minimum Protection and Return to Function Phases

The advanced phases of rehabilitation, which begin about 5 weeks after surgery, are characterized by the progression of interventions initiated during the moderate protection phase, and activity-specific training for return to work or sport function. The aim is to educate the patient to resume full activity slowly while monitoring signs and symptoms. The return to function phase focuses on advanced training for sport or occupational demands.

NOTE: Continued use of patellar taping or a patellar tracking orthosis during exercise may be useful during the progression of exercises and transition to functional activities.

During this phase a self-managed maintenance program and plan for adherence should be developed. Patients usually can return to a full level of activity by 6 to 8 weeks postoperatively.

Outcomes

As an independent procedure, LRR can be useful for alleviating or reducing patellofemoral pain if the cause of the pain stems from compression of lateral structures of the knee as the result of an excessive lateral tilt of the patella.^{70,73,180,188} Comparably favorable outcomes have been reported for arthroscopic and open procedures.⁷⁰ Good to excellent short-term reduction of pain and associated patellofemoral symptoms have been reported for 65% to 75% of patients, although it may take 3 to 6 months after surgery to achieve maximum function.⁷⁵ Long-term effectiveness of LRR is questionable, especially in patients with a history of patellar instability.¹⁸⁸

Proximal Realignment of the Extensor Mechanism

Proximal realignment of the extensor mechanism usually is reserved for the patient with a history of recurrent lateral instability (dislocation/subluxation) of the patella who continues to be symptomatic despite a course of nonoperative management. It is often performed in the skeletally immature patient with patellar instability or in conjunction with distal realignment involving an osteotomy in the skeletally mature patient.^{73,95} If performed in isolation, it is not appropriate solely for the management of patellofemoral pain.⁷³

Indications for Surgery

Proximal realignment of the extensor mechanism is indicated for a combination of the following findings.^{73,74,95,158,180,188}

- Deficiency (acute injury, chronic laxity) of the medial patellar support structures, in particular the medial patellofemoral ligament, leading to extensor mechanism malalignment and recurrent instability of the patella
- Excessive (or abnormal) lateral tracking of the patella and insufficiency of the VMO

- Painful, lateral compressive forces at the patellofemoral joint and persistent lateral tilt of the patella despite an LRR
- Appropriate realignment option for the skeletally immature patient with patellar instability

CONTRAINDICATIONS: Proximal realignment is not appropriate for patients with articular degeneration of the medial patella, patella alta, or trochlear dysplasia as it may exacerbate or have no impact on symptoms.^{73,95}

Procedures

Background and Operative Overview

A proximal realignment procedure, which is performed as an open procedure through a medial parapatellar incision after arthroscopic examination of the knee and removal of loose osteochondral fragments, is characterized by a repair or reconstruction (tightening/imbrication) of the medial patellofemoral ligament, often coupled with advancement of the VMO muscle to a more central and distal location to improve its resting length-tension relationship.^{73,158,180,188} For the patient with an acute dislocation who does not respond to nonoperative management, direct repair of the medial patellofemoral ligament, rather than reconstruction, often is sufficient.⁹⁵

The medial patellofemoral ligament is repaired or imbricated with nonabsorbable sutures at its patellar or medial epicondylar attachment, depending on the location of damage. Use of an autogenous hamstring or fascia lata graft also has been advocated to reinforce the reconstruction of the medial patellofemoral ligament damaged in an acute dislocation.⁴⁹ Sometimes the medial patellotibial and medial patellomeniscal ligaments also must be tightened or repaired.^{73,74}

If a lateral release is indicated to restore or maintain the balance of the patella in the trochlea, it is performed arthroscopically. The use of a concomitant soft tissue or bony distal realignment procedure has been advocated in the presence of an abnormally increased Q-angle.^{74,158}

Complications

In addition to complications that can occur with other patellofemoral surgeries, such as hemarthrosis, adhesions, infection, or a DVT, there are complications seen in proximal realignment procedures.^{73,126} For example, significant scarring or overtightening of the medial patellofemoral ligament and/or VMO can exacerbate pain caused by increased loads on a medial articular lesion that may have occurred as the result of an acute dislocation. Scarring or overtightening also can cause increased patellar rotation and excessive medial tracking leading to retropatellar erosion or increased risk of *medial* instability of the patella. However, inadequate transfer of the VMO may result in no change in patellar position, tracking, or a patient's symptoms.

Entrapment, irritation, or a neuroma of the saphenous nerve as it passes the adductor tubercle and splits at the pes anserine tendon can occur with procedures involving structures on the medial side of the knee. Reflex sympathetic

dystrophy, also referred to as complex regional pain syndrome, occasionally develops (see Chapter 13).³⁷

Complications are more likely to occur with an open rather than an arthroscopic realignment procedure.¹²⁶ Surgical advances in proximal realignment procedures by arthroscopic intervention have decreased the morbidity of this surgery.

Postoperative Management

Postoperative rehabilitation after proximal realignment follows a course similar to that seen after LRR (see Table 21.5) with the exception of a longer maximum protection phase and more gradual progression of exercise and weight bearing to allow adequate time for the reconstructed soft tissues to heal (about 5 to 6 weeks).^{10,126}

As with postoperative management after LRR and nonoperative management of patellofemoral dysfunction, many of the exercises selected for a patient's rehabilitation traditionally have focused on regaining pain-free ROM, maintaining patellar mobility, and recruiting the quadriceps mechanism as a unit and the VMO in particular. These interventions are designed to prevent or remediate patellar restrictions and an extensor lag (quadriceps lag).^{4,10,47,106,126,226,235} Equally important to the success of rehabilitation following repair of the extensor mechanism is remediating deficits in strength, endurance, and flexibility of the trunk, hip and ankle musculature.^{100,132,187,189}

Immobilization and Weight-Bearing Considerations

The knee is immobilized in a range-limiting, hinged orthosis or a posterior splint in full or nearly full extension to protect the reconstructed soft tissues. Some surgeons allow removal of the immobilizer for early ROM in a protected range within a few days after surgery or while wearing the hinged orthosis,¹²⁶ whereas others advocate continuous immobilization for a week postoperatively.^{10,95,126,188}

During ambulation with crutches, the knee immobilizer should be locked in extension. Either no weight or touch-down/toe-touch weight bearing is permitted on the operated extremity for the first 10 to 14 days postoperatively, followed by gradual progression to 75% weight bearing by 4 weeks. Full weight bearing without assistive devices should be achieved by weeks 8 to 10 but only in the absence of an extensor lag.^{126,188}

Exercise Progression

Refer to goals and interventions for LRR (see Table 21.5), but progress exercises to increase the range of knee flexion and to improve strength and muscular endurance more gradually than after LRR. Too rapid progression after extensor mechanism realignment may cause suture failure in the approximated soft tissues leading to an inability to control patellar position.¹²⁶

Goals, a progression of exercise interventions, and criteria to advance from one phase of rehabilitation to the next after proximal realignment procedures are summarized in the following sections.^{74,126} Exercise precautions after proximal and distal extensor realignment procedures are noted in Box 21.7.^{10,95,126}

BOX 21.7 Exercise Precautions after Proximal or Distal Realignment of the Extensor Mechanism

- Initiate A-AROM and AROM exercises in a hinged, range-limiting orthosis to prevent excessive knee flexion or a valgus stress to the knee.
- Progress knee flexion gradually so as not to disrupt sutures after advancement of the VMO or medial transfer of the patellar tendon and tibial tubercle.
- When assisting with supine-lying hip and knee flexion/extension ROM, stand on the contralateral side of the operated extremity to avoid placing a valgus stress on the knee and stretching repaired medial structures.
- To protect the medial structures during the initial phase of healing after a proximal repair, use patellar taping to maintain the patella in a central or slightly medial position during quadriceps training.
- Postpone unilateral closed-chain exercises that involve full weight bearing on the operated side for at least 4 to 6 weeks after soft tissue reconstruction and for at least 8 weeks or until radiographic healing has occurred after a distal realignment involving a bony procedure.
- Do not perform a maximum voluntary contraction (MVC) of the quadriceps for at least 12 weeks after proximal or distal realignment procedures.

Exercise: Maximum Protection Phase

Goals. During the first 4 weeks after surgery, goals are to control pain and swelling, prevent adhesions, regain mobility and muscle control, and establish a home exercise program while protecting the reconstructed soft tissues.

Interventions. While symptoms are acute, apply cold intermittently. Limit weight bearing and the range of knee motion permissible and include the following interventions while the reconstructed extensor mechanism is most vulnerable to excessive stresses.

- **ROM.** Perform knee flexion/extension exercises (A-AROM and AROM) in the range-limiting orthosis from 0° to 60° during the first 2 weeks, to 90° by end of week 3, and to 110° to 120° by end of week 4.^{74,126} Stretch hip and ankle musculature, if restricted.
- **Joint mobility.** Use gentle (grade I and II) joint mobilizations of the patellofemoral and tibiofemoral joints to decrease pain and prevent adhesions.
- **Muscle performance.** Begin isometrics for quadriceps control and active superior patellar gliding with emphasis on VMO activation augmented with neuromuscular electrical muscle stimulation or biofeedback. While wearing the knee immobilizer, initiate SLRs in supine, prone, and side-lying positions for hip control. Also, begin partial-range heel-slides in the supine position.

Criteria to advance to next phase. Criteria include minimal pain, full active knee extension, and 110° to 120° of knee flexion.

Exercise: Moderate Protection Phase: 4 to 8 Weeks

Goals. During the second phase of rehabilitation, goals are to attain unassisted, pain-free ambulation, full active knee flexion/extension, increase flexibility of hip and ankle structures if restricted, increase strength and endurance of lower extremity and trunk musculature, improve balance, and progress and reinforce the home exercise program.

Interventions. As symptoms subside, and the patient gradually places full weight on the operated extremity, the following interventions are appropriate.

- **ROM and joint mobility.** Begin low-intensity, prolonged stretching and grade III joint mobilization to increase ROM of restricted areas.
- **Muscle performance and balance.** Initiate pain-free, closed-chain and open-chain resistance training to increase strength and endurance in the entire lower extremity and proprioceptive training to improve balance control. Perform resisted exercises only in pain-free ranges and in positions consistent with weight-bearing precautions.

Criteria to advance to next phase. No swelling or extensor lag, pain-free functional ROM of the knee (0° to 135°), 4/5 strength of knee musculature.¹²⁶

Exercise: Minimum Protection/Return to Function Phases: Beyond 8 to 10 Weeks

Goals. The goals of the final phases of rehabilitation are to participate in gradually more demanding activities without recurrence of pain, patellar instability, or joint effusion and to return to a full level of activity without symptoms by 14 to 20 weeks postoperatively with modification of some activities, as necessary.

Interventions. Emphasize activity-specific training. Efforts should be made to modify the patient's lifestyle to avoid symptom-provoking activities at least on a temporary basis.

Refer to the exercise progression previously discussed for advanced nonoperative management and the selected exercises described in the final sections of this chapter.

Outcomes

Outcomes for proximal realignment of the extensor mechanism vary considerably among studies with most involving a combination of lateral release or distal realignment with proximal realignment. However, in a retrospective case series Drez and co-investigators⁴⁹ reported the use of medial patellofemoral ligament reconstruction with a soft tissue graft (and no distal realignment) in 15 patients with recurrent lateral instability after patellar dislocation. At a mean follow-up of 31.5 months (minimum of 2 years), 93% of patients had excellent results (10 patients) or good results (3 patients) on an objective functional outcome and patient satisfaction scale. Only 1 of the 15 patients reported one episode of subluxation during the follow-up period.

Poor results reported in the literature appear to be due more to retropatellar pain than to recurrent instability.

ty.⁹⁵ Patients with generalized joint hypomobility or uncorrected trochlear dysplasia tend to have a high rate of redislocation.⁷⁴

Distal Realignment of the Extensor Mechanism

For a patient with recurrent subluxation/dislocation of the patella with or without degeneration of the lateral and distal articular surfaces of the patella, distal realignment of the extensor mechanism may be the surgical intervention of choice. A medial transfer and possibly anteriorization of the tibial tubercle decreases laterally directed forces on the patella to improve patellar tracking and shifts contact stresses in a medial and proximal direction away from chondral lesions of the distal and lateral articular surface of the patella.⁷² Distal realignment procedures often are coupled with an LRR and sometimes with advancement of the VMO and repair of medial structures.^{74,158}

Indications for Surgery

The following are indications for distal realignment procedures.^{72,73,145,158,180,188}

- Recurrent episodes of patellar instability (dislocation/subluxation) and a sense of the knee “giving way” because of patellar malalignment due to lateralization of the tibial tubercle and patellar tendon insertion that cannot be corrected with LRR and proximal realignment procedures.
- Abnormally increased Q-angle.
- Patellofemoral arthrosis (chondral or osteochondral defects) on the lateral and distal retropatellar surfaces

CONTRAINDICATION: Bony procedures are not recommended for the skeletally immature patient whose tibial tubercle growth plate is open. Recurvatum of the knee can develop with premature closure of this epiphyseal plate.^{72,95,158}

Procedures

Background and Operative Overview

The purpose of distal realignment procedures is to transfer the patellar tendon medially to reduce the Q-angle and improve patellar tracking by decreasing the laterally directed moment.^{72,73,180,188} Distal realignment procedures are performed using an open surgical approach. However, examination of the knee joint and débridement of the articular surface of the patella typically precede the distal realignment procedure.

Several techniques of distal realignment have been reported. An osteotomy of the tibial tubercle is performed; the bony prominence is then transferred medially and secured with single-screw or double-screw fixation.^{72,74} Anteriorization (elevation) of the tibial tubercle serves to reduce shear forces and articular stresses on the patella.^{72,188} The procedure involves anteriorly displacing the tibial tubercle by means of a bone graft.¹⁸⁸ For the skeletally immature patient, a distal medialization procedure involves

only a soft tissues transfer. When the patellar tendon and tibial tubercle are reattached, often the knee is flexed 30° to prevent overtightening the quadriceps mechanism.¹⁵⁸

Complications

Uncommon but serious complications associated with distal realignment procedures include tibial fracture during placement of fixation screws, neurovascular injury during surgery, inadequate skin closure or sloughing over the osteotomy site, soft tissue infection or osteomyelitis, and nonunion of the transposed bone.^{72,188} Redislocation can occur laterally because of undercorrection or medially with overcorrection, particularly in patients who return to high-demand activities.^{72,158}

Pain at the anterior tibial tubercle from the fixation screws is not unusual. Therefore, screws are removed routinely 6 to 12 months after surgery.⁷² As with all patellofemoral surgeries, patellar adhesions can occur, restricting knee motion. Because distal realignment shifts retropatellar loads medially and proximally, arthrosis in these areas also can develop over time, causing knee pain.

Postoperative Management

Depending on the type of fixation used, rehabilitation after distal realignment involving bony procedures may progress even more gradually than rehabilitation following LRR and proximal realignment of soft tissues to allow time for bony healing. Ambulation with crutches while wearing a knee immobilizer locked in extension is permissible the day after surgery. Weight bearing is limited to touch-down/toe-touch for the first 4 weeks or until radiographic verification of bone callus formation at the osteotomy site has occurred.^{10,72,126} Weight bearing is progressed gradually, with full weight bearing permissible without the immobilizer at 8 weeks if quadriceps control is sufficient.¹²⁶

ROM also is progressed more gradually than after soft tissue procedures. (Refer to exercise precautions noted in Box 21.7.) A range-limiting orthosis is worn that allows motion from only 0° to 30°¹²⁶ or 0° to 60°⁷⁴ of flexion during the first week, to 90° of flexion by the end of week 4, and 135° (full knee flexion) by the end of week 8.¹²⁶ Otherwise, exercises are similar to those for nonoperative management, LRR, and proximal realignment procedures. The return to full activity generally takes about 5 to 6 months and is based on bone healing and lower extremity strength.

Outcomes

Successful outcomes after distal realignment surgeries for patellar instability, possibly associated with chronic knee pain from chondral lesions, are contingent on correctly determining the underlying causes of the patient's symptoms. Patients without degeneration of the retropatellar surface or those with lateral and distal lesions tend to have better results than those with medial articular lesions.¹⁴⁵

Often distal realignment procedures are coupled with a proximal repair and/or lateral release to correct malalignment and relieve symptoms. Results of studies of combined procedures reflect good to excellent out-

comes for most patients measured by one or more objective assessment tools. For example, Garth and colleagues⁷⁴ studied a group of young adults (mean age 18 years) with recurrent patellar instability despite a course of conservative management after sustaining an acute, traumatic, lateral dislocation of the patella. After undergoing distal realignment coupled with repair of the medial patellofemoral ligament and advancement of the patellomeniscal ligament, 90% (18/20) patients reported good to excellent results in knee function and patient satisfaction and no recurrence of symptoms at a minimum follow-up of 24 months. The results of another study in which three procedures were performed (lateral release, repair of medial supporting structures, and distal realignment) revealed that 32 of 42 knees (76%) in 37 patients had good or excellent outcomes at follow-up a mean of 44 months (minimum follow-up 25 months, range 25 to 85 months). At the time of follow-up, redislocation had occurred in four knees (9.5%).

LIGAMENT INJURIES: NONOPERATIVE MANAGEMENT

Mechanisms of Injury

Ligament injuries occur most frequently in individuals between 20 and 40 years of age as the result of sport injuries (e.g., skiing, soccer, football) but can occur in individuals of all ages. The anterior cruciate ligament (ACL) is the most commonly injured ligament. Often more than one ligament is damaged as the result of a single injury.

Anterior Cruciate Ligament

Anterior cruciate ligament (ACL) injuries occur from both contact and noncontact mechanisms. The most common contact mechanism is a blow to the lateral side of the knee resulting in a valgus force to the knee. This mechanism can result in injury not only to the ACL but to the medial collateral ligament (MCL) and the medial meniscus as well. This injury is termed the “unholy triad” injury because of the frequency of these three structures being injured from a common blow. The most common noncontact mechanism is a rotational mechanism in which the tibia is externally rotated on the planted foot. Literature supports that this mechanism can account for up to 78% of all ACL injuries.¹⁶⁵ The second most common noncontact mechanism is forceful hyperextension of the knee.

With prolonged ambulation on a knee that has a deficient ACL, the secondary restraints (lateral collateral ligament and posterolateral joint capsule) are stressed and become lax, and the individual may develop a “quadriceps avoidance gait.”⁹² The quadriceps avoidance gait in ACL-deficient knees was originally documented and described by Berchuck and colleagues¹¹ as a reduction in the magnitude of the flexion moment about the knee during the limb loading phase of gait due to the patient’s effort to reduce contraction of the quadriceps.

Posterior Cruciate Ligament

The posterior cruciate ligament (PCL) is most commonly injured by a forceful blow to the anterior tibia while the knee is flexed, such as a blow to the dashboard or falling onto a flexed knee.

Medial Collateral Ligament

Isolated injuries to the medial collateral ligament (MCL) can occur from valgus forces being placed across the medial joint line of the knee. Whereas most injuries to the ACL and PCL are complete tears of the ligament, injuries to the MCL can be partial or incomplete and are graded utilizing a I, II, III grading classification of ligament injuries described in Chapter 10.

Lateral Collateral Ligament

Injuries to the lateral collateral ligament (LCL) are infrequent and usually result from a traumatic varus force across the knee. It is not uncommon that more than one ligament, joint capsule, and sometimes the menisci are damaged as the result of a single injury.

Ligament Injuries in the Female Athlete

With an increase in the number of female athletes since the passage of Title IX in 1972, a concurrent increase in the number of injuries to female athletes has been seen, most significantly an increase in the number of knee injuries. What is interesting is that when injury to the ACL is sustained in a noncontact manner, a woman is three times more likely to tear the ACL than a man.⁵ With the increased number of noncontact ACL injuries in female athletes being reported, the American Academy of Orthopaedic Surgeons published a consensus paper examining the risk factors and prevention strategies of noncontact ACL injuries.⁸² In addition, results from a research retreat on “ACL Injuries—The Gender Bias” were published in the *Journal of Orthopaedic and Sports Physical Therapy*.⁴¹ Risk factors fall into four major categories: environmental, anatomical, hormonal, and biomechanical.

- *Environmental factors* center on the use of prophylactic knee braces to prevent knee injuries and a shoe-to-surface interface that may improve performance but may also increase the risk of injury.
- *Anatomical risk factors* include femoral notch size, ACL size, and lower extremity alignment. Insufficient data relating to each of these factors have resulted in an incomplete understanding of the influence of these factors at this time.
- *Hormonal differences* between males and females have also been postulated to be one possible factor related to the increased incidence of female ACL injuries. In 1996, hormone receptor sites for estrogen and progesterone were found in the ACL of humans. Since that time, research has been conducted to study the effects of such hormones on the mechanical properties of the ACL and other musculoskeletal tissues. To date, however, results of multiple studies differ in their conclusions.

- Biomechanical risk factors summarized by the consensus panel⁸² included the effect of the total chain (trunk, hip, knee, and ankle) on ACL injuries, awkward or improper dynamic body movements, deceleration and change of direction, and neuromuscular control of the joint.

Common Impairments and Functional Limitations/Disabilities

- Following trauma, the joint usually does not swell for several hours. If blood vessels are torn, swelling is usually immediate.
- If tested when the joint is not swollen, the patient feels pain when the injured ligament is stressed.
- If there is a complete tear, instability is detected when the torn ligament is tested.
- When swollen, motion is restricted, the joint assumes a position of minimum stress (usually flexed 25°), and inhibition (shut down) of the quadriceps muscle occurs.²²⁵
- When acute, the knee cannot bear weight, and the person cannot ambulate without an assistive device.
- With a complete tear, there is instability, and the knee may give way during weight bearing.

Ligament Injuries: Nonoperative Management

Acute sprains and partial ligament tears of the knee can be treated conservatively with rest, joint protection, and exercise. After the acute stage of healing, exercises should be geared toward regaining normal ROM, balance control, normalization of gait, and strengthening of muscles that support and stabilize the joint during functional activities. The degree of instability with ligament tears affects the demands the patient can place on the knee when returning to full activity. An intensive rehabilitation program, including balance/perturbation training to stimulate neuromuscular control, has been shown to be effective in selected athletes after ACL injury.^{63,64} With extensive damage and in general for those desiring to return to high-level work or sports, surgical repair often is necessary for return to a desired level of function.

If the collateral or coronary ligaments are involved, because of their superficial location cross-fiber massage to the structure helps align the healing fibers and maintain their mobility. Because of the structural characteristics of the MCL (a broad, flat ligament with deep and superficial portions, parallel alignment of collagen fibers, and fan-shaped attachments both proximally and distally), injuries to the MCL are typically managed with a conservative (nonsurgical) approach.²⁵¹ Conservative management of MCL injuries is described in Table 21.6; progression is based on presenting signs and symptoms.¹⁶⁷ A similar rehabilitation program for ACL injuries is followed with appropriate precautions (as noted below) regarding stress to the ligament.

Nonoperative Management: Maximum Protection Phase

Follow the principles described for an acute joint lesion.

- If possible, examine before effusion sets in.
- Utilize cold and compression with rest and elevation.
- Protect the joint during ambulation with use of crutches; partial weight bearing as tolerated. Teach safe transfer activities to avoid pivoting on the involved extremity.
- Initiate quadriceps-setting exercises. The knee may not fully extend for end-range muscle-setting exercises, so begin the exercises in the range most comfortable for the patient. As the swelling decreases, initiate ROM within tolerance.

Nonoperative Management: Moderate Protection (Controlled Motion) Through Return to Activity

As the swelling decreases, examine the patient for impairments and functional losses. Initiate joint movement and exercises to improve muscle performance, functional status, and cardiopulmonary conditioning.

Improve Joint Mobility and Protection

Joint mobility. Use supine wall slides (see Fig. 21.14), patellar mobilizations, and stationary cycling; encourage as much movement as possible. Unless there has been an extended period of immobilization, there should be minimal need to stretch contractures.

Protective bracing. Bracing may be necessary for weight-bearing activities to decrease stress to the healing ligament or to provide stability where ligament integrity has been compromised. Bracing can be one of two types: range-limiting postoperative type braces that are used to protect healing tissues and discarded during later phases of rehabilitation or functional braces that are used during rehabilitation and also when returning to functional activities. The patient must be advised to modify activities until appropriate stability is obtained.

Improve Muscle Performance and Function

Strength and endurance. Initiate isometric quadriceps and hamstring exercises and progress to dynamic strength and muscular endurance training. Neuromuscular control is compromised when stabilizing muscles fatigue.⁹⁴

- Utilize both open-chain and closed-chain resistance. Reinforce quadriceps contractions with high-intensity electrical stimulation if there is an extensor lag.²²² Progress muscular endurance and strengthening exercises using partial squats, step-ups, leg press, and heel-raises
- Emphasize neuromuscular control with stabilization and perturbation training in weight-bearing positions.

PRECAUTIONS: Open-chain terminal knee extension exercises (from 40° to 0°) with resistance applied to the distal leg and squatting between 60° and 90° cause increased anterior translation of the tibia and stress to the ACL. Exercises using either of these activities in the designated ranges should not be attempted with ACL injuries.^{82,250,253}

Teach the patient closed-chain strengthening activities from 60° to 0° and open-chain strengthening from 90° to 40°.²⁵³ Isolated open-chain knee flexion exercises (hamstring curls)

TABLE 21.6 Nonoperative Management of MCL Injuries—Intervention for Each Phase of Rehabilitation*

increase posterior translation of the tibia and should not be done with PCL injuries.

Cardiopulmonary conditioning. Utilize a program that is consistent with the patient's goals such as biking (begin with a stationary bike), jogging (begin with walking on a treadmill), ski machine, or swimming.

Functional training. Progress neuromuscular training. Develop activity-specific drills that replicate the demands of the individual's outcome goals.²⁴⁰ Suggestions for functional training are described in the exercise section of this chapter.

Focus on Evidence

In a randomized controlled study, 26 level I or level II athletes with an acute ACL injury or rupture of ACL grafts participated in a standard rehabilitation program or a standard rehabilitation program with perturbation training.⁶³ Of those in the perturbation group ($n = 12$), only one had unsuccessful rehabilitation, with the knee giving way while playing football prior to completing the program. In the control group (no perturbation training; $n = 14$) one-half of the subjects had unsuccessful outcomes and were considered at high risk for reinjury at the 6-month follow-up examination. The authors stated that although both groups returned to high-level physical activities those in the perturbation training group demonstrated greater long-term success.⁶³

LIGAMENT INJURIES: SURGICAL AND POSTOPERATIVE MANAGEMENT

Background

Ligaments of the knee provide the key stabilizing forces for accessory motions of the knee (see Fig. 21.2). Specifically, these accessory motions are anterior and posterior translation and medial/lateral pivots (valgus/varus/rotation). Strong ligamentous support is necessary, in part, because of the shallow design of the concave tibial articulating surface that allows significant translatory motions if unrestrained. Acute traumatic disruption or chronic laxity of the ligaments results in excessive accessory motions of the joint, which can impair functional abilities.^{26,68,146} Although injuries to each of the four primary knee ligaments (ACL, PCL, MCL, LCL) are discussed extensively in the literature, the ACL is, by far, the most frequently injured and surgically repaired.^{15,165}

Factors influencing the decision for surgical reconstruction of a knee ligament include the ligament injured (differences in healing capacities among ligaments), the location and size of the lesion, the degree of instability experienced by the patient, the presence of other pathology such as a meniscal or articular damage, the desired level of function to which the patient wishes to return, and the risk of reinjury.^{12,60,108,146,233} Prevention of future impairment is

also a consideration because acute ligament injury can lead to chronic instability and degeneration of joint structures over time if not managed and monitored adequately.¹⁵

General indications for ligament surgery. Surgical intervention for ligament injury is indicated if the patient has failed to meet functional goals established in a conservative rehabilitation program or early degenerative changes of the joint are apparent. Many authors^{15,26,69,146,213,233} recommend surgical intervention for acute, isolated ACL and LCL injuries after a brief period of acute symptom management in recreationally active individuals. Surgical management of chronic ligament injuries is advocated when the patient's function has become limited or when secondary pathology (e.g., meniscus damage, other ligament involvement, articular surface degeneration) has developed.

Types of ligament surgery. Ligament surgeries are classified as *intra-articular*, *extra-articular*, or combined procedures and can be performed using an open, arthroscopically assisted, or endoscopic approach.^{26,115,146} Prior to the development and refinement of arthroscopy, an open approach involving a large incision and arthrotomy was the only option available for surgically managing a ligament injury.

The first type of intra-articular procedure was a *direct repair* through an open approach. The repair was accomplished by reopposing and suturing the torn ligament. Postoperatively, a long period of immobilization and restricted weight bearing were required because of extensive tissue disruption associated with the open approach and the poor healing qualities of ligamentous tissue.¹¹⁵ Results of this procedure were unacceptable due to postimmobilization contractures, patellofemoral dysfunction, weakness, and an unacceptably high incidence of rerupture. Consequently, use of direct repair was abandoned as procedures involving intra-articular or extra-articular *reconstruction* were developed.

Intra-articular reconstruction of ligament injuries, which has evolved over the past four decades, has become the primary means by which ACL and PCL injuries are managed surgically. In general terms, reconstruction involves the use of a tissue graft to replicate the function of the damaged ligament and act as an inert restraint of the knee.^{16,26,115,129,146,162,233} Early reconstruction procedures were performed through an open approach. Although open reconstruction restored knee stability, the need for lengthy postoperative immobilization continued.¹¹⁵ Today, intra-articular ligament reconstruction is performed through an arthroscopically assisted or an endoscopic approach, causing far less tissue morbidity and resulting in a faster postoperative recovery.

NOTE: Overviews of intra-articular ACL and PCL reconstruction procedures are described in this chapter.

Extra-articular reconstruction procedures, which involve the transposition of dynamic musculotendinous stabilizers or inert restraints around the knee, such as the IT band, were designed to provide external stability to

the knee joint. Extra-articular procedures, in common use in the past, particularly for MCL and LCL injuries, are used rarely today as primary procedures because they do not restore normal kinematics to the knee as effectively as intra-articular procedures. Use of extra-articular procedures to augment intra-articular reconstruction in difficult cases also has been shown to have little benefit.¹¹⁵

Grafts: types, healing characteristics, and fixation. Intra-articular reconstruction is achieved through the use of tissue grafts, most often an *autograft* (the patient's own tissue) or occasionally an *allograft* (donor tissue) or a *synthetic graft*.^{109,115,143,162} An allograft or synthetic graft is used only when a suitable autogenous graft is not available, for example when a patient's own tissue is not suitable for graft harvesting.^{115,162} However, there is concern that remodeling and incorporation of the graft after implantation may be slower with an allograft (possibly due to sterilization to prevent disease transmission) or a synthetic graft than with an autograft.¹⁴³ (Refer to Chapter 12 and Box 12.7 for additional information about tissue grafts.)

Although a variety of tissues have been used for knee ligament reconstruction,^{109,117,129,143,150,162} a bone–patellar tendon–bone autograft has been used reliably and has been considered the gold standard for ACL reconstruction for several decades.^{117,166} It remains the most frequently selected graft material for this procedure.^{16,26,60,68,109,117,129,146} A frequently selected alternative to a patellar tendon graft for ACL reconstruction is a semitendinosus–gracilis tendon graft.^{115,117,150,209,234} Research has shown that the strength and stiffness of a bone–patellar tendon–bone graft and a quadrupled (four-strand) hamstring tendon graft are actually greater than that of the ACL ligament.²⁰⁹

An extensive body of knowledge exists on graft healing, placement, and fixation as well as the strength and stiffness of various tissues selected as grafts and their responses to imposed loads. Most research has focused on grafts for ACL reconstruction.^{16,24,68,91,108,117,219} Because the characteristics of grafts and graft fixation affect the rehabilitation process and the outcome of surgery, it is important to understand that a graft undergoes a series of changes after implantation as it heals. Initially, there is a period of avascular necrosis during which the graft loses substantial strength. This period is followed by a period of revascularization, then remodeling, and finally maturation, which typically takes at least 1 year. During the first 6 to 8 weeks postoperatively the graft is most vulnerable to excessive loads because the strength of the graft is derived solely from the fixation device, not the graft itself.^{16,24,108,109}

The need for a long postoperative period of immobilization and protected weight bearing after ligament reconstruction has been eliminated following primary ACL reconstruction for some time because of advances in graft selection, preparation, placement and fixation, and the evolution of arthroscopic techniques.^{16,24,219} Nevertheless, there is still a need to select and progress the stresses imposed on the healing graft carefully during early rehabilitation.

Goals of ligament surgery and rehabilitation. The goals of surgery and postoperative rehabilitation after ligament reconstruction are (1) restoration of joint stability and motion, (2) pain-free and stable weight bearing, (3) sufficient postoperative strength and endurance to meet functional demands, and (4) the ability to return to preinjury activities.

To meet these goals, successful postoperative outcomes start whenever possible with a *preoperative* program that includes edema control, exercise to minimize atrophy and maintain as much ROM as possible, protected ambulation, and patient education.^{45,183,211,253} Preoperative intervention is often possible because ligament reconstruction typically is delayed until acute symptoms subside. Exercises are similar to those used for the acute phase of nonoperative management of ligament injuries already discussed. Preoperative exercises should not further irritate the injured tissues or cause additional swelling or pain.

The *rate and progression* of postoperative rehabilitation programs vary; and no one program has been shown to be most effective or most efficient. Emphasis is placed on restoring a patient's functional abilities while protecting the healing graft and preventing postoperative complications and reinjury. Early controlled motion and weight bearing, hallmarks of current-day rehabilitation, have been shown to decrease the incidence of postoperative complications, such as contracture, patellofemoral pain, and muscle atrophy,^{183,211,214,253} and to allow patients to return to activity more quickly without compromising the integrity of the reconstructed ligament.²¹⁴

For more than a decade there has been a move away from adherence to strict time-based rehabilitation protocols toward guidelines that are progressed based on the attainment of specific criteria and measurable goals or performance on functional tests.^{45,52,90,125,127,157,167,253} For example, an exercise program is progressed only after full active knee extension has been achieved or arthrometer testing indicates that a particular level of joint stability is present. Open communication with the surgeon enables the therapist to discuss any precautions or concerns specific to individual patients and procedures.

Anterior Cruciate Ligament Reconstruction

Unlike the MCL, which heals readily with nonoperative management, the healing capacity of a torn ACL is poor, giving rise to the frequent need for surgical reconstruction to restore knee stability, particularly in the young, active individual.¹⁰⁸ The incidence of reinjury of the knee is lower after ACL reconstruction than with nonoperative management, particularly in patients younger than 25 years of age.⁵⁰

Indications for Surgery

Although there are no rigid criteria for patient selection, the most frequently cited indications for reconstruction of the anterior cruciate ligament include the following.^{15,26,129,146,150,162}

- Disabling instability of the knee due to ACL deficiency caused by a complete or partial acute tear or chronic laxity
- Frequent episodes of the knee giving way (buckling) during routine ADLs despite a course of nonoperative management
- A positive pivot-shift test because an ACL deficit is often associated with a lesion of other structures of the knee, such as the MCL, resulting in rotatory instability of the joint
- Injury of the MCL at the time of ACL injury to prevent lax healing of the MCL
- High risk of reinjury because of participation in high-demand, high-joint-load activities related to work, sports, or recreational activities

NOTE: Increased anterior translation of the tibia on the femur compared with the contralateral, noninvolved knee, as measured by an arthrometer, is considered a questionable indication because a strong correlation between these measurements of stability and a patient's symptoms of instability has not been established.¹⁵

CONTRAINDICATIONS: Relative, not absolute, contraindications for ACL reconstruction are noted in Box 21.8.^{15,26,129,150}

Procedures

Operative Overview

Surgical approach, graft selection, and harvesting. Over the past 20 years, surgical management of the deficient ACL has evolved and continues to be refined with a move away from entirely open reconstruction to most procedures now using arthroscopically assisted or endoscopic techniques to reduce tissue morbidity and reduce recovery time.^{15,16,58,115} In an arthroscopically assisted approach only the intra-articular portions of the procedure, such as meniscus débridement or repair, enlargement of the infracondylar notch of the femur, or drilling the femoral and tibial bone tunnels, are performed arthroscopically.¹¹⁵

The most common ACL reconstruction procedure today is an arthroscopically assisted or endoscopic procedure using an autograft. If a bone–patellar tendon–bone

graft is selected, it is harvested through a small, longitudinal incision over the patellar tendon from the patient's involved knee^{17,26,60,129,146} or occasionally from the contralateral knee.²¹³ The central one-third portion of the tendon is dissected along with small bone plugs attached to the tendon. If a semitendinosus–gracilis tendon autograft (hamstring tendon graft) is selected, it is harvested through an incision centered over the tibial insertion of the semitendinosus and gracilis tendons.^{58,150,209,216,219,234}

There are a number of advantages, disadvantages, and potential complications associated with bone–patellar tendon–bone and hamstring tendon autografts. For example, transition from mechanical fixation to biological fixation is thought to occur more rapidly with a patellar tendon graft, which involves bone-to-bone healing, than a hamstring tendon graft, which requires tendon-to-bone healing (6 to 8 weeks versus 12 weeks, respectively).²¹⁹ Other reported advantages and disadvantages of these two types of autografts are summarized in Boxes 21.9 and 21.10.^{1,58,115,117,198,209,216,234} It should be noted, however, that recently the use of a bone–hamstring tendon–bone autograft for ACL reconstruction was reported, allowing bone-to-bone healing and affording some of the same advantages associated with a bone–patellar tendon–bone autograft.¹³³

Graft placement and fixation. After the graft is harvested and prepared for implantation, the arthroscopic instrumentation is reinserted to drill femoral and tibial bone tunnels.^{16,69,115,129} Graft placement is achieved by passing the graft through the tunnels to its final position in the tibia and femur. Precise, anatomical graft placement is crucial for restoration of joint stability and mobility.⁹¹ Improper graft placement can lead to loss of ROM postoperatively.¹ A graft placed too far posteriorly may result in failure to

BOX 21.9 Advantages and Disadvantages/Complications of the Bone–Patellar Tendon–Bone Autograft

Advantages

- High tensile strength/stiffness, similar or greater than the ACL
- Secure and reliable bone-to-bone graft fixation with interference screws
- Rapid revascularization/biological fixation (6 weeks) at the bone-to-bone interface permitting safe, accelerated rehabilitation
- Ability to return to preinjury, high-demand activities safely

Disadvantages/Potential Complications

- Anterior knee pain in area of graft harvest site
- Pain during kneeling
- Extensor mechanism/patellofemoral dysfunction
- Long-term quadriceps muscle weakness
- Patellar fracture during graft harvest (rare, but significant adverse effects)
- Patellar tendon rupture (rare)

BOX 21.8 Relative Contraindications to ACL Reconstruction

- Relatively inactive individual with little to no exposure to work, sport, and recreational activities that place high demands on the knee
- Ability to make lifestyle modifications to eliminate high-risk activities
- Ability to cope with infrequent episodes of instability
- Advanced arthritis of the knee
- Poor likelihood of complying with postoperative restrictions and adhering to a rehabilitation program

BOX 21.10 Advantages and Disadvantages/Complications of the Semitendinosus–Gracilis Autograft
Advantages

- High tensile strength/stiffness greater than ACL with quadrupled graft
- No disturbance of epiphyseal plate in skeletally immature patient
- Evidence of hamstring tendon regeneration at donor site
- Loss of knee flexor muscle strength remediated by 2 years postoperatively

Disadvantages/Potential Complications

- Tendon-to-bone fixation devices (particularly tibial fixation) not as reliable as bone-to-bone fixation
- Longer healing time (12 weeks) at tendon-bone interface
- Hamstring muscle strain during early rehabilitation
- Short- and long-term knee flexor muscle weakness (not associated with functional limitation)
- Possible increased anterior knee translation (not associated with functional limitations)

regain full flexion, and a graft placed too far anteriorly may limit extension.²⁴

NOTE: Limited ROM into extension also may be caused by graft impingement due to an inadequate femoral notch size or buildup of scar tissue in the notch.¹ A *femoral notchplasty* (enlargement of the intercondylar notch) is performed to ensure adequate clearance of the graft as the knee extends.

Graft fixation is vital to the success of ACL reconstruction. With a bone–patellar tendon–bone graft, the bone plugs are secured at each end in the prepared tunnels (bone-to-bone fixation) by means of screw fixation (metal or bioabsorbable interference screws).^{24,26,69,117,129,219} Several types of soft tissue fixation device have been used to secure a hamstring tendon graft, including endobuttons, washers, and staples. Recently, several types of soft tissue screw (interference and transfixation) have been introduced.^{24,58,115,150,209} Despite these advances, strong tendon–bone fixation, particularly tibial fixation, remains a challenge.

An advantage of current-day fixation devices is that they can withstand early, but controlled, tensile forces placed across the graft with a low risk of compromising the security of the graft itself provided proper placement and fit of the fixation devices are achieved.^{16,24,58} This, in turn, permits early initiation of weight bearing and ROM of the knee, both typical elements of today's accelerated rehabilitation programs.^{90,127,209,214,253}

After graft fixation and prior to closure, the knee is moved through the ROM to check the graft's integrity and the tension on the graft during knee movement. As with graft placement, proper graft tension at the time of fixation has a direct effect on postoperative joint mobility and stability. Too little tension can result in excessive knee laxity

and potential instability, and too much tension can limit knee ROM.¹⁶ After the incision is closed, a small compression dressing is immediately placed on the knee, and often the leg is placed in a knee immobilizer for protection.

Complications

There are a number of operative and postoperative complications that can compromise outcomes after ACL reconstruction. Some of these complications were noted in Boxes 21.9 and 21.10. Even minor technical errors during reconstruction can affect function adversely. As discussed in the previous section, inappropriate placement of the graft or bone tunnels, problems with graft harvesting such as inadequate graft length, and improper graft tension can adversely affect joint stability and mobility.^{1,206,232} Insufficient graft length occurs more frequently during hamstring than patellar tendon graft harvesting. If graft fixation is insufficient, graft slippage and early failure can occur.^{206,209} With a bone–patellar tendon–bone graft, a bone plug can fracture during harvesting or implantation, necessitating an alternative autograft or an allograft.²⁰⁶

Postoperatively, potential complications are knee pain, loss of motion, persistent strength deficits, and inadequate joint stability.^{1,150,206,232} Anterior knee pain at the donor site of a patellar tendon graft or at the patellofemoral joint may affect functional activities. A neuroma of the infrapatellar branch of the saphenous nerve can cause significant knee pain during kneeling. Loss of full knee extension and quadriceps weakness are recognized as significant complications after ACL reconstruction. There may be permanent damage to the extensor mechanism after patellar tendon graft harvesting, leading to quadriceps weakness or even patellar tendon rupture in rare instances. Limited ROM of the knee may have been present prior to surgery or may develop after surgery. One possible cause is a buildup of scar tissue in the intracondylar notch, necessitating arthroscopic notchplasty. Loss of patellar mobility also may be a source of limited knee ROM. It has been suggested that a patient's preoperative strength and ROM also may have an impact on postoperative knee motion and strength.

 **Focus on Evidence**

McHugh et al.¹³⁹ evaluated 102 patients (age 31 ± 1 year) within 2 weeks of primary ACL reconstruction and 6 months after surgery to determine preoperative indicators of postoperative motion loss (lack of full knee extension) and quadriceps weakness. They found that patients with loss of knee extension preoperatively (in comparison to the noninvolved contralateral knee) were more likely to have limited knee extension postoperatively. However, a preoperative deficit of quadriceps muscle strength ($\geq 20\%$ compared with contralateral quadriceps strength) was not an indicator of postoperative quadriceps weakness 6 months after surgery.

Finally, graft failure and the need for revision reconstruction may occur even in the absence of risk factors related to surgical technique. It has been shown that graft

failure is most likely to occur during the early months after surgery.⁷¹ It has also been suggested that the most common cause of graft failure is poor adherence to postoperative rehabilitation, in particular returning to high-risk, high-joint-load activities prematurely.^{1,71,206}

Postoperative Management

Just over two decades ago, rehabilitation after ACL reconstruction involved long periods of continuous immobilization of the knee in a position of flexion and an extended period (often 6 to 8 weeks) of restricted weight bearing. Return to full activity often took a full year.^{25,125,171,212} With advances in surgical techniques and a better understanding of graft healing and the impact of stress on the healing graft, early postoperative motion and weight bearing—often referred to as “accelerated rehabilitation”—has become the standard of care after primary ACL reconstruction with an autogenous graft for the active, typically young patient.^{52,90,127,181,183,211,212,214,253}

Accelerated rehabilitation is based on the premise that a precisely placed and appropriately tensioned graft not only is strong enough to withstand the stresses of early motion and weight bearing, but that the graft responds favorably to these stresses during the healing process.^{16,211,212,214,253} Table 21.7 outlines a contemporary, accelerated program for postoperative management after primary ACL reconstruction.

NOTE: It is important to recognize that although the descriptor “accelerated” is used frequently in the literature to characterize current-day rehabilitation after primary ACL reconstruction, there is no consensus on the components, progression, or duration of postoperative exercise, weight bearing, and other interventions. Therefore, the sequence of goals and interventions described in Table 21.6 reflects guidelines common to a number of programs published in the literature.^{30,52,90,127,157,181,183,195,211,214,253}

Immobilization and Protective Bracing

The rationale for bracing after ACL reconstruction is protection of the graft and prevention of a knee flexion contracture during early rehabilitation.¹⁶ However, with advances in graft fixation, the need for and benefits of protective bracing during rehabilitation has become a point of debate—recommended by some but not by others.^{16,181,211,253}

The decision about whether postoperative bracing is prescribed is based on many factors, including the surgeon's philosophy, the type of graft used, intraoperative

observations about the quality of fixation, co-morbidities and concomitant surgical procedures (e.g., meniscus or collateral ligament repair), and an assessment of the patient's expected level of adherence to a postoperative rehabilitation program.^{90,183}

Position and duration of immobilization. If bracing is prescribed during early recovery, it usually is a hinged and possibly range-limiting orthosis. The following are commonly recommended guidelines for the position and duration of immobilization. When the brace is locked, it holds

the knee in full extension to prevent a knee flexion contracture or excessive hyperextension.^{26,45,52,90,150,181,183,211,214,253} In addition, the hinged orthosis initially may be set to limit full knee flexion during exercise (e.g., allowing movement from 0° to 90° or more the first week after surgery). Even though the greatest stress on the graft occurs between 20° of flexion and full knee extension, precise graft placement and tension allow full knee extension without disrupting the graft's integrity.

Typically, the brace is worn throughout the day for anywhere from a few weeks to 6 weeks¹⁶ and sometimes is also worn during sleep for the first week postoperatively.¹⁸³ During the first week or two the protective brace is locked in full extension during ambulation with crutches in the event of a fall.^{90,183,211,253} By the beginning of week 3 the brace is unlocked, allowing motion between full extension to 125° of flexion during ambulation and other weight-bearing activities. Depending on the stability of the knee, sometimes the protective brace may need to be worn for 2 to 3 months or possibly longer. These timelines are progressed more slowly when ACL reconstruction is combined with another procedure, such as a collateral ligament, meniscus, or articular cartilage repair.¹⁸¹ Some patients are advised to wear a functional brace during the advanced phases of rehabilitation and during high-demand sports or heavy manual labor after completing their rehabilitation program.

The literature provides some insight into the effectiveness of protective bracing during early rehabilitation.

Focus on Evidence

A review of the literature by Beynnon and colleagues¹⁶ identified only three randomized, controlled studies of the effects of brace use after primary ACL reconstruction. After analyzing the studies, the reviewers concluded that there was general consensus among investigators that use of a hinged brace during early recovery after surgery was associated with less joint swelling, wound drainage, and pain. However, at follow-up 1 and 2 years after surgery, no significant differences were identified in anterior-posterior knee stability, ROM, functional testing (hop test), thigh muscle strength, or patients' activity level and subjective assessment of outcomes in groups who did and did not use bracing during early rehabilitation.

Weight-Bearing Considerations

As with ROM, early weight bearing is possible after primary ACL reconstruction with a bone–patellar tendon–bone or hamstring tendon autograft because of advances in graft fixation. However, recommendations for a period of protected weight bearing immediately after surgery vary, ranging from some degree of restricted weight bearing the first 2 weeks to weight bearing as tolerated with use of two crutches immediately after surgery.^{17,58,139,181,198,211,240,253} Weight bearing is increased during the next 2 to 3 weeks based on the patient's symptoms. Protected weight bearing continues for a longer period of time if other structures in

the knee have been injured and/or repaired (e.g., after repair of an articular cartilage defect of a femoral or tibial condyle).²⁵³

Full weight bearing and ambulation without crutches while wearing an unlocked protective brace usually is permitted by 3 to 4 weeks if weight bearing is pain-free and the patient has achieved full, *active* knee extension and sufficient strength of the quadriceps to control the knee.^{90,150,183}

Weight-bearing recommendations do not appear to be based on the type of graft or graft fixation used or whether protective bracing is worn but, rather, are determined on an empirical basis. The few randomized studies in the literature indicate that immediate and delayed weight bearing during the first few weeks after surgery produce similar outcomes.¹⁶

Focus on Evidence

Tyler and colleagues²⁴¹ conducted a prospective, randomized, controlled study with 49 patients comparing the effects of immediate versus delayed weight bearing during the first 2 weeks after ACL reconstruction with bone–patellar tendon–bone fixation. The immediate weight-bearing group was advised to bear weight as tolerated and discontinue crutch use as soon as they felt comfortable doing so. The delayed weight-bearing group was advised not to wear a shoe on the operated side and remain non-weight bearing during ambulation with crutches for the first 2 weeks. After that, there were no restrictions placed on the progression of weight bearing. Neither group wore protective bracing. With the exception of weight-bearing status, the rehabilitation program for all patients was the same.

At a mean of 7.3 months, there were no significant differences between groups with respect to knee ROM, knee stability (measured by clinical examination and arthrometer), VMO activation (measured by EMG activity), or overall function. However, patients in the immediate weight-bearing group had a lower incidence of anterior knee pain than patients in the delayed weight-bearing group (8% and 35%, respectively). The investigators concluded that immediate weight bearing did not compromise knee joint stability or function and was beneficial in that it resulted in a lower incidence of postoperative anterior knee pain.

Exercise Progression

A progression of carefully selected exercises and functional activities coupled with patient education is a foundation of rehabilitation following ACL injury and reconstruction. Because surgery typically is delayed after injury until acute symptoms have subsided, there is ample time to implement a *preoperative* exercise program to restore full knee ROM, particularly extension, prevent atrophy and weakness of thigh musculature, and improve the strength and flexibility of hip and ankle musculature.^{45,183,211,253}

After reconstruction of the ACL, exercise begins immediately on the first postoperative day. Use of strong

grafts, such as bone–patellar tendon–bone and quadrupled hamstring autografts, and reliable graft fixation make early motion possible.^{90,127,181,183,211,253}

Sometimes CPM is used while a patient is hospitalized or at home after discharge. Although a valid mechanism for controlling postoperative pain and initiating early motion,^{48,134,169,211} it is used less frequently today than in the recent past.⁹⁰ It has been suggested that the CPM unit should be used without a calf band to minimize anterior translation of the tibia and prevent excessive stress to the graft site.⁴⁸

It is important to remember that a tendon graft goes through a necrotizing process the first 2 to 3 weeks postoperatively before revascularization commences and maturation gradually occurs.^{16,68,108,109} Therefore, exercises are progressed cautiously during each phase of rehabilitation, even during an accelerated program. If protective bracing has been prescribed, exercises are carried out while wearing the brace.

The rate of progression of exercise and functional training after ACL reconstruction depends on many factors. For example, patient-related facts, such as age and preinjury health status, affect the healing process, enabling younger, healthier patients to progress exercises more rapidly. The type of graft and graft fixation also may influence the progression of exercise. Some resources advocate more rapid progression of exercise for bone-to-bone fixation with a patellar tendon graft than for tendon-to-bone fixation with a quadrupled hamstring graft, suggesting that bone-to-bone healing may be faster than soft tissue-to-bone healing.^{90,183,253} In contrast, others advocate the same accelerated program for both procedures.^{58,198,209}

If, in addition to an ACL reconstruction, concomitant injuries are present or were managed surgically, the progression of exercises, as with weight bearing, typically is more gradual than after isolated ACL injury and reconstruction.²⁰³

Exercises for progressive phases of rehabilitation after ACL reconstruction, summarized in Table 21.6, are described in the following sections. Exercise precautions are noted in Box 21.11.^{90,139,211,222,249,253}

Exercise: Maximum Protection Phase

During the early postoperative period, a delicate balance exists between adequate protection of the healing graft and donor site and prevention of adhesions, contractures, articular degeneration, and muscle weakness and atrophy associated with immobilization. Early motion places beneficial stresses that strengthen the graft but must be carefully controlled to avoid stretching the graft while in a weakened state, particularly during the first 6 to 8 weeks after implantation.

The following goals and exercise interventions are emphasized during the first 4 weeks after surgery when considerable protection of knee structures is required.^{90,127,139,181,183,211,253}

Goals. Immediately after surgery through the first few postoperative weeks, in addition to controlling pain and

BOX 21.11 Exercise Precautions after ACL Reconstruction

Resistance Training—General Precautions

- Progress exercises more gradually for reconstruction with hamstring tendon graft than bone–patellar tendon–bone graft.
- Progress knee flexor strengthening exercises cautiously if a hamstring tendon graft was harvested and knee extensor strengthening if a patellar tendon graft was harvested.

Closed-Chain Training

- When squatting in an upright position be sure that the knees do not move anterior to the toes as the hips descend because this increases shear forces on the tibia and could potentially place excess stress on the autograft.
- Avoid closed-chain strengthening of the quadriceps between 60° to 90° of knee flexion.*

Open-Chain Training

- During PRE to strengthen hip musculature, initially place the resistance above the knee until knee control is established.
- Avoid resisted, open-chain knee extension between 45° to 15°.*
- Avoid applying resistance to the distal tibia during quadriceps strengthening.*

*Contraction of the quadriceps in these positions and ranges causes the greatest anterior tibial translation and can create potentially excessive stress to the graft during the early stage of healing.^{56,83,249,253}

swelling and initiating ambulation with crutches, exercise goals are to prevent reflex inhibition of knee musculature, prevent adhesions, restore full knee mobility, regain kinesthetic awareness and neuromuscular control (static and dynamic) of the lower extremity, and improve strength and flexibility of hip and ankle musculature.

The goal for knee ROM is to achieve 90° of flexion and full passive extension by the end of the first week as joint swelling subsides and then 110° to 125° of flexion by 3 to 4 weeks.

Interventions. Pain, swelling, and peripheral edema are controlled in a standard manner. Exercises begin the day of or the day after surgery with an emphasis on (1) preventing vascular complications (DVTs); (2) activating knee musculature, particularly the quadriceps; and (3) establishing knee mobility. Patient education during the first phase of rehabilitation focuses on the home exercise program.

When weight-bearing exercises are initiated, they are performed in a protective brace if one has been prescribed. Low-intensity closed-chain exercises and proprioceptive/neuromuscular control training are initiated as soon as weight bearing is permissible. The value of closed-chain exercises and proprioceptive/neuromuscular control training after ACL reconstruction has been supported by many

authors and is discussed in the exercise section of this chapter.^{7,30,45,90,127,195,211,253}

Focus on Evidence

Bynum and colleagues³⁰ conducted a prospective, randomized controlled study comparing open-chain and closed-chain rehabilitation after primary ACL reconstruction with a bone–patellar tendon–bone autograft. Immediately after surgery all patients followed the same exercise program, emphasizing early ROM (against no external resistance) and isometric quadriceps control. All patients wore a protective brace and ambulated with crutches, bearing weight as tolerated. When strengthening exercises were initiated, one group followed an open-chain regimen and the other a closed-chain regimen. One year after surgery 66% of patients participated in a follow-up examination that included subjective and objective measurements; it was conducted by someone blind to group assignment. Patients in the closed-chain exercise group compared with the open-chain group had significantly less anterior knee pain, knee stability closer to normal as measured by an arthrometer, earlier return to functional activities, and greater overall satisfaction with the outcome of the surgery.

The following exercises are advocated for the maximum protection phase.^{90,127,139,183,195,211,249,253}

- **Voluntary activation of knee musculature.** Begin muscle setting of quadriceps, hamstrings, and hip abductors and adductors within the patient's comfort level. Use electrical stimulation or biofeedback to augment quadriceps activation. Perform four-position SLRs, first with assistance, then progressing to active hip motions with the knee maintained in extension. Add external resistance when the patient is able to maintain knee control during hip movements. Initiate low-intensity, multiple-angle isometrics of the knee musculature with emphasis on quadriceps control. To activate the hamstrings dynamically include supine heel-slides to a comfortable level of hip and knee flexion, active knee flexion in a standing position (hamstring curls without resistance added), and scooting forward while seated on a rolling stool (see Fig. 21.22).
- **ROM and patellar mobility.** Begin ROM in a protected range. Include therapist-controlled PROM or A-AROM within the patient's comfort level. Include patellar mobilization to prevent adhesions. To increase passive knee extension, assume a supine or long-sitting position and prop the heel on a rolled towel or bolster with the knee unsupported. To increase knee flexion, include supine, gravity-assisted wall slides. Stretch hip and ankle musculature if flexibility is limited.
- **Neuromuscular control, proprioception, and dynamic stability of the operated lower extremity.** While wearing a protective brace, if prescribed, begin trunk and lower extremity stabilization exercises in a standing position with weight distributed equally on both lower extremities and some weight on the hands for support, progressing

to bilateral mini-squats in the 0° to 30° range and weight-shifting, stepping, and marching movements. Gradually decrease upper extremity support. When the knee is pain-free and full weight bearing is possible, begin unilateral activities. Add stationary cycling and exercise on a seated leg press machine or in a semi-reclining position on a Total Gym® unit at 3 to 4 weeks and exercises in a pool as incision healing allows.

NOTE: A quadriceps contraction with the knee in full extension generates little to no anterior translation of the tibia on the femur because the knee is in a closed-pack position.

Criteria to advance to next phase. Criteria include minimal pain and swelling, full active knee extension (no extensor lag), 50% to 60% quadriceps strength (measured isometrically at 60°), greater than 110° of knee flexion, and no evidence of excessive joint laxity (determined by arthrometry measurements).

Exercise: Moderate Protection Phase

The moderate protection phase, which begins about 4 to 5 weeks postoperatively or at a point when identified criteria have been met, extends to about 10 to 12 weeks postoperatively. The emphasis of this phase is to achieve full knee ROM and increase strength, endurance, and balance in preparation for a transition to functional activities without compromising the stability of the knee. The hinged, protective brace is worn for gait and most exercises.

NOTE: By 8 to 10 weeks revascularization of the graft is becoming well established, and therefore exercises can be performed more vigorously.^{68,108,109}

Goals. Rehabilitation goals during the intermediate phase are to attain full ROM (full knee extension and 125° to 135° flexion), improve lower extremity strength and muscular endurance, ambulate without assistive device and protective brace using a normal gait pattern, continue to improve neuromuscular control, proprioception, and balance, and regain cardiopulmonary fitness.

Interventions. Include and progress the following interventions during the moderate protection phase.^{90,127,139,183,195,211,253}

- **ROM and joint mobility.** Continue low-intensity, end-range self-stretching to gain full knee ROM. Use grade III joint mobilization techniques to restore full knee flexion. Continue flexibility exercises for hip and ankle musculature, especially the hamstrings, IT band, and plantarflexors.
- **Strength and muscle endurance.** Initiate closed-chain and open-chain PRE in appropriate portions of knee ROM (see Box 21.11). Emphasize progressive closed-chain quadriceps training.
- **Neuromuscular control, proprioceptive training, and balance activities.** Progress closed-chain training, adding standing wall-slides, unilateral squats or lunges on the Total Gym®, lateral and diagonal step-ups, step-downs,

partial lunges, and use of a stair-stepping machine. Perform balance activities bilaterally, progressing to unilateral balance activities on stable and then unstable surfaces. Initiate beginning-level plyometric training during the later weeks of this phase.

- **Gait training.** Practice ambulation in a controlled environment with the protective brace unlocked and without crutches. Emphasize symmetrical alignment, step length, and timing. Gradually discontinue protective bracing; use a functional brace or sleeve if necessary.
- **Aerobic conditioning.** Begin a swimming or pool walking/running program or ski machine or treadmill training; or continue stationary cycling, increasing the duration and speed.
- **Activity-specific training.** Integrate simulated functional activities or components of activities into the exercise program.

Criteria to advance to next phase. Criteria to progress to the advanced phases of rehabilitation include absence of pain, full active knee ROM, 75% strength of knee musculature compared to the contralateral side, no evidence of knee instability on arthrometer readings or clinical examination.

Exercise: Minimum Protection and Return-to-Activity Phases

The advanced phases of rehabilitation and preparation for a return to a preinjury level of activity begin at about 10 to 12 weeks postoperatively or at a point when the patient has met specified criteria. Most post-ACL reconstruction rehabilitation programs described in the literature continue until about 6 months postoperatively.^{16,90,181,183,253} The intensity and duration of training typically are based on the patient's goals and the level of activity to which the patient wishes to return. Individuals involved in high-joint-loading, work-related activities or competitive sports are advised to participate in a maintenance exercise program.

Goals. From 12 to 24 weeks postoperatively the aim is to further increase strength, endurance, and power; further enhance neuromuscular control and agility; and participate in progressively more demanding functional activities. A functional knee brace often is worn to reduce the risk of reinjury during high-demand activities, particularly those that involve turning, twisting, cutting, or jumping motions.

Interventions. Exercise interventions during the final phases of rehabilitation include PRE with an emphasis on eccentric training, advanced neuromuscular and balance training, plyometrics, agility drills, and activity-specific training coupled with a gradual return to high-demand activities. Patient education, emphasizing prevention of reinjury, continues throughout the advanced phases of rehabilitation and as the patient returns to full activity.

Return to activity. Recommended timelines for returning to vigorous activities, including competitive sports, vary considerably, ranging from as early as 4 to 6 months^{198,209,214} to a year after surgery. Criteria to return to a preinjury level

BOX 21.12 Criteria to Return to High-Demand Activities after ACL Reconstruction

- No knee pain or joint effusion
- Full active knee ROM
- Quadriceps strength $\geq 85\%$ of contralateral side or peak torque/body mass 40% and 60% for men and 30% and 50% for women (tested at 300°/sec and 180°/sec, respectively).
- Hamstring strength 100% of contralateral side
- No postoperative history of knee instability/giving way
- Negative pivot shift test
- Knee stability measured by arthrometer: < 3 mm difference between reconstructed and uninjured side
- Proprioceptive testing: 100%
- Functional testing (hop, jump, and squat tests): $\geq 85\%$ of contralateral side or normative values
- Acceptable patient-reported score on comprehensive, quantitative knee function measurement tool, such as the International Knee Documentation Committee Subjective Knee Form

of activity must be individualized for each patient and are contingent on clinical examination findings, particularly the stability of the knee, and the expected work-related, recreational, or sports-related demands. Box 21.12 identifies criteria, suggested by several sources,^{114,157,214,249,253} that should be met prior to a return to high-risk, high-joint-loading activities.

Outcomes

Reconstruction of the ACL followed by a carefully progressed postoperative rehabilitation program is a reliable means of re-establishing knee stability. Consequently, ACL reconstruction results in a high rate ($> 90\%$) of patient satisfaction.²¹⁹ However, outcomes are predicated on numerous factors, including the patient's age, sex, and overall health status, the presence or absence of injuries associated with the ACL injury, various aspects of the surgical procedure, postoperative complications, and the patient's adherence to the rehabilitation program. The effects of several of these variables are addressed in this section.

Graft selection and outcomes. Numerous prospective and retrospective studies have been conducted comparing the effects of graft selection on outcomes. Bone–patellar tendon–bone and hamstring tendon autografts are studied most often. An extensive review and analysis of the literature revealed that although both types of grafts have their merits and limitations (summarized in Boxes 21.9 and 21.10) long-term (2 years or more) functional outcomes are essentially the same.²¹⁶

Functional bracing. The effect of functional bracing during the intermediate and advanced phases of rehabilitation and its use during high-risk sports after completion of rehabilitation is unclear. Risberg et al.¹⁹⁴ carried out a

prospective investigation in which 60 patients were randomly assigned to a braced or a nonbraced group. After ACL reconstruction with a patellar tendon autograft, patients in the braced group wore a protective brace for 2 weeks and then wore a functional brace most of the time for an additional 10 weeks. At the conclusion of rehabilitation the braced group was advised to wear the functional brace for all high-joint-loading activities. The nonbraced group had no brace at any time during or after rehabilitation. Otherwise, both groups underwent the same rehabilitation program and patient education. At a 2-year follow-up there were no significant differences between groups for knee ROM, knee joint laxity, muscle strength, functional testing, or incidence of reinjury to the ACL. The results of this study are similar to the findings of a more recent randomized, controlled multicenter study by McDevitt et al.,¹³⁷ who found that use of an “off the shelf” functional brace for 1 year after ACL reconstruction during all high-demand activities (jumping, pivoting, cutting) had no significant impact on knee function or reinjury.

Sterett et al.²²⁹ also investigated the role of functional bracing in preventing reinjury in patients returning to an advanced, high-demand activity after ACL reconstruction, specifically snow skiing. Over several consecutive ski seasons at a large ski resort, the investigators conducted a prospective, nonrandomized cohort study of 820 skiers who were employees of the ski resort and had undergone ACL reconstruction with a patellar tendon autograft at least 2 years previously. Of the 820 post-ACL reconstruction skier/employees, 257 were considered at significant risk for reinjury of the ACL based on the results of preseason screening. These individuals were given and advised to wear a functional knee brace during skiing. The remaining 563 skier/employees were not determined to be at significant risk for reinjury and were not issued a functional brace.

Analysis of data during the course of the study over several years indicated that 61 ACL reinjuries occurred: 51 in the nonbraced skiers and 10 in the braced skiers. The nonbraced group was 2.74 times more likely to sustain reinjury to the ACL than the braced group. Based on the results of their study, the authors recommended functional knee bracing after recovery from ACL reconstruction for patients returning to the high-demand sport of skiing regardless of their assessed risk of reinjury. The authors, although noting the limitations of this nonrandomized study, suggested that the findings of this study were of interest because of the large number of participants in the study.

Approaches to rehabilitation. There is limited evidence in the literature to determine the effects of variables in a postoperative exercise program, such as the degree of supervision or the duration of the program, on outcomes. Beynnon and co-investigators¹⁷ conducted a prospective, randomized, double-blind study comparing the results of an accelerated (19 weeks) and nonaccelerated (32 weeks) rehabilitation program following ACL reconstruction with

bone–patellar tendon–bone autografts. The two programs contained the same components but were implemented over two different timelines. A total of 25 patients entered the study, and 22 patients (10 in the accelerated/19-week program and 12 in the nonaccelerated/32-week program) completed the program and were available for final follow-up. At 24 months postoperatively there were no significant differences in knee laxity, functional testing, or patient satisfaction and activity level.

The effect of supervision during rehabilitation has also been studied. Specifically, home-based rehabilitation with limited therapist supervision has been compared with clinic-based rehabilitation with therapist supervision throughout the program. A review of the literature revealed that, for the most part, these two approaches produced similar outcomes.¹⁶ However, the reviewers pointed out that all patients who participated in the various studies had some instruction and supervision from a therapist. The reviewers emphasized the importance of therapist-directed assessments and initial instruction in an exercise program but recommended periodic, rather than continuous, supervision over the course of rehabilitation.

Posterior Cruciate Ligament Reconstruction

In contrast to injury of the ACL, injury of the posterior cruciate ligament (PCL) is relatively infrequent.²⁵⁵ When an injury does occur, it usually is accompanied by damage to other structures of the knee. There is general agreement that a PCL injury, combined with an injury to another ligament or other structures of the knee, usually warrants early surgical intervention.^{61,168,170}

When an isolated PCL injury occurs, most patients respond well to nonoperative management and are able to return to a preinjury level of activity without surgical intervention. However, after a severe PCL injury an increased incidence of OA in the medial compartment of the knee over time has been observed.²²⁵ Recently, motion analysis of the PCL-deficient knee, as the result of an isolated rupture, has demonstrated altered kinematics of the medial compartment of the knee, specifically anterior subluxation of the medial femoral condyle (posterior subluxation of the medial tibial plateau).¹²¹ These findings provide a possible explanation for the degenerative changes observed in the PCL-deficient knee and lend support for surgical intervention.

Indications for Surgery

Although there is limited consensus, the most frequently cited indications for surgical reconstruction of the PCL include the following.^{3,61,159,170,233,255}

- Complete tear or avulsion of the PCL with posterolateral, posteromedial, or rotary instability of the knee combined with damage to another ligament and often the menisci or articular cartilage.
- Isolated, symptomatic, grade 3 PCL tear with more than 10 to 15 mm posterior displacement resulting in instability during functional activities.

- Chronic PCL insufficiency associated with posterolateral instability, pain, limitations in functional activities, and deterioration of articular surfaces of the knee.

Procedures

Operative Overview

There are a number of arthroscopic, arthroscopically assisted, or open procedures available for management of a torn or ruptured PCL. Although an acute bony avulsion occasionally is managed with primary repair, reconstruction is by far the more frequently selected option.⁶¹ As with the ACL, PCL reconstruction involves implantation of a graft to replace the damaged ligament. Graft options using single-bundle or double-bundle reconstruction include a bone–patellar tendon–bone autograft, a hamstring (semitendinosus–gracilis) or quadriceps tendon autograft, an Achilles tendon allograft, or occasionally a synthetic graft.^{3,61,159,170,233,255} Of these choices, the patellar tendon graft reconstruction is the most common.

The operative procedure begins with diagnostic arthroscopy followed by graft harvest if an autograft is to be used for reconstruction. After femoral and tibial tunnels are drilled and prepared, the grafts are drawn through and secured in the tunnels with bony or soft tissue fixation devices, such as interference screws and washers or staples. Graft placement must be precise to mimic the function of the PCL. Prior to closure, the knee is flexed and extended to be certain that graft placement and tension allow full ROM. After wound closure, a sterile compression dressing is applied, and the knee is immobilized in full extension.

Complications

Because PCL reconstruction involves the posterior aspect of the knee, there is risk of damage to the popliteal neurovascular bundle. Risk is highest during drilling of the tibial bone tunnel. Postoperatively, bleeding can lead to compartment syndrome. If a patellar tendon autograft was harvested, the patient may experience anterior knee pain and pain during kneeling. If motion is lost postoperatively, usually knee flexion becomes limited. As with any ligament reconstruction, graft failure can occur, leading to loss of joint stability and the need for revision reconstruction.⁶¹

Postoperative Management

Immobilization, Protective Bracing, and Weight Bearing

Initially, the knee is immobilized in a hinged, range-limiting brace locked in full extension. The immobilizer is worn during the day and even during sleep for the first 4 weeks to prevent posterior displacement of the tibia as the result of gravity or sudden knee flexion. It is unlocked or removed for exercise 1 day to a week after surgery.^{3,61,168,170,255} The protective brace remains locked in extension during weight bearing for an extended period of time.

In contrast to weight bearing after ACL reconstruction, weight bearing is progressed more gradually after PCL surgery.^{54,61,168,170,255} The time frame for initiating

and progressing weight bearing varies considerably in the literature. Recommendations range from partial weight bearing immediately after surgery using two crutches and wearing the protective brace locked in extension^{39,168,170} to non-weight bearing for a week to 5 weeks postoperatively.^{61,255} Weight bearing is increased over several weeks while keeping the brace locked in extension. As quadriceps control improves, enabling the patient to fully extend the knee, and pain and joint effusion are well controlled, the brace is unlocked, allowing movement in a protected range during ambulation with crutches and weight-bearing exercises. Crutches are discontinued and full weight bearing with the brace unlocked is permitted when the patient has minimal to no pain or joint effusion, approximately 70% quadriceps strength, and active knee motion from 0° to 120°, which typically is possible at approximately 8 to 10 weeks.^{39,168,170} Brace use is then discontinued gradually.

Exercise

After PCL reconstruction many of the postoperative exercises performed during progressive phases of rehabilitation are similar to those following ACL reconstruction (see Table 21.7).^{39,54,61,168,170} The key differences are that exercises are progressed more slowly and those that place posterior shear forces on the tibia are postponed during the early phase of rehabilitation when the graft is most vulnerable. When resistance exercises for hamstring strengthening are initiated during advanced rehabilitation, they are adjusted based on the stability of the knee. Box 21.13 summarizes precautions for exercise and functional activities after PCL reconstruction.^{39,168,170}

Exercise: Maximum Protection Phase

The emphasis during the first, maximum protection phase of rehabilitation, which extends for 4 to 6 weeks, is to protect the integrity of the graft while simultaneously regaining a functional degree of mobility and developing quadriceps control.^{39,54,61,168,170}

Goals. During this phase of rehabilitation goals are to control or reduce acute symptoms (pain, swelling), prevent vascular complications (DVTs), re-establish control of the quadriceps mechanism, maintain patellar mobility, regain approximately 90° of knee flexion by 2 to 4 weeks after initiating knee motion, begin to re-establish proprioception, neuromuscular control, and balance, improve the strength and flexibility of the hip and ankle musculature if limited, and improve cardiopulmonary fitness.^{39,168,170}

Interventions. Control pain and swelling in a standard manner. Immediately after surgery begin ankle pumping exercises, patellar gliding techniques, quadriceps-setting exercises (augmented by neuromuscular electrical stimulation), and multiplanar SLRs while wearing the protective brace locked in full extension. Use an upper extremity ergometer for aerobic conditioning.

When knee motion is permitted, follow the exercise precautions for early rehabilitation described in Box 21.13. Begin multiple-angle isometrics of the quadriceps from full extension to 25° to 30° of flexion. Perform assisted knee

BOX 21.13 Exercise Precautions After PCL Reconstruction

General Precaution: Avoid exercises and activities that place excessive posterior shear forces and cause posterior displacement of the tibia on the femur, thus disrupting the healing graft.

Early and Intermediate Rehabilitation

- Begin exercise to restore knee flexion while in a seated position, allowing gravity to passively flex the knee and the hamstrings to remain essentially inactive.
- Postpone open-chain, active knee flexion against the resistance of gravity (prone or standing) for 6 to 12 weeks.
- During squatting exercises to increase quadriceps strength, avoid excessive trunk flexion as it causes increased activity in the hamstrings.

Advanced Rehabilitation

- Postpone resistance training for the knee flexors, such as use of a hamstring curl machine, for 5 to 6 months.
- When performing resisted hamstring curls, use low loads.
- Avoid downhill inclines during walking, jogging, or hiking.
- Avoid activities that involve knee flexion combined with rapid deceleration when one or both feet are planted.
- Postpone returning to vigorous functional activities for at least 9 to 12 months. Consider wearing a functional knee brace during high-demand activities.

extension, progressing to active knee extension while seated. To regain knee flexion, begin with gravity-assisted flexion. Hold the patient's leg in full knee extension and have the patient control leg lowering as gravity flexes the knee.

To the extent that weight-bearing restrictions allow and while wearing the locked brace, begin trunk and lower extremity stabilization exercises in a supported standing position (in the parallel bars or with crutches). Begin bilateral closed-chain quadriceps strengthening while holding on to a stable surface for support when it is permissible to unlock the protective brace. Stretch the hip and ankle musculature, in particular the hamstrings, IT band, and plantarflexors.

Criteria to advance to next phase. If there is minimal joint swelling and the patient has minimal pain and has achieved full active knee extension (no extensor lag) and at least 100° of knee flexion, it is appropriate to progress to the next phase of rehabilitation.^{39,168,170}

Exercise: Moderate and Minimum Protection Phases

Goals and interventions. As with early rehabilitation, the goals and interventions during the intermediate and advanced phases of rehabilitation following PCL reconstruction are similar to those following ACL reconstruction (see Table 21.7), although the suggested timelines continue to be more extended. The exercises and activities during

the intermediate phase of rehabilitation are essentially an extension of those initiated during the first phase. By 9 to 12 weeks postoperatively the patient should have achieved full knee ROM (0° to 135°), making it possible to discontinue use of the protective brace if quadriceps control is sufficient.^{39,168,170}

During the intermediate and advanced phases of rehabilitation, precautions to prevent excessive posterior shear forces on the tibia during exercises and functional activities continue (see Box 21.13). Strengthening focuses on the quadriceps to re-establish full active knee extension and sufficient strength in the quadriceps, hip, and ankle musculature for functional weight-bearing activities. Resistance training to improve strength and muscular endurance of the hamstrings (hamstring curls) is based on the posterior stability of the knee. Strengthening of the knee flexors typically is delayed until 2 to 3 months postoperatively and, when initiated, is progressed cautiously.

Advanced neuromuscular training with plyometrics, balance activities, and agility drills, progressive aerobic conditioning, and activity-specific training are critical for a safe transition to a full level of functional activities. A full return to vigorous activities after PCL reconstruction often takes 9 months to a year.^{39,61,168,170}

MENISCAL TEARS: NONOPERATIVE MANAGEMENT

Mechanisms of Injury

The medial meniscus is injured more frequently than the lateral meniscus. Insult may occur when the foot is fixed on the ground and the femur is rotated internally, as when pivoting, getting out of a car, or receiving a clipping injury. An ACL injury often accompanies a medial meniscus tear. Lateral rotation of the femur on a fixed tibia may tear the lateral meniscus. Simple squatting or trauma may also cause a tear.

Common Impairments and Functional Limitations/Disabilities

Meniscal tears can cause acute locking of the knee or chronic symptoms with intermittent locking. Pain occurs along the joint line (due to stress to the coronary ligament) along with joint swelling and some degree of quadriceps atrophy. When there is joint locking, the knee does not fully extend, and there is a springy end-feel when passive extension is attempted. If the joint is swollen, there is usually slight limitation of flexion or extension. The McMurray or Apley grinding tests may be positive.¹²³

When the meniscus tear is acute, the patient may be unable to bear weight on the involved side. Unexpected locking or giving way during ambulation often occurs, causing safety problems.

Management

- Often the patient can actively move the leg to “unlock” the knee, or the unlocking happens spontaneously.
- Passive manipulative reduction of the medial meniscus may unlock the knee (Fig. 21.12). *Patient position and procedure:* Supine. Passively flex the involved knee and hip and simultaneously rotate the tibia internally and externally. When the knee is fully flexed, externally rotate the tibia and apply a valgus stress at the knee. Hold the tibia in this position and extend the knee. The meniscus may click into place. Once reduced, the knee may react as an acute joint lesion. If this occurs, treat as described earlier in the chapter in the section on nonoperative management of joint hypomobility.
- After acute symptoms have subsided, exercises should be performed in open-chain and closed-chain positions to improve strength and endurance in isolated muscle groups and to prepare the patient for functional activities.

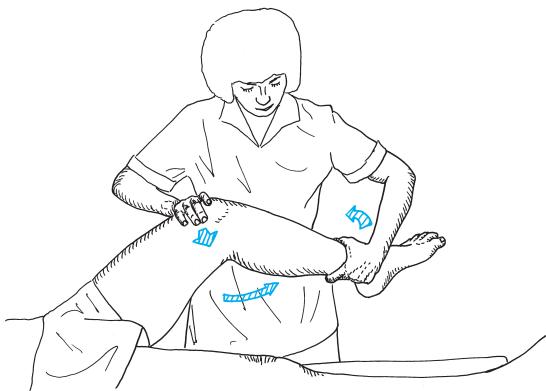

FIGURE 21.12 Manipulative reduction of a medial meniscus. Internally and externally rotate the tibia as you flex the hip and knee (not shown); then laterally rotate the tibia and apply a valgus stress at the knee as you extend it. The meniscus may click into place.

MENISCAL TEARS: SURGICAL AND POSTOPERATIVE MANAGEMENT

When a significant tear or rupture of the medial or lateral meniscus occurs or if nonoperative management of a partial tear has been unsuccessful, surgical intervention often is necessary. Current-day surgical procedures are designed to retain as much of the meniscus as possible as a means of preserving the load transmission and shock-absorbing functions of the menisci and to reduce stress on the tibiofemoral articular surfaces.

Primary surgical options are *partial meniscectomy* and *meniscal repair*, both of which are considered preferable to total meniscectomy.^{230,238} The location and nature of the tear influences the selection of a procedure, as does the patient’s age and level of activity. Tears of the outer area of a meniscus, which has a rich vascular supply, heal well, whereas tears extending into the central portion, where the vascular supply is considerably less, have marginal healing

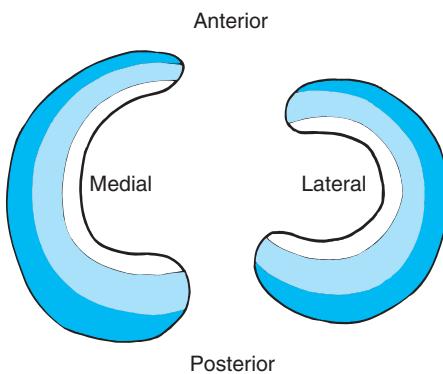

FIGURE 21.13 Vascularity of the medial and lateral menisci. The peripheral zone (outer one-third) is highly vascular; the central one-third is relatively avascular; and the inner one-third is avascular.

properties (Fig. 21.13).²³⁹ Age and the patient’s activity level factor into the decision-making process because it has been shown that loss of even a portion of a meniscus increases the long-term risk of articular degeneration.²³⁹

Traditionally, partial meniscectomy has been performed to manage complex, fragmented tears and tears involving the central (middle third), relatively avascular zone of a meniscus.²³⁸ In contrast, peripheral tears involving the highly vascular portion of a meniscus have been shown to lend themselves well to repair rather than excision of the torn portion.²³⁹ However, if a patient with a central zone tear is young or physically active but older, some surgeons now advocate repair of the torn meniscus.^{89,142,160,161} If there is extensive damage to a major portion of the meniscus and it is determined to be unsalvageable, total meniscectomy remains the only surgical option.²³⁸

For the relatively young and/or active patient, who previously underwent total meniscectomy and now is symptomatic as the result of early osteoarthritic changes in the tibiofemoral joint, a recently developed option, *meniscal transplantation*, using human allograft tissue has become available.^{89,163,184}

The progression of postoperative rehabilitation and the time required to return to full activity after each of these procedures depends on the extent and location of the tear and the type of surgical approach and procedure performed. Rehabilitation proceeds more conservatively after repair or implantation of a meniscus or total meniscectomy than after partial meniscectomy. Damage and repair or reconstruction of other soft tissues of the knee, such as the ACL, also affect the course and progression of rehabilitation after surgery.

Meniscus Repair

Indications for Surgery

Repair of a torn meniscus is indicated in the following situations.^{89,160,230,238}

- A lesion in the vascular outer third of the medial or lateral meniscus

- A tear extending into the central, relatively avascular third of the meniscus of a young (under age 40 to 50) or physically active older (over age 50) individual

CONTRAINDICATIONS: Contraindications include the presence of a tear localized to the inner, avascular third of the meniscus; a tear in which there is considerable tissue fragmentation; or a tear that cannot be completely reopposed during surgery.⁸⁹

Procedure

Operative Overview

Prior to the operative procedure, a comprehensive arthroscopic examination of the joint is performed to determine if a meniscus tear is suitable for repair and to identify any concomitant injuries, such as ACL damage. The repair itself typically is performed using an arthroscopically assisted open approach or a fully arthroscopic approach.^{89,151,152,160} The determination of which approach is selected generally is based on the location and nature of the tear.²³⁸

There are several surgical procedures—referred to as inside-out, outside-in, or all-inside techniques—for meniscus repair. The inside-out and outside-in techniques are arthroscopically assisted, with a portion of the procedure being performed through an incision at the posteromedial or posterolateral aspect of the knee.^{151,160} The all-inside technique is fully arthroscopic.^{152,239}

There are also various suturing techniques with non-absorbable or bioabsorbable sutures that can be used during the repair. Use of other fixation devices, such as darts or staples, also has been reported. Of the many variations of meniscus repair, the arthroscopically assisted, inside-out suture repair is most common and considered by some in the orthopedic community to be the “gold standard.”^{89,151,160,239}

At the beginning of the procedure small incisions are made at the knee for portals, and saline is arthroscopically introduced into the joint to distend the capsule. After the joint has been examined, arthroscopic débridement is performed to remove all unstable tissue fragments and prepare the torn meniscus for repair. During the repair itself (performed endoscopically or through a posteromedial or posterolateral incision), the edges of the tear are closely approximated, and sutures are placed every 3 to 4 mm to ensure complete closure (no gapping) along the tear line. All sutures are tied with the knee fully extended or in 10° of flexion to allow full extension postoperatively without causing undue stress on the repaired meniscus.

After closure, a compression dressing, extending above and below the knee, is applied to control postoperative joint effusion, and the knee is placed in an immobilizer.

NOTE: Detailed descriptions of medial and lateral meniscal allograft transplantation techniques are published in several resources.^{89,163,164,184}

Complications

Complications specific to meniscus surgery include intraoperative damage to the neurovascular bundle at the poste-

rior aspect of the knee during the suturing process. With a medial meniscus repair there is a risk of damage to the saphenous nerve; and with a lateral meniscus repair there is risk of damage to the peroneal nerve. Postoperatively, these same nerves can become entrapped by adherent scar tissue.^{151,238,239}

A flexion contracture or an extensor lag postoperatively compromises knee alignment and stability during gait and functional activities. The risk of failure of the repair is greatest during activities that involve joint loading and knee flexion beyond 45°. This risk is greatest during the first few postoperative months.^{142,230}

Postoperative Management

Factors that influence the components and progression of postoperative rehabilitation after meniscus repair are noted in Box 21.14.^{39,89,142,160} Some variables permit relatively rapid rehabilitation, whereas others necessitate a more cautious progression. For example, exercise and weight bearing are progressed more rapidly after repair of a peripheral zone tear than a central tear and after a single tear than after a complex pattern tear.

Another factor, malalignment of the knee, affects forces placed on a repaired meniscus and thus influences the progression of weight bearing during ambulation and exercise. With varus alignment, a repaired medial meniscus is subjected to increased stress and increased risk of displacement during healing. Therefore, weight bearing must be progressed more slowly in this situation than is necessary when there is normal alignment of the knee.³⁹

NOTE: Although timelines vary somewhat in published protocols, the progression of exercises presented in the following sections are appropriate after *isolated* meniscus repair in a cruciate-stable knee. These same guidelines are appropriate after meniscal transplantation, although the duration of rehabilitation and protection of the transplanted meniscus is longer.^{89,184} If a concomitant procedure, such as ligament reconstruction, is performed, adjustments also are made.

Immobilization, Protective Bracing, and Weight Bearing

Immobilization and protective bracing. The knee is held in full extension, first in the postoperative immobilizer and then in a long-leg brace when the bulky compression dressing is removed a few days after surgery.^{39,89,238} Occasional-

BOX 21.14 Factors Influencing the Progression of Rehabilitation After Meniscus Repair

- Location and size of the tear [i.e., the zone(s) affected and their vascularity]
- Type of tear (tear pattern and complexity)
- Security of the suture fixation observed intraoperatively
- Alignment of the knee joint (normal, varus, valgus)
- Concomitant injuries (ligament, chondral defect) *with or without* reconstruction or repair

ly, for carefully selected patients with a peripheral zone repair, no protective bracing is used after the postoperative dressing is removed.¹⁵¹ The patient continues to wear a thigh-high compression stocking to control swelling.

To protect the repaired meniscus during the first few postoperative weeks, the range-limiting brace is worn continuously (day and night) and locked in full extension, except during ROM exercises. Depending on the site of the lesion and repair, the protective brace is set to allow 0° to no more than 90° of flexion for the first 2 weeks or longer. Each week the range allowed by the brace is increased by about 10° until full flexion has been achieved.⁸⁹ The brace is unlocked during daily activities as early as 2 weeks if the patient has achieved full knee extension.

After a central zone repair, the patient typically wears the brace for about 6 weeks or until adequate quadriceps control has been established. After a meniscal transplant, the brace may be worn a few weeks longer.

Weight bearing. Partial weight bearing (ranging from 25% to 50%) during ambulation with crutches and the brace locked in full extension is allowed during the immediate postoperative period. The percent of body weight permitted during weight bearing is progressed more cautiously after a central zone or transplant than after a peripheral zone repair. Regardless of the type of procedure, however, weight bearing is progressed gradually and always is based on the patient's signs and symptoms.

If quadriceps control is sufficient, full weight bearing may be permitted by 4 to 6 weeks after a peripheral repair⁸⁹ and by 6 to 8 weeks after a central repair or transplant.^{39,89,142,163,184}

Exercise: Maximum Protection Phase

Exercises and gait training with crutches are begun the first postoperative day. A standard approach (cold, compression, elevation) to control pain, joint effusion, and vascular complications (ankle pumping exercises) is used. Patient education focuses on establishing a home exercise program and reinforcing weight-bearing precautions. Exercise precautions are noted in Box 21.15.^{39,89,142,238,239}

Goals. During the first 4 weeks after surgery, exercise goals are to regain functional ROM, prevent patellar restrictions, re-establish control of knee musculature, restore postural stability, improve strength and flexibility of the hip and ankle, and maintain cardiopulmonary fitness. By 4 weeks the patient should achieve full, active knee extension. Recommendations for maximum flexion during the first 2 weeks vary from 60° to 90°.^{22,39,89,142,208,230,238} After 4 weeks the patient should attain 120° of knee flexion.⁸⁹

Interventions. During the first 4 weeks after meniscus repair, the following interventions are included.^{22,39,89,102,142,208}

- **ROM of the knee.** CPM is prescribed at the surgeon's discretion. Begin A-AROM and AROM exercises of the knee the day after surgery. Knee flexion is restricted by

BOX 21.15 Exercise Precautions After Meniscus Repair*

General Precautions

- Progress exercises and weight bearing more gradually after a central zone meniscus repair or meniscus transplantsations than after a peripheral zone repair.
- If the patient experiences a clicking sensation in the knee during exercise or weight-bearing activities, report it immediately to the surgeon.

Early and Intermediate Rehabilitation

- Increase knee flexion gradually, especially after a central zone repair.
- If a stationary bicycle is used for cardiopulmonary conditioning, set the seat height as high as possible to limit the range of knee flexion.
- During weight-bearing exercises, such as lunges and squatting, do not perform knee flexion beyond 45° for 4 weeks or beyond 60° to 70° for 8 weeks. Flexion beyond 60° to 70° places posterior translation forces on a repaired meniscus, increasing the risk of displacement during early healing.
- Postpone use of a leg press machine until about 8 weeks. Limit motion from 0° to 60°.
- Avoid twisting motions during weight-bearing activities.
- Postpone hamstring curls until about 8 weeks.

Advanced Rehabilitation

- Do not perform exercises that involve deep squatting, deep lunges, twisting, or pivoting for at least 4 to 6 months. (The greater the flexion angle, the greater is the stress on the meniscus.)
- Do not begin jogging or running program until 5 to 6 months.

Return to Activity

- Refrain from recreational and sports activities that involve repetitive, high joint compressions and shear forces.
- Avoid prolonged squatting in full flexion.

*These precautions also are applicable after meniscus transplantation, but time frames for the precautions are longer.

a hinged, controlled-motion brace. Include exercises such as gravity-assisted knee flexion in a sitting position and assisted progressing to active heel slides in a supine position.

- **Patellar mobility.** Teach the patient grade I and II patellar gliding exercises.
- **Activation of knee musculature.** Emphasize quadriceps control in full extension with quadriceps setting exercises, assisted SLRs in the supine position, and assisted progressing to active open-chain knee extension/flexion in a sitting position for concentric/eccentric quadriceps control. Augment quadriceps activation with electrical muscle stimulation or biofeedback. Also, perform hamstring-setting exercises and multiple-angle isometrics.

- **Neuromuscular control, proprioception, and balance.** Begin balance activities in a standing position within the limits of weight-bearing restrictions and with the brace locked. Emphasize trunk and lower extremity stabilization exercises. When it is permissible to unlock the brace during carefully controlled weight bearing, initiate bilateral closed-chain exercises, such as mini-squats and standing wall-slides, initially limiting flexion to no more than 45°.
- **Flexibility and strength of the hip and ankle musculature.** Stretch the hamstrings and plantarflexors, if restricted. Begin gluteal and adductor setting exercises the first postoperative day. Perform four-position SLRs with the brace locked or when the patient can perform an SLR in supine position without an extensor lag. Perform bilateral heel raises when 50% weight bearing is permitted.
- **Cardiopulmonary function.** Use an upper body ergometer for aerobic conditioning exercises.

Criteria to advance to next phase. Joint effusion and pain should be minimal, and the patient should have evidence of superior gliding of the patella with quadriceps setting, full active knee extension, and approximately 120° of knee flexion.

Exercise: Moderate Protection Phase

The moderate protection phase extends from 4 to 6 weeks to about 12 weeks postoperatively. The knee brace is discontinued at about 6 to 8 weeks if there is adequate control of the knee and no extensor lag. Use of a cane or single crutch is advisable to provide some degree of protection during ambulation.

Goals. Restoring full knee ROM, improving lower extremity flexibility, strength, and muscular endurance, continuing to re-establish neuromuscular control and balance, and improving overall aerobic fitness are emphasized during the moderate protection phase of rehabilitation.

Interventions. Include and progress the following exercises and activities during the intermediate phase of rehabilitation.^{22,39,89,102,142,208}

- **ROM.** Progress low-load, long-duration stretching exercises if the patient is having difficulty achieving full knee ROM.
- **Muscle performance (strength and muscular endurance).** Initiate stationary cycling against light resistance. Use elastic resistance for low-intensity, open-chain and closed-chain exercises. Progress hip and ankle strengthening exercises
- **Neuromuscular control, proprioception, and balance.** Continue or, if not initiated previously, begin closed-chain exercises. Add disturbed balance activities (perturbation training) standing on an unstable surface, such as a mini-trampoline or wobble board. When full weight bearing is permissible, begin unilateral balance activities, partial lunges, step-ups, and step-downs. Practice walking on an unstable surface, such as high-density foam rubber. Initiate low-intensity agility drills.

- **Flexibility of the hip and ankle.** Stretch the IT band and rectus femoris after the patient has achieved full knee flexion with hip flexion.
- **Cardiopulmonary fitness.** Begin stationary cycling or a pool-walking program at the beginning of this phase. Initiate treadmill training, land walking, or use of a cross-country ski machine at around 9 to 12 weeks.
- **Functional activities.** Gradually resume light functional activities during this phase.

Criteria to advance to next phase. By 12 to 16 weeks postoperatively, there should be no pain or joint effusion and full active knee ROM. Lower extremity strength (maximum isometric contraction) should be at the 60% to 80% level.

Exercise: Minimum Protection/Return-to-Activity Phase

Some degree of protection still is warranted at the beginning of the final phase of rehabilitation, which typically begins at around 12 to 16 weeks and may continue until 6 to 9 months. The return to a high level of physical activity depends on achieving adequate strength, full, nonpainful ROM, and an acceptable clinical examination.^{39,89,142}

Goals. The primary goal of this phase is to prepare the patient to resume a full level of functional activities while continuing patient education to reinforce the importance of selecting activities that do not overstress the repaired meniscus (see Box 21.15).

Interventions. During resistance training incorporate movement patterns that simulate functional activities. Begin and gradually progress drills to improve power, such as plyometric training. Increase the duration or intensity of the aerobic conditioning program. Transition from a walking program to a jogging/running program, if desired, at about 5 to 6 months. A detailed progression of aerobic conditioning activities after meniscus repair is available in the literature.^{89,142}

Outcomes

Repair of a torn medial or lateral meniscus using any one of several surgical techniques is a well tested procedure designed to preserve these important structures and results in predictably successful outcomes. This is particularly true for suture repair of a peripheral zone tear.^{89,151,239} Although the results of repair of tears extending into the central zone are not as predictable, there is increasing evidence that repairs in this zone heal well and provide long-term relief of symptoms.^{160,161}

Although the use of various surgical techniques and the frequency of concomitant pathologies and surgeries make it difficult to compare outcomes of studies, several generalizations can be made. One of the most important factors influencing outcomes of meniscus repair is the status of the ACL. When an ACL injury occurs in combination with a meniscus tear, patients who undergo ACL reconstruction have better outcomes than patients with ACL deficiency. A recurrent tear of a repaired meniscus

occurs more frequently in an ACL-deficient knee than an ACL-stable knee.^{161,239}

Although the age of a patient typically is cited as a factor influencing the decision of whether to repair a torn meniscus, particularly a tear in the central zone, and although most repairs are performed in patients under age 40, a study by Noyes and colleagues¹⁶⁰ demonstrated a high success rate in a group of patients 40 years of age or older who had central zone tears.

With regard to postoperative rehabilitation, no single protocol has been shown to result in superior outcomes.²³⁹

Lastly, short-term results of meniscus transplantation with an allograft are promising, but the long-term effectiveness of this procedure remains unclear.^{163,184}

Partial Meniscectomy

Indications for Surgery

The following are indications for partial meniscectomy as a surgical option for a tear of the medial or lateral meniscus.²³⁸

- A symptomatic (pain and locking), displaced tear of the meniscus sustained by an older, inactive individual associated with pain and locking of the knee
- A tear extending into the central, less vascular third of the meniscus if not determined repairable when arthroscopically visualized and probed
- A tear localized to the inner, avascular third of the meniscus

Procedure

Arthroscopic meniscectomy typically is performed on an outpatient basis under local anesthesia. Small incisions are made at the knee for portals (usually three); and saline solution is injected through one of the portals, distending the knee. The torn portion of the meniscus is identified, grasped, and divided endoscopically by knife or scissors and removed by vacuum. Intra-articular debris or loose bodies also are removed. After the knee is irrigated and drained, skin incisions at the portal sites are closed, and a compression dressing is applied to the knee.^{230,238}

Postoperative Management

The overall goal of rehabilitation after partial meniscectomy is to restore ROM of the knee and develop strength in the lower extremity to reduce stresses on the knee and protect its articular surfaces.

Immobilization and Weight Bearing

A compression dressing is placed on the knee, but it is not necessary to immobilize the knee postoperatively with a splint or motion-controlling orthosis. For the first few postoperative days, cryotherapy, compression, and elevation of the operated leg are used to control edema and pain. Weight bearing is progressed as tolerated.^{39,208,238}

Exercise: Maximum and Moderate Protection Phases

Although the ideal situation is to begin exercise instruction on the day of or after surgery, most patients do not see a

therapist for supervised exercise immediately after an outpatient procedure. When a patient is referred for supervised therapy, the emphasis typically is placed on establishing a home exercise program. Under these circumstances it is preferable to teach the patient initial exercises to reduce atrophy and prevent contracture *preoperatively* so he or she can initiate the exercises at home immediately after surgery.

After arthroscopic partial meniscectomy there is no need for an extended period of maximum protection postoperatively as there is little soft tissue trauma during surgery. However, moderate protection is warranted for approximately 3 to 4 weeks. All exercises and weight-bearing activities should be pain-free and progressed gradually during the first few postoperative weeks.^{22,208}

Goals and interventions. Immediately after surgery, begin muscle-setting exercises, SLRs, active knee ROM, and weight bearing as tolerated. Full weight bearing usually is achieved by 4 to 7 days, and at least 90° of knee flexion and full extension are attained by 10 days. Initiate closed-chain exercises and stationary cycling a few days after surgery or as pain and weight bearing status allow, with the goal of regaining dynamic strength and endurance of the knee.

PRECAUTION: Patients who have undergone partial meniscectomy must be cautioned not to push themselves too quickly. Too rapid progression of exercise can cause recurrent joint effusion and possible damage to articular cartilage.

Exercise: Minimum Protection and Return-to-Activity Phases

By 3 or 4 weeks postoperatively, minimum protection of the knee is necessary, but full active knee ROM should be achieved before progressing to high-demand exercises. Resistance training, endurance activities, bilateral and unilateral closed-chain exercises, and proprioceptive/balance training to develop neuromuscular control all can be progressed rapidly. Advanced activities such as plyometrics, maximum effort isokinetic training, and simulated high-demand functional activities can be initiated as early as 4 to 6 weeks or 6 to 8 weeks postoperatively.

PRECAUTION: High-impact weight-bearing activities such as jogging or jumping, if included in the program, should be added and progressed cautiously to prevent future or additional articular damage to the knee.

EXERCISE INTERVENTIONS FOR THE KNEE

Strength and flexibility imbalances between muscle groups can result from a variety of causes, some of which are disuse, faulty joint mechanics, joint swelling, immobilization (due to fracture, surgery, or trauma), and nerve injury. In addition to the hamstrings and rectus femoris, most of the

two-joint muscles crossing the knee function primarily at the hip or the ankle, yet they also have an effect on the knee. If there is an imbalance in length or strength in the hip or ankle muscles, altered mechanics usually occur throughout the lower extremity. Refer to the chapters on the hip and the ankle and the foot for a complete picture of these interrelationships.

EXERCISE TECHNIQUES TO INCREASE FLEXIBILITY AND RANGE OF MOTION

When attempting to increase ROM, the mechanics of the tibiofemoral and patellofemoral joints and their importance in lower extremity function must be respected. Because the knee is a weight-bearing joint, the need for stability takes precedence over the need for mobility, although mobility coupled with adequate strength is also necessary for normal function.

Principles of neuromuscular inhibition and passive stretching were presented in Chapter 4, joint mobilization in Chapter 5, and techniques directed toward specific joint restrictions at the knee and patella earlier in the chapter. Additional manual and self-stretching techniques to increase knee ROM are described in this section.

To Increase Knee Extension

Decreased flexibility in the hamstring musculature and periarticular tissue posterior to the knee can restrict full knee extension. Increasing knee extension is a two-step process. First, full extension of the knee is obtained without placing tension on the hamstrings at the hip (the hip is maintained at or near 0° extension). After full knee extension has been attained, a stretch is applied to the two-joint hamstring muscle group by progressively flexing the hip while maintaining the knee in extension (SLR position). Techniques to stretch the hamstrings using SLRs are described in Chapter 4 and the exercise section of Chapter 20.

Neuromuscular Inhibition Techniques

- *Patient position and procedure:* Supine, with the hip and knee extended as much as possible. Resist knee flexion with an isometric hold using your hand proximal to the ankle; have the patient relax and then passively (or have the patient actively) extend the knee into the end of the range (hold-relax and hold-relax/agonist-contraction techniques, respectively).
- *Patient position and procedure:* Prone, with the hip and knee extended as much as possible. Place a small pad or folded hand towel under the femur proximal to the patella to protect the patella from compressive forces. Stabilize the pelvis to prevent hip flexion and then apply the hold-relax technique to increase knee extension.

Passive Stretching Techniques

Use a low-intensity, long-duration stretch to ensure that the patient stays as relaxed as possible.

- *Patient position and procedure:* Prone, hips extended with the patient's foot off the edge of the treatment table. Place a rolled towel under the patient's femur just proximal to the patella and a cuff weight around the ankle. As the muscle relaxes, the weight places a sustained passive stretch on the hamstrings, which increases knee extension.
 - *Patient position and procedure:* Supine, with the knee extended as far as possible. Place a rolled towel or padding under the distal leg to elevate the calf and knee off the table. Secure a cuff weight across the distal femur for a sustained stretch.
- NOTE:** This position is not effective for severe knee flexion contractures. Use it only for restrictions that are near the end of the range of knee extension.

Self-Stretching Technique

Patient position and procedure: Long sitting, with the distal leg supported on a rolled towel. Have the patient press down with the hands against the femur just above (not on) the patella to cause a sustained force to increase knee extension.

To Increase Knee Flexion

Before stretching to increase knee flexion, be sure the patella is mobile and is able to glide distally in the trochlear groove as the knee flexes; otherwise, it restricts knee flexion. Patellar mobilization techniques to increase patellar gliding are described in Chapter 5 (see Figs. 5.53 and 5.54). Once full range of knee flexion is reached, the two-joint rectus femoris and tensor fasciae latae muscles should be stretched across the hip joint while maintaining the knee in flexion. These techniques are described in Chapter 20.

Neuromuscular Inhibition Techniques

Patient position and procedure: Sitting, with the knee at the edge of the treatment table and flexed as far as possible. Manually resist an isometric contraction of the knee extensors proximal to the ankle. Have the patient relax and then passively (or have the patient actively) flex the knee to the end of the range.

Passive Stretching Technique

Patient position and procedure: Sitting with knee flexed to the end of its available range. Instruct the patient to relax the muscles and let the weight of the leg cause a low-intensity, long-duration stretch. Apply a manual stretch force, or strap a light weight around the distal leg to increase the stretch force.

Self-Stretching Techniques

Gravity-Assisted Supine Wall Slides

Patient position and procedure: Supine, with buttocks close to the wall and lower extremities resting vertically against

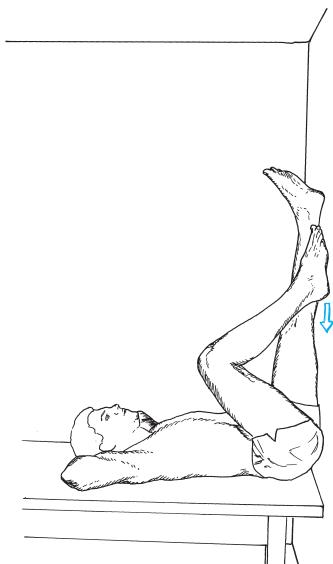

FIGURE 21.14 Gravity-assisted supine wall slide. The patient flexes the knee to the limit of its range and holds it there for a sustained stretch to the quadriceps femoris muscle.

the wall (hips flexed, knees extended). Instruct the patient to slowly flex the involved knee by sliding the foot down the wall until a gentle stretch sensation is felt, hold in a comfortable position, then slide the foot back up the wall (Fig. 21.14).

Rocking Forward on a Step

Patient position and procedure: Standing, with the foot of the involved knee on a step. Have the patient rock forward over the stabilized foot, flexing the knee to the limit of its range, then rock back and forth in a slow, rhythmic manner or hold the stretched position (Fig. 21.15). Begin with a low step or stool; increase the height as more range is obtained.

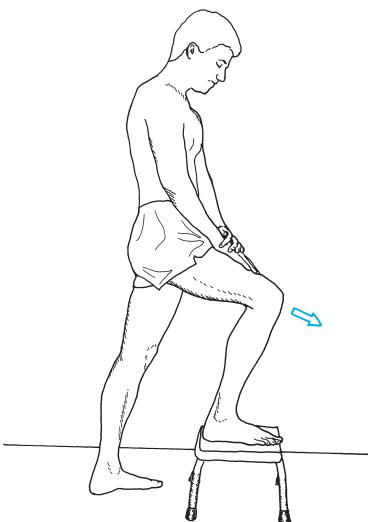

FIGURE 21.15 Self-stretching rock on step. The patient places the foot of the involved side on a step, then rocks forward over the stabilized foot to the limit of knee flexion to stretch the quadriceps femoris muscle. Use a higher step for greater flexion.

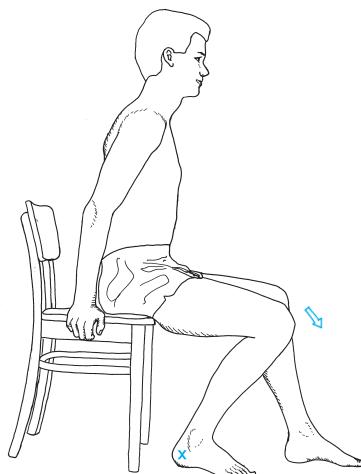

FIGURE 21.16 Self-stretching in a chair. The patient fixates the foot of the involved leg on the floor, then moves forward in the chair over the stabilized foot to place a sustained stretch on the quadriceps femoris muscle and increase knee flexion.

Sitting

Patient position and procedure: Sitting in a chair, with the involved knee flexed to the end of its available range and the foot firmly planted on the floor. Have the patient move forward in the chair, not allowing the foot to slide, then hold the position for a comfortable, sustained stretch of the knee extensors (Fig. 21.16).

EXERCISES TO DEVELOP AND IMPROVE MUSCLE PERFORMANCE AND FUNCTIONAL CONTROL

When strengthening exercises for knee musculature are selected, implemented, and progressed in a rehabilitation program, the stability of the knee (which involves co-contraction of the quadriceps and hamstrings muscles) and safe patellofemoral and extensor mechanism biomechanics (which allow appropriate patellar tracking) are primary concerns. After stability and patellar mechanics are well established, coordination and timing of muscle contractions as well as endurance are emphasized. *Closed-chain exercises* with an emphasis on low-intensity (low resistance)/high-repetition activities are more effective than open-chain exercises for improving stability and muscular endurance of the knee for dynamic control during weight-bearing activities.

Although closed-chain control of the knee is essential, remember that the knee functions in both an open- and closed-chain fashion during most ADLs. The quadriceps and hamstrings must contract simultaneously (co-contraction) as well as contract concentrically and eccentrically during functional activities. Therefore, exercises under all of these varying conditions should be incorporated into a comprehensive knee rehabilitation program. It is also important to change the position of the hip during quadriceps- and

hamstring-strengthening exercises to affect the length-tension relationship of the rectus femoris and hamstrings.⁶² Only after a thorough examination and understanding of a patient's pathology, impairments, and functional limitations can a therapist select and design an exercise plan to meet an individual patient's needs.

Considerable research has been done comparing joint reaction forces and muscle function during open-chain and closed-chain exercises. Comparisons of outcomes are difficult because of differing research designs and exercise variables.⁵⁶ Table 21.8 summarizes results from a recent study comparing two dynamic exercises, with recommendations for exercise modification with specific knee impairments. Special adaptations also have been highlighted in the conservative management and surgical management sections of this chapter.

In the exercises that follow, open-chain exercises are described before closed-chain exercises simply because weight bearing after knee injury or surgery is often restricted for a time. Isolated activation of knee musculature also is necessary for ADLs that involve open-chain movements, such as lifting the leg to get in and out of bed or a car or flexing and extending the knee during dressing. Closed-chain exercises during partial weight bearing and later during full weight bearing should be initiated as soon as healing allows progressing to balance and proprioceptive training and functional weight-bearing activities.

Nonweight-Bearing Exercises

To Develop Control of Knee Extension and Progress Strength (Quadriceps Femoris)

A wide variety of static and dynamic exercises can be used to improve the function of the quadriceps femoris muscles in open-chain positions. Because of variations in muscle fiber orientation and attachments of the knee extensor muscles, individual components of the quadri-

ceps femoris muscle group place different biomechanical stresses on the patella. Even though it is not possible to isolate contraction of the different parts of the quadriceps femoris muscle because of the common innervation, emphasis is often placed on activation of the vastus medialis obliquus (VMO) and vastus medialis (VM) muscles to develop appropriate patellar tracking. Tactile cues, biofeedback, and electrical muscle stimulation over the VMO can reinforce awareness of the muscle contracting for patellar control. In this section, the effectiveness of various quadriceps exercises with regard to training and strengthening the VMO are discussed.

Quadriceps Setting (Quad Sets)

NOTE: Of the many variations of static and dynamic exercises that have been proposed to selectively train the VMO, quadriceps setting coupled with electrical stimulation or biofeedback has been shown to be most effective.²²⁴

Patient position and procedure: Supine, sitting in a chair (with the heel on the floor) or long-sitting with the knee extended (or flexed a few degrees) but not hyperextended. Have the patient contract the quadriceps isometrically, causing the patella to glide proximally; then hold for a count of 10 and repeat.

- Use verbal cues such as, "Try to push your knee back and tighten your thigh muscle" or "Try to tighten your thigh muscle and pull your kneecap up." When the patient sets the muscle properly, offer verbal reinforcement immediately and then have the patient repeat the activity.
- Have the patient dorsiflex the ankle and then hold an isometric contraction of the quadriceps.⁴

Straight-Leg Raise

NOTE: An SLR in supine combines dynamic hip flexion with an isometric contraction of the quadriceps. The effec-

TABLE 21.8 Comparison of Forces and Muscle Action at the Knee During Dynamic Open-Chain and Closed-Chain Exercises^{56,249}

Parameter	Open-Chain Exercise—Variable Resistance: Sitting, Knee Extension Machine	Closed-Chain Exercise—Variable Resistance: Squatting, Leg-Press Machine (Body Moves Away from Fixed Feet)
Rectus femoris development	More effective	Less effective
VMO development	Less effective	More effective for VMO (and VL)
Other muscle development	None	Effective for hamstrings
ACL tensile forces*	ACL under tension <25°	
PCL tensile forces*	PCL under tension of 25°–95° (peak at 1.0 × body weight)	PCL under tension throughout range (1.5–2.0 × body weight)
Patellofemoral compression	Peak stress at 60°, peak compression at 75°†	Compression increases with knee flexion, peaking at 90°†
Tibiofemoral compression	Higher compression (more stability) < 30°	Higher compression (more stability) >70°

*The 0–25° range should be excluded in open-chain exercises following ACL injury, but may be included after PCL injury.

†Squat exercises: exercise only from 0° to 50° with patellofemoral dysfunctions.

‡Open-chain exercise from 0° to 30° and 75° to 90° with patellofemoral dysfunctions. (Note: there is controversy in the literature regarding compressive forces in the patellofemoral joint from 0° to 30°.)

tive resistance of gravity (or any additional weight added at the ankle) decreases as the lower extremity elevates because of the decreasing moment arm of the resistance force. The rectus femoris is the primary muscle in the quadriceps group that is active during SLR exercise.²²⁴

Patient position and procedure: Supine, with the knee extended. To stabilize the pelvis and low back, the opposite hip and knee are flexed, and the foot is placed flat on the exercise table. First, instruct the patient to set the quadriceps muscle; then lift the leg to about 45° of hip flexion while keeping the knee extended; hold the leg in that position for a count of 10 and then lower it.

- As the patient progresses, have the patient lift to only 30° of hip flexion and hold the position. Later, have the patient flex the hip to only 15°. The most significant resistance to the quadriceps is during the first few degrees of SLR.
- To increase resistance, place a cuff weight around the patient's ankle.

Focus on Evidence

It has been proposed that if an SLR in the supine position is coupled with external rotation or isometric adduction of the hip, the VMO or VM muscles are preferentially activated and strengthened.^{4,10,28,47,135} The rationale for advocating these exercises is that many fibers of the VMO muscle originate from the adductor magnus tendon.^{4,106} Although a number of authors^{4,10} have advocated these adaptations to SLRs to increase the medially directed forces on the patella, there is lack of evidence to substantiate the effect. In two quantitative studies comparing quadriceps muscle activity during quad sets and variations of SLRs, quad sets were found to be associated with significantly more VMO or VM activity than several variations of SLRs.^{106,224}

Straight-Leg Lowering

Patient position and procedure: Supine. If the patient cannot perform an SLR because of a quadriceps lag or weakness, begin by passively placing the leg in a 90° of SLR position (or as far as the flexibility of the hamstrings allows) and have the patient gradually lower the extremity while keeping the knee fully extended.

- Be prepared to control the descent of the leg with your hand under the heel as the torque created by gravity increases.
- If the knee begins to flex as the extremity is lowered, have the patient stop at that point, then raise the extremity upward to 90°.
- Have the patient repeat the motion and attempt to lower the extremity a little farther each time while keeping the knee extended.
- Once the patient can keep the knee extended while lowering the leg through the full ROM, SLRs can be initiated.

Multiple-Angle Isometric Exercises

- **Patient position and procedure:** Supine or long-sitting. Have the patient perform bent leg raises with the knee in multiple angles of flexion.
- **Patient position and procedure:** Seated at the edge of a treatment table. When tolerated, resistance is applied at the ankle manually or mechanically to strengthen the quadriceps isometrically in varying degrees of knee flexion. An effective co-contraction with the hamstrings can be activated (except in the last 10° to 15° of knee extension) by having the patient push the thigh downward into the table while holding the knee in extension against maximum resistance.⁸⁵

Short-Arc Terminal Extension

NOTE: Although in the past it was thought that the VMO was responsible for the terminal phase of knee extension, it is now well documented that all components of the quadriceps femoris muscle group are active throughout active knee extension and that the VMO primarily affects patellar alignment.²²⁴

Patient position and procedure: Supine or long-sitting. Place a rolled towel or bolster under the knee to support it in flexion (Fig. 21.17). The patient can also assume a short-sitting position at the edge of a table with the seat of a chair or a stool placed under the heel to stop knee flexion at the desired angle. Begin with the knee in a few degrees of flexion. Increase the degrees of flexion as tolerated by the patient or dictated by the condition.

- Initially have the patient extend the knee only against the resistance of gravity. Later, add cuff weights around the ankle to increase the resistance if the patient does not experience pain or crepitus.
- Combine short-arc terminal extension with an isometric hold and/or SLR when the knee is in full extension.
- To prevent lateral shear forces at the knee, have the patient invert the foot as he or she extends the knee.^{4,83}

PRECAUTION: When adding resistance to the distal leg, the amount of torque generated by the quadriceps muscle increases significantly in the terminal ranges of knee

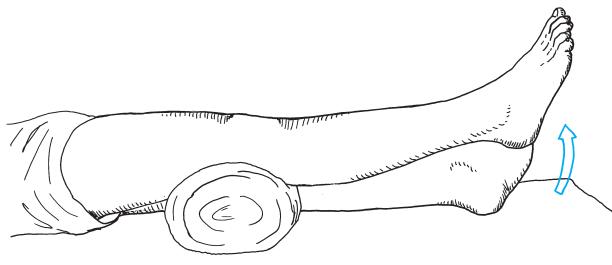

FIGURE 21.17 Short-arc terminal extension exercise to strengthen the quadriceps femoris muscle. When tolerated, resistance is added proximal to the ankle.

extension. In this portion of the range, the quadriceps has a poor mechanical advantage and poor physiological length while having to contract against an external resistance force that has a long lever arm. The amount of muscle force generated causes an anterior translation force on the tibia, which is restrained by the ACL. This exercise is not appropriate for a person with an unstable knee after an ACL injury or during postoperative rehabilitation before the ligament has healed.

Full-Arc Extension

Patient position and procedure: Sitting or supine. Have the patient extend the knee from 90° to full extension. Apply resistance to the motion as tolerated.

NOTE: Resistance from 90° to 60° causes less anterior tibial translation than closed-chain squatting in this range. Resistance applied in open-chain extension from 30° to 0°, however, increases anterior translation more than does performing mini-squats in the same range.²⁴⁹

- Apply resistance through the full arc of motion only during the later stages of rehabilitation if the knee is pain-free, stable, and asymptomatic. If there is pain, resistance should be applied only through those parts of the range with no symptoms.
- Various forms of mechanical resistance equipment discussed in Chapter 6 can be used to strengthen the knee extensors. Emphasize high-repetition, low-resistance training with weight-training equipment and medium- to high-speed training with isokinetic equipment to minimize compressive and shear forces to knee joint structures during exercise. When using equipment, the tibial pad against which the patient pushes while extending the knee can be placed more proximally than distally on the lower leg to minimize excessive stress to supporting structures of the knee.
- If a cuff weight is applied to the tibia to provide resistance, it causes a distraction to the joint and stress on the ligaments when the patient sits or lies supine with the knee flexed to 90° and the tibia over the edge of the treatment table. To avoid this stress to ligaments, place a stool under the foot so it can be supported when the leg is in the dependent position.³¹

To Strengthen Knee Flexion (Hamstrings)

Hamstring-Setting (Hamstring Sets)

Patient position and procedure: Supine or long-sitting, with the knee in extension or slight flexion with a towel roll under the knee. Have the patient isometrically contract the knee flexors just enough to feel tension developing in the muscle group by gently pushing the heel into the treatment table and holding the contraction. Have the patient relax and then repeat the contraction.

Multiple-Angle Isometric Exercises

Patient position and procedure: Supine or long-sitting. Apply either manual or mechanical resistance to a static hamstring muscle contraction with the knee flexed to several positions in the ROM.

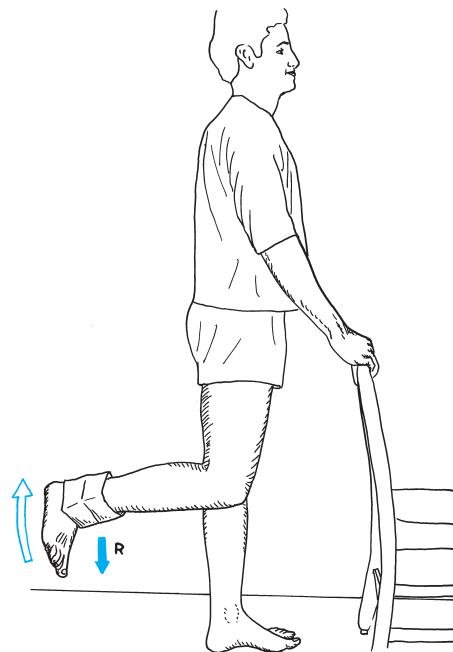

FIGURE 21.18 Hamstring curls; resistance exercises to the knee flexors with the patient standing. Maximal resistance occurs when the knee is at 90°.

- Place the tibia in internal or external rotation prior to resisting knee flexion to emphasize the medial or lateral hamstring muscles, respectively.
- Teach the patient to apply self-resistance at multiple points in the ROM by placing the opposite foot behind the ankle of the leg to be resisted.

Hamstring Curls (Open-Chain Knee Flexion)

- *Patient position and procedure:* Standing, holding onto a solid object for balance. Have the patient pick up the foot and flex the knee (Fig. 21.18). Maximum resistance from gravity occurs when the knee is at 90° flexion. Add resistance with ankle weights or a weighted boot. If the patient flexes the hip, stabilize it by having the patient place the anterior thigh against a wall or solid object.
- *Patient position and procedure:* Prone. Place a small towel roll or foam rubber under the femur just proximal to the patella to avoid compression of the patella between the treatment table and the femur. With a cuff weight around the ankle, have the patient flex the knee to only 90°. Maximum resistance from gravity occurs when the knee first starts to flex at 0°. If hamstring curls are performed in the prone position using manual resistance, a weight-pulley system or isokinetic equipment resistance to the knee flexors can be applied throughout the range of knee flexion.

PRECAUTION: Open-chain hamstring curls performed against resistance placed on the distal tibia cause posterior tibial translation. A patient with a PCL injury or reconstruction should avoid this exercise during the early stages of rehabilitation.

Closed-Chain Exercises

Progressive closed-chain exercises are beneficial for activating and training the musculature of the lower extremity to respond to specific functional demands. As the quadriceps contract eccentrically to control knee flexion or contract concentrically to extend the knee, the hamstrings and soleus function to stabilize the tibia against the anterior translating force of the quadriceps at the knee joint. This synergy along with the compressive loading on the joints provides support to the cruciate ligaments.^{56,178} In addition, because the hip extends and the ankle plantarflexes as the knee extends (and vice versa) during closed-chain activities, the two-joint hamstrings and gastrocnemius and the one-joint soleus are maintaining favorable length-tension relationships through action at the hip and ankle, respectively.

In a rehabilitation program, closed-chain exercises can be incorporated in an exercise regimen as soon as partial or full weight bearing is safe. Closed-chain strengthening exercises generate less shear force on knee ligaments, particularly anterior tibial translation, than open-chain quadriceps-strengthening activities.⁵² Therefore, resistance can be added to closed-chain activities sooner after injury or surgery than to open-chain exercises while still protecting healing structures such as the ACL. Clinically, closed-chain exercises enable a patient to develop strength, endurance, and stability of the lower extremity in functional patterns sooner after knee injury or surgery than do open-chain exercises. The progression of closed-chain exercises described in Chapter 20 also are appropriate for knee rehabilitation programs.

If the patient does not tolerate or is not permitted to be full weight bearing, begin exercises in the parallel bars or in a pool to partially unload body weight. During the healing phase after surgical procedures or with anterior knee pain problems, the knee should be taped or supported in a hinged brace during exercise. Begin exercises at a level tolerated by the patient and at which there is complete control and no exacerbation of symptoms.

Because the knee is the intermediate link in the lower extremity chain, it is influenced by hip and trunk as well as foot and ankle function during weight bearing. Proximal stability of the hip and the trunk may influence the kinematics of the knee,¹⁸⁹ and therefore exercises for these regions should be included in the rehabilitation of the knee if any impairments are detected during the examination.

Closed-Chain Isometric Exercises

Closed-chain isometric exercises are done to facilitate co-contraction of the quadriceps and hamstrings.

Setting Exercises

Patient position and procedure: Sitting on a chair, with the knee extended or slightly flexed and the heel on the floor. Have the patient press the heel against the floor and the thigh against the seat of the chair and concentrate on contracting the quadriceps and hamstrings simultaneously to facilitate co-contraction around the knee joint. Hold the muscle contraction, relax, and repeat. Use biofeedback to enhance learning of the co-contraction.

Stabilization Exercises

Patient position and procedure: Standing, with weight equally distributed through both lower extremities. Apply manual resistance to the pelvis in alternating directions as the patient holds the position. This facilitates isometric contractions of muscles in the ankles, knees, and hips.

- Increase the speed of application of the resistive forces to train the muscles to respond to sudden shifts in forces.
- Progress the stabilization activity by applying the alternating resistance against the shoulders to develop trunk stabilization and then by having the patient bear weight only on the involved lower extremity while resistance is applied.

Closed-Chain Isometrics Against Elastic Resistance

Patient position and procedure: Standing on the involved extremity, with elastic resistance looped around the thigh of the opposite extremity and secured to a stable object (see Fig. 20.22). Have the patient flex and extend the hip of the non-weight-bearing lower extremity to facilitate co-contraction of muscles and stability of the weight-bearing leg. This closed-chain exercise also facilitates proprioceptive input and balance on the weight-bearing (involved) lower extremity.

Closed-Chain Dynamic Exercises

Patient position is standing in all of the following exercises.

Unilateral Closed-Chain Terminal Knee Extension

Loop elastic resistance around the distal thigh and secure it to a stationary structure (Fig. 21.19). Have the patient actively perform terminal knee extension while bearing partial to full weight on the involved extremity.

Partial Squats, Mini-Squats, and Short-Arc Training

Begin by having the patient flex both knees up to 30° to 45° and then extend them. Progress by using elastic resistance placed under both feet (Fig. 21.20) or by holding

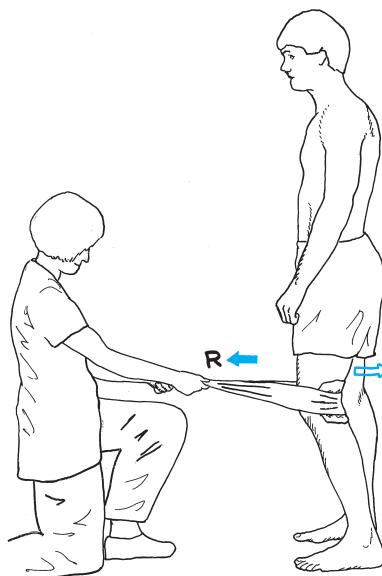

FIGURE 21.19 Unilateral closed-chain extension.

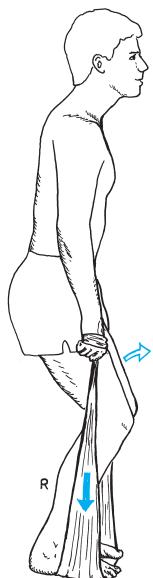

FIGURE 21.20 Resisted mini-squats; closed-chain short-arc training. Elastic resistance to knee extension is provided for short-arc motion. It is important to use the quadriceps femoris muscles rather than substitute with the hamstring muscles for proper strengthening.

weights in the hands. The patient should maintain the trunk upright and concentrate on the sensation of the quadriceps muscle contracting, not pulling back on the femur with the hip extensors.

- Progress squats to greater ranges of knee flexion during the advanced phases of treatment if necessary.
- Increase the difficulty of the exercise by performing unilateral resisted mini-squats.
- It has been suggested but not documented through research that if partial squats are performed with the legs slightly externally rotated the VMO muscle is in an optimal line of pull and may be more readily activated.¹⁰

NOTE: Squatting can be accomplished in one of two ways, each with positive and negative effects. When the knees move anterior to the toes, as the hips descend there is increased shear forces on the tibia and strain on the ACL. This can be dangerous if the patient squats while carrying considerable weight or after ACL surgery. Yet this is a more normal method for squatting and maintaining balance over the base of support. Squatting, as if sitting on a chair, during which the tibia remains relatively vertical, requires greater trunk flexion to maintain balance and a stronger quadriceps contraction to support the load of the pelvis posterior to the knee axis at an angle where patellar compressive loads are great. Yet this method reduces stress on the ACL. Positioning should be based on the patient's symptoms and pathological condition.

Forward, Backward, and Lateral Step-Ups and Step-Downs

- Begin with a low step, 2 to 3 inches in height, and increase the height as the patient is able. Make sure the patient keeps the trunk upright.

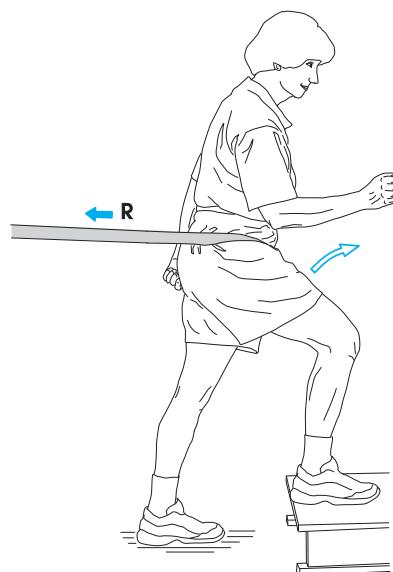

FIGURE 21.21 Resisted step-ups against elastic resistance or a pulley to strengthen knee extension.

- Emphasize control of body weight during concentric (step-up) and eccentric (step-down) quadriceps activity. To emphasize the quadriceps and minimize pushing off with the plantarflexors of the trailing extremity, instruct the patient that the heel is to be the last to leave the floor and the first to return or to "keep the toes up."
- Add resistance with a weight belt, handheld weights, or ankle weights around the non-weight-bearing leg if there is good ligamentous integrity, or place elastic resistance or a belt attached to a pulley system around the patient's hips and have the patient step up against the resistance force (Fig. 21.21).

Standing Wall Slides

Patient position and procedure: Standing, with back against the wall (see Fig. 20.24A); flex the hips and knees and slide the back down and then up the wall, lowering and lifting the body weight.

- As control improves, have the patient move into greater knee flexion, up to a maximum of 60°. Knee flexion beyond 60° is not advocated to avoid excessive shear forces on ligamentous structures of the knee and compressive forces on the patellofemoral joint.
- Add isometric training by having the patient stay in the partial-squat position. If the patient is able, he or she maintains the partial squat and alternately extends one leg and then the other.
- Wall slides performed with a gym ball behind the back decrease stability and require more control (see Fig. 20.24B).
- Unpublished data suggest that doing wall slides with a small ball between the knees activates a stronger contraction in the VMO.¹²⁸

Partial and Full Lunges

- Have the patient assume a step-forward stance position and rock his or her body weight forward, allowing the knee to flex slightly, and then rock backward and control knee extension.
- Progress the activity with full lunges (see Fig. 20.23). The patient begins with the feet together and then lunges forward with the involved extremity, beginning with a small stride and a small amount of knee flexion. He or she then returns upright by extending the knee and then bringing the foot back beside the other foot. Instruct the patient to keep the flexing knee in alignment with the toes and not to flex beyond a vertical line coming up from the toes. As the patient gains control, the stride length is increased and knee flexion is increased accordingly. Weights can be added to the trunk or be placed in the patient's hands for progressive strengthening. The speed of the activity is also increased as control improves.
- Progress by having the patient lunge diagonally forward, then out to the side, then diagonally backward, and then backward. This is facilitated by placing four intersecting lines on the floor (like spokes on a wheel) and having the patient stand in the middle of the intersecting lines. The patient then steps out onto one of the lines and returns. This same motion can be repeated multiple times before progressing to the next line, or the patient can step out onto each line in succession.

Chair Scooting

Patient position and procedure: Sitting, on a rolling stool or chair. Have the patient “walk” forward to use the hamstrings or “walk” backward to use the quadriceps. Increase the challenge of the exercise by having the patient steer around an obstacle course, roll the stool across carpeting, or pull against a resistance (such as pulling another person who is also on a rolling stool) (Fig. 21.22).

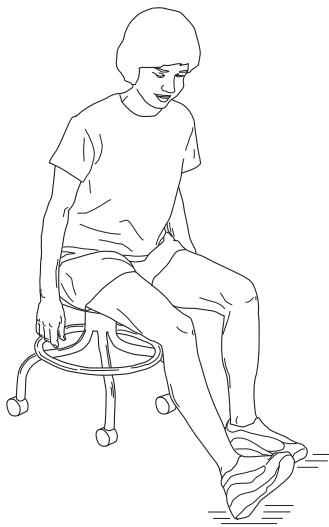

FIGURE 21.22 Forward chair scooting to strengthen knee flexion and backward scooting to strengthen knee extension.

Techniques to Simulate Functional Activities

To prepare for functional activities, it is important to develop muscular endurance, control of balance, and ability to respond to expected or unexpected perturbations. The principle of specificity of training is used to progress the patient's activities toward the desired outcome. Activities previously described are progressed for endurance by increasing the number of repetitions or time element at each resistance level. Once control has developed, emphasis is placed on balance, coordination, timing, and skill acquisition specific to the desired activity of the patient. Also refer to the exercises described in the hip chapter for balance stability and training.

Strength and Muscle Endurance Training

Mechanical equipment such as a leg press, Total Gym® unit, isokinetic dynamometer, treadmill, stationary bicycle, and stair-stepping units is useful for strengthening and endurance training and provides motivational feedback to the patient. When implementing isokinetic training for the quadriceps and hamstrings, use velocity-spectrum rehabilitation at medium to fast velocities.²⁰⁰ Place the tibia pad in a relatively proximal position on the knee to decrease anterior shear forces²⁵⁰ and program in range-limiting parameters whenever necessary.

Conditioning Activities

Activities such as swimming, progressive walking, running, cross-country ski machine training, and biking are designed for general cardiovascular/pulmonary conditioning and are graded to the patient's tolerance. If the patient is planning on returning to a sport activity, choose a conditioning activity that best replicates the muscle activity used in the sport

Proprioceptive and Balance

Activities (Perturbation Training)

Begin as early as weight bearing is allowed with balance activities. Suggestions include:

- Partial weight bearing in parallel bars and shifting weight; progress to full weight bearing.
- Stabilization exercises against alternating resistive forces.
- Stepping and marching in place.
- Balancing with arm movements in sagittal, frontal, and transverse planes; then progressing to diagonal planes.
- Walking; progress to walking in different directions, walking against resistance, and walking on uneven surfaces.
- Bilateral then unilateral stance on a balance (rocker) board, roller board, or BAPS board. Increase the challenge by adding destabilizing forces while the patient is balancing, such as tossing a weighted ball to the patient or pulling against elastic resistance that the patient is holding.
- If the patient is returning to a sport activity, replicate the stresses that will be placed on the knee in a controlled and then progressively uncontrolled manner.^{63,64,240,254}

Plyometric Training

High-speed, stretch-shortening exercises, which are designed to improve power, are appropriate for selected patients intending to return to high-demand functional or recreational activities. Jumping on and off surfaces of varying heights (Fig. 21.23) and incorporating directional changes in the movements are appropriate during the later stages of knee rehabilitation.

Drills

To improve coordination and agility, have the patient begin by stepping over and around objects that are placed on the ground as obstacles. Progress the training by increasing the speed of moving around the obstacles, or jump or hop over the obstacles. Initiate running, sprinting, pivoting, cutting, and sport-specific drills, monitoring for appropriate progression and correct mechanics.

Simulated Work-Related Activities

A patient returning to a repetitive lifting job requires strength in the trunk stabilizers as well as hip and knee extensors for safe body mechanics. A progression of lifting tasks, including squats and lunges, should also include use of proper body mechanics during lifting tasks. This progression is described in detail in Chapter 16.

FIGURE 21.23 Plyometric training using lateral jumps from a step. When the patient lands on the ground the hips and knees flex, then quickly extend to jump back up on the step. This plies a quick lengthening prior to shortening of the quadriceps muscle.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Observe a functional activity, such as putting on a pair of socks, rising from a chair, or climbing on to a city bus.
 - What ROM is needed in the knee joint? Also include hip and ankle in the analysis.
 - If motion is restricted, what muscles would have decreased mobility? What joint glides would have decreased mobility?
 - What muscles are functioning, and what level of strength is needed?
 - Assume there is 50% loss of range and strength. Design an exercise program to progress functional recovery.
2. Describe the function of all the two-joint muscles that cross the knee; include the function of each muscle at its “other joint” and how each muscle can function most efficiently at the knee in terms of its length-tension relationship.
3. Describe the role of the knee musculature during the gait cycle.
 - What ROM is needed, and when during the gait cycle does the maximum degree of flexion and extension occur?
 - During the gait cycle, when is each of the muscles active at the knee, and what is their function?
 - What gait deviations occur when there is muscle shortening, muscle weakness, and joint pain? Explain why each deviation occurs.

4. Two patients, both in their seventies, who underwent TKA 10 days ago because of joint degeneration from OA of the right knee have been referred to you in your home health practice. One patient had a cemented TKA and the other had a “hybrid” TKA. How does their postoperative management differ or how is it similar?
5. Differentiate among structures involved with a lateral retinacular release, a proximal realignment of the extensor mechanism, and a distal realignment procedure. How would these differences have an impact on postoperative rehabilitation?

● Laboratory Practice

1. Design, set up, and then perform a circuit training course for hamstring and quadriceps activation and strengthening and balance exercises. Sequence the activities from basic to advanced. Observe the accuracy and safety with each exercise and note the stresses involved.
2. Using mechanical resistance (pulleys, elastic resistance, and free weights), set up exercises to meet each of the following situations.
 - Strengthen the quadriceps with the greatest mechanical torque occurring when the knee is at 90°, at 45°, and at 25°.
 - Strengthen the hamstrings with the greatest mechanical torque occurring when the knee is at 90°, at 45°, and at 0°.

3. Review all the joint mobilization techniques for the knee; include basic glides, accessory motions, patellar mobilizations, and mobilization with movement techniques.
 - Identify and practice techniques that increase knee extension, beginning with the knee at 45° and progressing by 15° increments until full extension is reached.
 - Do the same for knee flexion, beginning at 25° and progressing at 15° increments until full range is achieved. What accessory motions are necessary?
 - What motions are restricted if the patella does not glide distally?
 - What function is lost if the patella does not glide proximally?
4. Review and practice soft tissue and patellar mobilization techniques that can be used to increase the mobility of the lateral retinaculum around the patella. How does mobilizing this tissue improve patellar tracking?
5. Identify all the two-joint muscles that cross the knee. Review and practice self-stretching techniques with and without equipment for each of these muscles.

Case Studies

1. Mrs. J. is a 49-year-old mother of three children. She is in good health but recently has experienced considerable right knee pain, especially after sitting for prolonged periods and then standing up, when descending stairs, and when shopping at the mall for longer than 2 hours. She has a history of a proximal tibial fracture 15 years ago. She reports that it took about a year before relatively normal mobility returned. On examination, you note no obvious deformities or joint swelling. Knee flexion is 125° with firm end-feel and pain on overpressure; extension is 0° with firm end-feel and pain on overpressure. There is a slight decrease in posterior glide accessory motion of the tibia and decreased mobility of the patella

- on the right compared to the left. Strength of the knee flexors and extensors is 4/5 bilaterally. She complains of pain in the right knee when squatting; pain begins at 45° flexion. She stops when the knees are at 75°, saying it hurts too much. She bends forward from the waist to pick up objects from the floor. She has difficulty lowering herself down to a low chair in a controlled manner.
- List her impairments and functional limitations, and state appropriate goals.
 - Develop an exercise program to meet the goals. How do you begin the exercises; how do you progress each exercise and the program?
 - Describe a rationale for each manual technique you would use and for each exercise you would teach the patient.
2. Mr. R., 25 years of age, was in a serious automobile accident and sustained multiple femoral and patellar fractures on the left side. His leg was immobilized in a long-leg cast for 3 months followed by a short leg cast for an additional month. He was allowed to perform partial weight bearing when in the short-leg cast. The cast was removed this morning, and now he is to begin his rehabilitation, although he will not be allowed to perform full weight bearing for an additional month. He describes significant stiffness and discomfort when attempting to flex his knee. Observation reveals significant atrophy in the thigh and leg. There are no open sores or joint swelling. Range is minimal: flexion to 25°, extension to 20°, and no joint play in the tibiofemoral or patellofemoral joints. He demonstrated the ability to do quad and hamstring sets, but strength could not be tested.
- Answer the same questions as in the previous case.
 - Even though patients in this and the previous case have restricted motion and demonstrate weakness, what are the differences in your intervention strategies? Are there different precautions that you will follow during treatment? If so, what are they?

The joints, ligaments, and muscles of the ankle and foot are designed to provide stability and mobility in the terminal structures of the lower extremity. During standing, the foot must bear the body weight with a minimum of muscle energy expenditure. In addition, the foot must be capable

of being either pliable or relatively rigid depending on various functional demands such as adapting to absorb forces and accommodate to uneven surfaces, or becoming a structural lever to propel the body forward during walking and running.

The anatomy and kinesiology of the ankle and foot are complex, but it is important to understand and be able to apply this knowledge to treat impairments in this region of the body effectively. The first section of this chapter reviews highlights of these areas that the reader should know and understand. The second section contains guidelines for the management of disorders and surgeries in the foot and ankle region, and the third section describes exercise interventions for this region. Chapters 10 through 13 present general information on principles of management; the reader should be familiar with the material in these chapters, and have a background in examination and evaluation in order to effectively design a therapeutic exercise program to improve ankle and foot function in patients with impairments from injury, pathology, or following surgery.

STRUCTURE AND FUNCTION OF THE ANKLE AND FOOT

The bones of the ankle and foot consist of the distal tibia and fibula, 7 tarsals, 5 metatarsals, and 14 phalanges (Fig. 22.1).

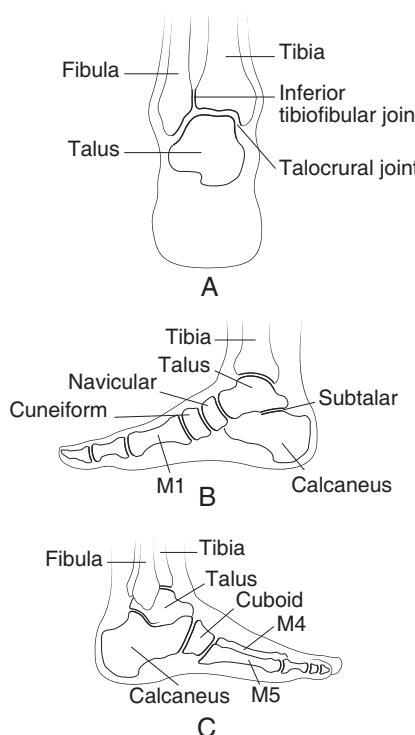

FIGURE 22.1 Bones of the ankle and foot. (A) Anterior view of the lower leg and ankle, (B) medial view, and (C) lateral view of the ankle and foot.

STRUCTURAL RELATIONSHIPS AND MOTIONS

Anatomical Characteristics

The leg is structurally designed to transmit the ground reaction forces from the foot upward to the knee joint and femur, and adapt as needed to provide stability to or allow motion of the ankle. The resulting motions in the ankle and foot are defined using primary plane descriptors and triplanar descriptors.

Leg

The tibia and fibula make up the leg. These two bones are bound together by an interosseous membrane along the shafts of the bones, by strong anterior and posterior inferior tibiofibular ligaments that hold the distal tibiofibular articulation together, and by a strong capsule that encloses the proximal tibiofibular articulation. Unlike the radius and ulna in the upper extremity, the tibia and fibula do not rotate around each other, but there is slight movement between the two bones that allows greater movement of the ankle joints.

Foot

The foot is divided into three segments: the hindfoot, midfoot, and forefoot.

Hindfoot. The talus and calcaneus make up the posterior segment.

Midfoot. The navicular, cuboid, and three cuneiforms make up the middle segment.

Forefoot. Five metatarsals and 14 phalanges make up the anterior segment. Each toe has three phalanges except for the large toe, which has two.

Motions of the Foot and Ankle Defined

Primary Plane Motions

Although motions in the foot and ankle do not occur purely in the cardinal planes, they are still defined as follows.^{19,20,70,88}

Sagittal plane motion around a frontal (coronal axis). *Dorsiflexion* is movement in a dorsal direction which decreases the angle between the leg and dorsum of the foot, and *plantarflexion* is movement in a plantar direction. Motion occurring at the toes may also be called dorsiflexion or extension, and plantarflexion or flexion.

Frontal plane motion around a sagittal (anteroposterior) axis. *Inversion* is inward turning of the foot and *eversion* is outward turning. Normally, an inward and outward motion is described by the terms *abduction* and *adduction*, but because the foot is at a right angle to the leg, the terms *abduction* and *adduction* are not used here.

Transverse plane motion around a vertical axis. *Abduction* is movement away from the midline, and *adduction* is movement toward the midline.

Triplanar Motions

Triplanar motion occurs around an oblique axis at each articulation of the ankle and foot. The definitions are descriptive of the movement of the distal bone on the proximal bone. When the proximal bone moves on the stabilized distal bone, as occurs in weight bearing, the motion of the proximal bone is opposite, although the relative joint motion is the same as defined.

Pronation. Pronation is a combination of dorsiflexion, eversion, and abduction. During weight bearing, pronation of the subtalar and transverse tarsal joints causes the arch of the foot to lower, and there is a relative supination of the forefoot with dorsiflexion of the first and plantarflexion of the fifth metatarsals. This is the loose-packed or mobile position of the foot and is assumed when the foot absorbs the impact of weight bearing and rotational forces of the rest of the lower extremity and when the foot conforms to the ground.²⁰

Supination. Supination is a combination of plantarflexion, inversion, and adduction. In the closed-chain, weight-bearing foot, supination of the subtalar and transverse tarsal joints with a pronation twist of the forefoot (plantarflexion of the first and dorsiflexion of the fifth metatarsals) increases the arch of the foot and is the close-packed or stable position of the joints of the foot. This is the position the foot assumes when a rigid lever is needed to propel the body forward during the push-off phase of ambulation.^{70,88}

NOTE : The terms inversion and supination, as well as eversion and pronation, are often interchanged.⁷⁶ This text uses the terms as defined above.

Leg, Ankle, and Foot Joint Characteristics and Arthrokinematics

The characteristics of each joint in the leg, ankle, and foot dictate how they contribute to the function of the foot.^{70,75,88,94}

Tibiofibular Joints

Anatomically, the superior and inferior tibiofibular joints are separate from the ankle but provide accessory motions that allow greater movement at the ankle. Fusion or immobility in these joints impairs ankle function. The strong mortise formed by the distal ends of the tibia and fibula forms the proximal surface of the ankle (talocrural) joint.

Superior tibiofibular joint characteristics. The superior tibiofibular joint is a plane synovial joint made up of the fibular head and a facet on the posterolateral aspect of the rim of the tibial condyle. The facet faces posteriorly, inferiorly, and laterally. Although near the knee joint, it has its own capsule which is reinforced by the anterior and posterior tibiofibular ligaments.

Inferior tibiofibular joint characteristics. The inferior tibiofibular joint is a syndesmosis with fibroadipose tissue between the two bony surfaces. This strong articulation is supported by the crural tibiofibular interosseous ligament and the anterior and posterior tibiofibular ligaments.

Accessory motions. With dorsiflexion and plantarflexion of the ankle, there are slight accessory movements of the fibula. The direction of movement is variable depending on facet orientation of the proximal tibiofibular joint and elasticity in the tibiofibular ligaments. However, movement is necessary to allow full range of the talus in the mortise during ankle dorsiflexion.

Ankle (Talocrural) Joint

Characteristics. The ankle (talocrural) joint is a synovial hinge joint formed by the mortise (distal end of the tibia and tibial and fibular malleoli) and trochlea (dome) of the talus, and is enclosed by a relatively thin and weak capsule. It, along with the subtalar joint, is supported medially by the medial collateral (deltoid) ligament and laterally by the lateral collateral (anterior and posterior talofibular and calcaneofibular) ligaments (Fig. 22.2).

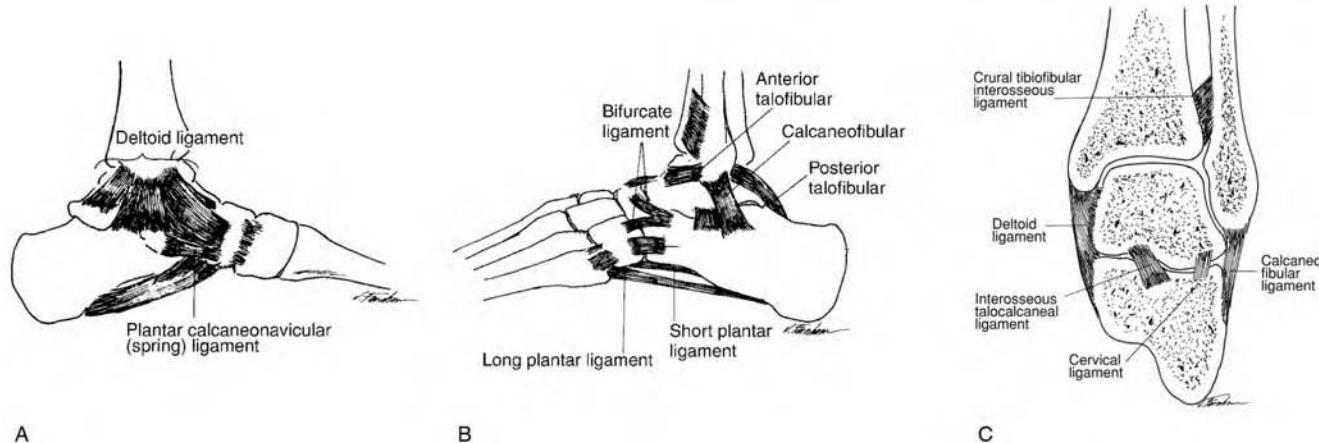

FIGURE 22.2 Ligaments of the ankle and foot. (A) Medial view, (B) lateral view, and (C) posterior (cross-sectional) view. (From Mueller in Levangie and Norkin,⁷⁰ A and B, p 442; C p 447, with permission.)

The fibular malleolus extends farther distally and posteriorly than the tibial malleolus so that the mortise angles outward and downward. This causes the axis of motion to be rotated laterally 20° to 30° and inclined downward 10°. The surface of the mortise is congruent with the articulating surface of the body of the talus.

The surface of the talus is wedge-shaped, being wider anteriorly, and is also cone-shaped, with the apex pointing medially. As a result of the orientation of the axis and shape of the talus when the foot dorsiflexes, the talus also abducts and slightly everts (pronation). When the foot plantarflexes, the talus also adducts and slightly inverts (supination). Dorsiflexion is the close-packed, stable position of the talocrural joint. Plantarflexion is the loose-packed position. The ankle joint is more vulnerable to injury when an individual is walking in high heels because of the less stable plantarflexed position at the same time that the subtalar and transverse tarsal joints are in their close-packed (rigid) position.

Arthrokinematics. The concave articulating surface is the mortise; the convex articulating surface is the body of the talus. With physiological motions of the foot, the articulating surface of the talus slides in the opposite direction (Box 22.1).

Subtalar (Talocalcaneal) Joint

Characteristics. The subtalar (talocalcaneal) joint is a complex joint with three articulations between the talus and calcaneus. It has an oblique axis of motion lying approximately 42° from the transverse plane and 16° from the sagittal plane, which allows the calcaneus to pronate and

supinate in a triplanar motion on the talus. Frontal plane inversion (turning heel inward) and eversion (turning heel outward) can be isolated only with passive motion. The subtalar joint is supported by the medial and lateral collateral ligaments, which also support the talocrural joint; by the interosseous talocalcaneal ligament in the tarsal canal; and by the posterior and lateral talocalcaneal ligaments. In closed-chain activities, the joint attenuates the rotatory forces between the leg and foot so that, normally, excessive inward or outward turning of the foot does not occur as the foot maintains contact with the supporting surface.

Of the three articulations between the talus and calcaneus, the posterior is separated from the anterior and middle by the tarsal canal. The canal divides the subtalar joint into two joint cavities. The posterior articulation has its own capsule. The anterior articulations are enclosed in the same capsule as the talonavicular articulation, forming the talocalcaneonavicular joint. Functionally, these articulations work together.

Arthrokinematics. The facet on the bottom of the talus in the posterior compartment is concave and the opposing facet on the calcaneus is convex. The facets of the anterior and middle articulations on the talus are convex, whereas the opposing facets on the calcaneus are concave. With open-chain physiological motions of the subtalar joint, the convex posterior portion of the calcaneus slides opposite to the motion; the concave anterior and middle facets on the calcaneus slide in the same direction, similar to turning a doorknob. Therefore, with the component motion of eversion, as the calcaneus swings laterally, the posterior articulating surface slides medially, and with inversion, the posterior articulating surface slides laterally (see Box 22.1).

Talonavicular Joint

Characteristics. The talonavicular joint is anatomically and functionally part of a complex articulation between the talus and navicular as well as anterior and medial facets of the subtalar joint. It is supported by the spring, the deltoid, the bifurcate, and the dorsal talonavicular ligaments. The triplanar motions of the navicular on the talus function with the subtalar joint, resulting in pronation and supination.

During pronation, in the weight-bearing foot, the head of the talus drops plantarward and medially, resulting in a pliable foot and decreased medial longitudinal arch. In essence, as the calcaneus everts, it cannot also dorsiflex and abduct with the foot on the ground, so the talus plantarflexes and inverts on the calcaneus. This downward and inward motion of the talar head results in an upward and outward motion of the navicular and a flattening of the arch. During supination, the opposite occurs, resulting in a structurally stable foot and an increased medial longitudinal arch. The calcaneus inverts, and the talus dorsiflexes and everts, resulting in the navicular plantarflexing, inverting, and adducting.

BOX 22.1 Arthrokinematics of the Ankle and Foot Joints

Physiologic motion	Roll	Slide
Talocrural joint: motion of talus		
Dorsiflexion	Anterior	Posterior
Plantarflexion	Posterior	Anterior
Subtalar joint: motion of calcaneus (posterior articulating surface)		
Supination with inversion	Medial	Lateral
Pronation with eversion	Lateral	Medial
Talonavicular joint: motion of navicular (open-chain)		
Supination	Plantar and medial	Plantar and medial
Pronation	Dorsal and lateral	Dorsal and lateral
Metatarsophalangeal and interphalangeal joints: motion of the phalanges		
Flexion	Plantar	Plantar
Extension	Dorsal	Dorsal

Arthrokinematics. The head of the talus is convex; the proximal articulating surface of the navicular is concave. With physiological motions of the foot, the navicular slides in the same direction as the motion of the forefoot. In the open-chain motion of pronation, the navicular slides dorsally and laterally (abduction and eversion), resulting in a flattening of the medial longitudinal arch. With supination, the navicular slides volarly and medially (adduction and inversion) (see Box 22.1).

Transverse Tarsal Joint

Characteristics. This functionally compound joint between the hind- and midfoot includes the anatomically separate talonavicular and calcaneocuboid joints. The *talonavicular joint* was described in the previous section. The *calcaneocuboid joint* is saddle-shaped. The transverse tarsal joint participates in the triplanar pronation/supination motions of the foot and makes compensatory movements to accommodate variations in the ground. Passive accessory motions include abduction/adduction, inversion/eversion, and dorsal/plantar gliding.

Arthrokinematics. The articulating surface of the calcaneus is convex in a dorsal-to-plantar direction and concave in a medial-to-lateral direction. The articulating surface of the cuboid is reciprocally concave and convex.

Remaining Intertarsal and Tarsometatarsal Joints

The remaining intertarsal and tarsometatarsal joints are plane joints that reinforce the function of transverse tarsal joints, and during weight bearing, help regulate the position of the forefoot on the ground.

Metatarsophalangeal and Interphalangeal Joints of the Toes

The metatarsophalangeal and interphalangeal joints of the toes are the same as the metacarpophalangeal and interphalangeal joints of the hand except that, in the toes, extension range of motion (ROM) is more important than is flexion (the opposite is true in the hand). Extension of the metatarsophalangeal (MTP) joints is necessary for normal walking. Also, unlike the thumb, the large toe does not function separately.

FUNCTION OF THE ANKLE AND FOOT

Structural Relationships

Interdependence of leg and foot motions. In the weight-bearing foot, subtalar motion and tibial rotation are interdependent. Supination of the subtalar joint results in or is caused by lateral rotation of the tibia, and conversely, pronation of the subtalar joint results in or is caused by medial rotation of the tibia.^{70,88}

Arches. The arches of the foot are visualized as a twisted osteoligamentous plate, with the metatarsal heads being the horizontally placed anterior edge of the plate, and the cal-

canus being the vertically placed posterior edge. The twist causes the longitudinal and transverse arches. When the foot is bearing weight, the plate tends to untwist and flatten the arches slightly.⁷⁰

- Primary support of the arches comes from the spring ligament, with additional support from the long plantar ligament, the plantar aponeurosis, and short plantar ligament. During push-off in gait, as the foot plantarflexes and supinates and the metatarsal phalangeal joints go into extension, increased tension is placed on the plantar aponeurosis, which helps increase the arch. This is called the windlass effect.
- In the normal static foot, muscles do little to support the arches, yet without muscle tension the passive support stretches, and foot pronation increases under weight-bearing loads. Muscles contribute to support during ambulation.

Effect on posture. During standing with weight equally distributed through both lower extremities, if one foot/ankle complex is more pronated than the other, the overall effect is a frontal plane asymmetry with a “short leg” on that side. All typical landmarks (crest of the ilium, greater trochanter, popliteal crease, head of the fibula, and medial malleolus) on the side of the pronated foot are slightly lower.

Abnormal foot postures. A person with a varus deformity of the calcaneus (observed nonweight-bearing) may compensate by standing with a pronated (or everted) calcaneus posture.^{19,21} The terms pes planus, pronated foot, and flat foot are often interchanged to mean a pronated posture of the hindfoot and decreased medial longitudinal arch. Pes cavus and supinated foot describe a high-arched foot.⁷⁶

Muscle Function in the Ankle and Foot

Plantarflexors. Plantarflexion is caused primarily by the two-joint gastrocnemius muscle and the one-joint soleus muscle, these muscles attach to the calcaneus via the Achilles tendon.

Secondary plantarflexors. Other muscles passing posteriorly to the axis of motion of plantarflexion contribute little to that motion, but they do have other functions.

- Tibialis posterior is a strong *supinator* and *invertor* that helps to control and reverse pronation during midstance of gait.
- The flexor hallucis longus and flexor digitorum longus muscles flex the toes and help support the medial longitudinal arch. To prevent clawing of the toes (MTP extension with IP flexion), intrinsic muscles must also function at the MTP joints.
- The peroneus longus and brevis muscles primarily *pronate* the foot at the subtalar joint, and the longus gives support to the transverse and lateral longitudinal arches during weight-bearing activities.⁷¹

Dorsiflexors. Dorsiflexion of the ankle is caused by the tibialis anterior muscle (which also inverts the ankle), the extensor hallucis longus and extensor digitorum longus (which also extend the toes), and the peroneus tertius muscles.

Intrinsic muscles. Intrinsic muscles of the foot function similar to those of the hand (except there is no thumb-like function in the foot). In addition, they provide support to the arches during gait.

Stability in standing. During normal standing, the gravitational line is anterior to the axis of the ankle joint, creating a dorsiflexion moment. The soleus muscle contracts to counter the gravitational moment through its pull on the tibia. Other extrinsic foot muscles help stabilize the foot during postural sway.

THE ANKLE/FOOT COMPLEX AND GAIT

During the normal gait cycle, the ankle goes through a ROM of 32° to 35°. Approximately 7° of dorsiflexion occurs at the end of midstance as the heel begins to rise, and 25° of plantarflexion occurs at the end of stance (toe off).⁷⁸

Function of the Ankle and Foot Joints During Gait

The shock-absorbing, terrain-conforming, and propulsion functions of the ankle and foot include the following.^{70,78,80}

- During the *loading response* (heel strike to foot flat), the heel strikes the ground in neutral or slight supination. As the foot lowers to the ground, it begins to pronate to its loose-packed position. The entire lower extremity rotates inward, which reinforces the loose-packed position of the foot. With the foot in a lax position, it can conform to variations in the ground contour and absorb some of the impact forces as the foot is lowered.
- Once the foot is fixed on the ground, dorsiflexion begins as the tibia comes up over the foot. The tibia continues to rotate internally, which reinforces pronation of the subtalar joint and loose-packed position of the foot.
- During *midstance* and continuing through *terminal stance*, the tibia begins to rotate externally, which initiates supination of the hindfoot and locking of the transverse tarsal joint. This brings the foot into its close-packed position, which is reinforced as the heel rises and the foot rocks up onto the toes, causing toe extension and tightening of the plantar aponeurosis (windlass effect). This stable position converts the foot into a rigid lever, ready to propel the body forward as the ankle plantarflexes from the pull of the gastrocnemius–soleus muscle group.

Muscle Control of the Ankle and Foot During Gait^{70,78,80}

Ankle dorsiflexors. The ankle dorsiflexors function during the initial foot contact and loading response (heel strike to foot flat) to counter the plantarflexion torque and to control the lowering of the foot to the ground. They also function during the swing phase to keep the foot from plantarflexing and dragging on the ground. With loss of the dorsiflexors, foot slap occurs at initial foot contact, and the hip and knee flex excessively during swing (otherwise the toe drags on the ground).

Ankle plantarflexors. The ankle plantarflexors function eccentrically early in stance to control the rate of forward movement of the tibia. Then at around 40% of the cycle (midstance) there is a burst of concentric activity to initiate plantarflexion of the ankle for push off. Loss of function results in a slight lag of the lower extremity during terminal stance with no push-off.

Ankle evertors. Contraction of the peroneus longus muscle late in the stance phase facilitates transfer of weight from the lateral to the medial side of the foot. It also stabilizes the first ray and facilitates the pronation twist of the tarsometatarsal joints as increased supination occurs in the hindfoot.

Ankle invertors. The tibialis anterior helps control the pronation force on the hindfoot during the loading response of gait.

Intrinsic muscles. The intrinsic muscles support the transverse and longitudinal arches during gait.

REFERRED PAIN AND NERVE INJURY

Several major nerves terminate in the foot. Injury or entrapment of the nerves may occur anywhere along their course, from the lumbosacral spine to near their termination. For treatment to be effective, it must be directed to the source of the problem. Therefore, a thorough history is obtained, and an examination is performed when the patient reports referred pain patterns, sensory changes, or muscle weakness. For a detailed description of referred pain patterns and peripheral nerve injuries in the foot and ankle region see Chapter 13.

Major Nerves Subject to Pressure and Trauma

Common peroneal nerve. Pressure on the common peroneal nerve may occur as it courses laterally around the fibular neck and passes through an opening in the peroneus longus muscle.

Posterior tibial nerve. Entrapment in the tarsal tunnel, causing tarsal tunnel syndrome, may occur from a space-occupying lesion posterior to the medial malleolus.

Plantar and calcaneal nerves. These branches of the posterior tibial nerve may become entrapped as they turn under the medial aspect of the foot and pass through open-

ings in the abductor hallucis muscle. Overpronation presses the nerves against these openings. Irritation of the nerves may elicit symptoms similar to those of acute foot strain (tenderness at the posteromedial plantar aspect of the foot), painful heel (inflamed calcaneal nerve), and pain in a pes cavus foot.

Common Sources of Segmental Sensory Reference in the Foot

The foot is the terminal point for the L4, L5, and S1 nerve roots coursing through the terminal branches of the peroneal and tibial nerves. Referred pain may occur with irritation to tissues derived from the same spinal segments, or sensory changes from irritation or damage to these nerve roots (see Fig. 13.2 in Chapter 13).

MANAGEMENT OF FOOT AND ANKLE DISORDERS AND SURGERIES

To make sound clinical decisions when managing patients with foot and ankle disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and identify presenting impairments, functional limitations, and possible disabilities. In this section common pathologies and surgeries are presented and related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*² (Table 22.1). Conservative and postoperative management of the conditions described in this section are based on principles of tissue healing and exercise intervention.

TABLE 22.1 Foot and Ankle Pathologies/Surgical Procedures and Preferred Practice Patterns

PATHOLOGY/SURGICAL PROCEDURE	PREFERRED PRACTICE PATTERNS AND ASSOCIATED IMPAIRMENTS ²
<ul style="list-style-type: none"> • Abnormal posture (pronated or supinated foot, tibial torsion) 	Pattern 4B—Impaired posture
<ul style="list-style-type: none"> • Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis, gout) • Post-immobilization stiffness • Synovitis • Joint instability, subluxation, dislocation (nontraumatic/recurrent) • Overuse syndromes/repetitive trauma syndromes (tendonitis, plantar fasciitis, shin splints) 	Pattern 4D—Impaired joint mobility, motor function, muscle performance, and range of motion associated with connective tissue dysfunction
<ul style="list-style-type: none"> • Arthritis—acute stage • Acute capsulitis • Acute plantar fasciitis, tendonitis, shin splints • Acute ankle sprains • Acute muscle tears 	Pattern 4E—Impaired joint mobility, motor function, muscle performance, and range of motion associated with localized inflammation
<ul style="list-style-type: none"> • Fractures 	Pattern 4G—Impaired joint mobility, muscle performance, and range of motion associated with fracture
<ul style="list-style-type: none"> • Arthroscopic débridement • Osteochondral drilling, mosaicplasty, osteochondral autologous transplantation • Excision arthroplasty with or without implant of the MTP or IP joints • Total joint arthroplasty 	Pattern 4H—Impaired joint mobility, motor function, muscle performance and range of motion associated with joint arthroplasty
<ul style="list-style-type: none"> • Fracture stabilization with internal fixation • Tendon and ligament repairs • Capsulorrhaphy • Synovectomy • Arthrodesis 	Pattern 4I—Impaired joint mobility, motor function, muscle performance and range of motion associated with bony or soft tissue surgery
<ul style="list-style-type: none"> • Peripheral nerve injury (common peroneal, posterior tibial, tarsal tunnel syndrome) 	Pattern 5F—Impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

JOINT HYPOMOBILITY: NONOPERATIVE MANAGEMENT

Common Joint Pathologies and Etiology of Symptoms

Pathologies such as rheumatoid arthritis (RA); juvenile rheumatoid arthritis (JRA); degenerative joint disease (DJD); and acute joint reactions after trauma, dislocations, or fractures affect the foot and ankle complex.

Post-immobilization contractures and adhesions develop in the joint capsules and surrounding tissues any time a joint is immobilized in a cast or splint, typically after dislocations and fractures. The reader is referred to Chapter 11 for background information on arthritis, post-immobilization stiffness, and etiology of symptoms. The following is specific to joint conditions in the ankle and foot:

Rheumatoid arthritis. Joint pathology of the foot and ankle as the result of RA commonly affects the forefoot early in the disease process, later the hindfoot, and least frequently, the ankle.^{14,41} Involvement may occur in the MTP, subtalar, talocrural joints of the foot, leading to instabilities and painful deformities, such as hallux valgus and subluxation of the metatarsal heads, that increase with the stress of weight bearing. Tendon rupture of foot and ankle musculature also may occur as the result of chronic inflammation and contribute to deformity.⁴¹

Degenerative joint disease (DJD) and joint trauma.

Degenerative symptoms occur in joints that are malaligned or repetitively traumatized, and acute joint symptoms are often seen in conjunction with ankle sprains, chronic instability, or fracture. Post-traumatic arthritis leading to DJD is by far the most common type of arthritis that affects the ankle, accounting for approximately 80% of all ankle arthritis. In contrast, primary osteoarthritis, a common type of arthritis in the hip and knee, is rare in the ankle, even in the older adult population.¹⁰⁵

Post-immobilization stiffness. Contractures and adhesions in the capsular tissues leading to joint hypomobilities as well as in the surrounding periarticular tissues may occur any time the joint is immobilized after a fracture or surgery.

Gout. Symptoms commonly affect the MTP joint of the great toe, causing pain during terminal stance so that there is a shorter stance and lack of smooth push-off.

Common Impairments and Functional Limitations/Disabilities

In RA, many of the following impairments and deformities occur with progression of the disease.^{18,92} With DJD and post-immobilization stiffness, only the affected joint or joints are limited.¹⁶ Functional limitations and disabilities occur primarily as a result of loss of weight-bearing abilities.

● **Restricted motion.** When symptoms are acute, the patient experiences swelling and restricted, painful motion, particularly during weight-bearing activities. When symptoms are chronic, there is restricted motion, decreased joint play, and a firm capsular end-feel in the affected joint.

- **Decreased mobility in the proximal and distal tibiofibular joints.** Restricted accessory motion in these joints usually occurs with periods of immobilization and limits ankle and subtalar joint motion.⁵⁶
- **Talocrural joint.** Passive plantarflexion is more limited than dorsiflexion (unless the gastrocnemius–soleus muscle group also is shortened, in which case dorsiflexion is limited accordingly).
- **Subtalar and transverse tarsal joints.** Progressive limitation of supination develops until eventually the joint fixes in pronation with flattening of the medial longitudinal arch. The close-packed position of the tarsals (supination) becomes more and more difficult to assume during the terminal stance (push-off) phase of gait.
- **MTP joint of the large toe.** Gross limitation of extension and some limitation of flexion develop; the rest of the MTP joints are variable. Lack of extension restricts the terminal stance phase of gait with an inability to rock up onto the metatarsal heads. This exacerbates the pronation posture and inability to supinate the foot during push-off in gait.

● **Common deformities.** Deformities occur due to a variety of factors including but not limited to muscle imbalances, faulty footwear, trauma, and heredity.

- **Hallux valgus.** This deformity in the great (large) toe develops as the proximal phalanx shifts laterally toward the second toe. Eventually the flexor and extensor muscles of the great toe shift laterally and further accentuate the deformity. The bursa over the medial aspect of the metatarsal head may become inflamed and the bone hypertrophies, causing a painful bunion.
- **Hallux rigidus.** Narrowing and eventual obliteration of the first MTP joint space occur with progressive loss of extension. This affects terminal stance by not allowing the foot to roll over the metatarsal heads and great toe for normal push-off. Instead, the individual turns the foot outward and rolls over the medial aspect of the large toe. This faulty pattern accentuates hallux valgus and foot pronation, and usually the MTP joint is quite painful.

• **Dorsal dislocation of the proximal phalanges on the metatarsal heads.** If this occurs, the fat pad, which is normally under the metatarsal heads, migrates dorsally with the phalanges, and the protective cushion on weight bearing is lost, leading to pain, callus formation, and potential ulceration.

- **Claw toe (MTP hyperextension and IP flexion) and hammer toe (MTP hyperextension, PIP flexion, and DIP hyperextension).** These result from muscle imbalances between the intrinsic and extrinsic muscles of the

toes. Friction from shoes may cause calluses to form where the toes rub.

- **Muscle weakness and decreased muscular endurance.** Inhibition resulting from pain and decreased use of the extremities lead to impaired muscle function.
- **Impaired balance and postural control.** The sensory receptors in the ankle joints and ligaments, as well as in the muscle spindles, provide important information for posture and movement, known as the *ankle strategy*. The ankle strategy is used in balance control during perturbations.^{37,84} Faulty feedback and balance deficits occur when there is instability, muscle impairments, or arthritis.
- **Increased frequency of falling.** Impaired balance may lead to frequent falling or fear of falling and thus restrict community outings.
- **Painful weight bearing.** When symptoms are acute, weight-bearing activities are painful, preventing independent ambulation and causing difficulty in rising from a chair and ascending and descending stairs.
- **Gait deviations.** If the patient experiences pain during weight bearing, there is a short stance phase, reduced single limb support, and decreased stride length on the side of involvement. Because of the restricting motion and loss of effective plantarflexion and supination in the arthritic foot, as well as pain in the forefoot area under the metatarsal heads, push-off is ineffective during terminal stance. Little or no heel rise occurs; instead, the person lifts up the involved foot.
- **Decreased ambulation.** Because of decreased ankle and foot mobility and resulting decreased length of stride, distance and speed of ambulation are decreased; the person may require use of assistive devices for ambulation. If pain, balance, or restricted motion is severe the person will be unable to ambulate and, therefore, requires a wheelchair for mobility.

Joint Hypomobility: Management—Protection Phase

The interventions selected for management depend on the signs and symptoms present. For acute problems, follow the general outline presented in Chapter 10 and summarized in Box 10.1. Suggested interventions for the various goals are described in this section.^{45,92,105}

Educate the Patient and Provide Joint Protection

Teach a home exercise program at the level of the patient's abilities. Teach the patient to be aware of signs of systemic fatigue (especially in RA), local muscle fatigue, and joint stress, and how to modify exercises and activities to remain active within safe levels. Emphasize the importance of daily ROM, endurance activities, and joint protection, including avoidance of faulty foot and ankle postures and protection of the feet from deforming weight-bearing forces and trauma imposed by improperly fitting footwear. If necessary, instruct the patient in safe use of assistive devices to decrease the effects of weight bearing and pain.

Decrease Pain

In addition to physician-prescribed medication, intra-articular injections of corticosteroids, or nonsteroidal anti-inflammatory medications, and therapeutic use of modalities the following are used to manage painful symptoms.

- **Manual therapy techniques.** Gentle grade I or II distraction and oscillation techniques may inhibit pain and move synovial fluid for nutrition within the involved joints.
- **Orthotic devices.** Orthotics and well-constructed shoes help protect the joints by realigning forces and providing support from faulty foot postures.^{45,62,65} Such support has been shown to decrease pain and improve functional mobility. Splinting or bracing may also be used to stabilize an arthritic joint.

Focus on Evidence

Kavlak and colleagues⁴⁵ reported the effects of prescribed orthotic devices in 18 patients with RA (no control group) and a variety of bilateral foot deformities, including pes planus, hallux valgus, hammer toe, subluxation of the metatarsal heads, and others. All patients in the study were community walkers with no history of surgery of the foot or ankle. All patients were prescribed custom-made orthotic inserts and shoe modifications, such as a medial longitudinal arch support, metatarsal pad, or heel and forefoot wedge, to meet their individual needs. Pain, temporal-distance characteristics of gait, and energy expenditure during walking were measured before and after the patients had been wearing the custom orthoses for 3 months. There was a significant reduction in pain and energy cost during ambulation and increases in step and stride length after use of the orthotic devices for 3 months. There were no significant changes in foot angle or the width of the base of support. The authors concluded that appropriately prescribed orthoses and shoe modifications were important elements of nonoperative treatment of foot pain and impaired gait in patients with RA.

Maintain Joint and Soft Tissue Mobility and Muscle Integrity

- **Passive, active-assistive, or active ROM.** It is important to move the joints as tolerated. If active exercises are tolerated, they are preferred because of the benefits of muscle action.
- **Aquatic therapy.** Aquatic therapy is an effective method of combining nonstressful buoyancy-assisted exercises with therapeutic heat.
- **Muscle setting.** Apply gentle multiangle muscle-setting techniques in pain-free positions and at an intensity that does not exacerbate symptoms.

Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

Examine the patient for signs of decreased muscle flexibility, joint restrictions, muscle weakness, and balance

impairments. Initiate exercises and mobilization procedures at a level appropriate for the condition of the patient.

PRECAUTIONS WITH RA: Modify the intensity of joint mobilization and stretching techniques used to counter any restrictions because the disease process and use of steroid therapy weaken the tensile quality of the connective tissue. Therefore, it is more easily torn. It may be necessary to continue joint protection with orthotics, proper fitting shoes, and assistive devices for ambulation.⁹² Encourage the patient to be active, but also to respect pain and fatigue.

Increase Joint Play and Accessory Motions

Joint mobilization techniques. Determine which articulations are restricted owing to decreased joint play, and apply grade III sustained or grade III and IV oscillation techniques to stretch the limitations. See Figures 5.55 through 5.64 and their descriptions in Chapter 5 for techniques to mobilize the leg, ankle, and foot articulations. Mobilizing the toes is the same as the fingers (see Figs. 5.42 through 5.43).

NOTE: Because weight-bearing forces and joint changes with arthritis accentuate pronation, mobilizing to increase pronation usually should not be undertaken in an arthritic foot. Perform these techniques only in the stiff foot after immobilization when the foot does not pronate sufficiently during the loading response in gait. In addition, extension of the toes at the MTP joints is important during terminal stance for normal push-off and development of the windlass effect in gait. The great toe requires from 40° to 50° extension to function effectively during this phase of gait.^{78,80}

Improve Joint Tracking of the Talocrural Joint

Apply mobilization with movement (MWM) techniques to increase ROM and/or decrease pain associated with movement.⁷² The principles of MWM are described in Chapter 5.

Plantarflexion MWM

Patient position and procedure: Supine with hip and knee flexed and heel on the table (Fig. 22.3). Stand at the foot of the table facing the patient and contact the patient's anterior tibia with the palm of your hand (for the right foot use the left hand). Produce a pain-free graded posterior glide of the tibia on the talus. The patient should now be unable to plantarflex. While maintaining the posterior tibial glide grip the talus with your other hand (for the right foot, use the right hand) and create a passive end-range plantarflexion movement, causing the talus to roll anteriorly.

The sustained plantarflexion must be painless. Repeat three to four times in sets of 6 to 10 and reassess to confirm improved range.

Dorsiflexion MWM

Patient position and procedure: The patient is standing with the affected foot placed on a chair or stool (Fig. 22.4). Kneel on the floor facing the patient with a mobilization belt around your buttocks and the patient's Achilles tendon

FIGURE 22.3 Mobilization with movement to increase ankle plantarflexion. Maintain a posterior glide of the tibia while moving the talus into planterflexion. This should not cause pain.

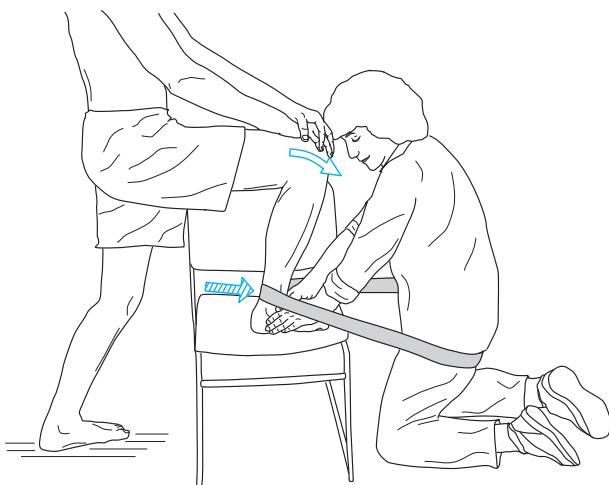

FIGURE 22.4 Mobilization with movement to increase ankle dorsiflexion. Maintain an anterior glide of the tibia with the mobilization belt while the patient lunges forward to move the ankle into dorsiflexion. This should not cause pain.

(padded with a towel). Place the web space of both hands around the neck of the talus with the palms on the dorsum of the foot. Hold the foot down and back and the subtalar joint in neutral pronation/supination. Use the belt to produce a pain-free graded anterior gliding force to the ankle joint. While maintaining this mobilization, have the patient lunge forward, bringing the affected ankle into dorsiflexion and causing painless end-range loading. Repeat in sets of 6 to 10, reassessing for effect.

Increase Mobility of Soft Tissues and Muscles

Perform passive stretching and inhibition techniques as described in Chapter 4. Self-stretching techniques are described later in this chapter.

Regain a Balance in Muscle Strength and Prepare for Functional Activities

Initiate resistive exercises at a level appropriate for the weakened muscles. Begin with isometric resistance in pain-free positions, and progress to dynamic resistance exercises through pain-free ranges using open- and closed-chain exercises. Resistive exercises are described later in this chapter. Low-load, weight-bearing exercises may be initiated in a pool or tank and progressed to full weight bearing as tolerated. Develop exercises that prepare the patient to return to functional activities.

Improve Balance and Proprioception

Initiate protected balance exercises, and progress the intensity as tolerated. Determine the level of stability and safety during ambulation and continue use of assistive devices if necessary to help prevent falls.

Develop Cardiopulmonary Fitness

Low-impact aerobic exercises should be initiated early in the treatment program and progressed as the patient is able. Repetitive exercises in a pool (water aerobics), swimming, treadmill walking, and bicycling may be within the

patient's tolerance. A person with degenerative or rheumatoid arthritis should not do high-impact (jumping, hopping, and jogging) aerobic exercises.

JOINT SURGERY AND POSTOPERATIVE MANAGEMENT

Advanced arthritis of the ankle or the joints of the foot can cause severe pain, limitation of motion, gross instability or deformity, and significant loss of function during activities that require weight bearing through the lower extremities (Fig. 22.5). When nonoperative management no longer alleviates symptoms, surgical options for early and advanced joint disease may be necessary (Box 22.2).^{6,12,14,41,47,51,105,107,111} The procedure(s) selected depends on the joints involved, the extent of articular damage, the severity of joint instability or deformity, and the postoperative functional goals of the patient.

Arthroscopic débridement of a symptomatic joint is appropriate for management of early joint changes but

A

B

FIGURE 22.5 Late-stage arthritis of the ankle. (A) Mortise view of the ankle shows severe loss of the normal joint space and partial erosion of the lateral tibia. (B) Lateral view shows tibial erosion with mild joint space loss in the subtalar region and significant osteophyte formation in the anterior ankle. (From Hasselman, CT, Wong, YS, Conti, SF: Total ankle replacement. In Kitaoka, HB (ed): Master Techniques in Orthopedic Surgery: The Foot and Ankle, ed 2. Lippincott Williams & Wilkins, Philadelphia, 2002, figure 39.1, p 583, with permission.)

BOX 22.2 Surgical Interventions for Early- and Late-Stage Ankle or Foot Arthritis and Joint Deformity
Early-Stage Procedures

- Arthroscopic débridement and cheilectomy (removal of osteophytes)
- Arthroscopic subchondral drilling, mosaicplasty, or osteochondral autologous implantation for small osteochondral lesions of the talus
- Articular distraction (widening of the joint space by means of a temporarily inserted external fixation device)
- Soft tissue reconstruction
- Synovectomy

Late-Stage Procedures

- Osteotomy
- Excision arthroplasty with or without implant
- Total joint arthroplasty
- Arthrodesis

offers little if there is significant destruction of articular cartilage.¹⁰⁵ For late-stage arthritis, arthrodesis provides pain-free weight bearing and stability of the involved joint(s) but sacrifices mobility of the operated joints, which, in turn, affects functional movement. Pain-free compensatory movements must be available in adjacent joints to absorb weight-bearing forces during ambulation. Arthrodesis typically is performed in young patients with high functional demands.^{6,12,14,47,105} Arthroplasty of the ankle^{14,36,51–53,86,105} or toes,^{14,107} an option far less frequently selected than arthrodesis, affords pain relief while retaining some degree of joint mobility. It is an alternative to arthrodesis for patients with severe joint symptoms but who are older or relatively inactive.

The anticipated outcomes of joint surgery at the ankle and foot and postoperative rehabilitation are (1) relief of pain with weight bearing and joint motion, (2) correction of deformity, (3) restoration of stability or mobility of the involved joints, and (4) improved strength and muscular endurance of the lower extremities for ambulation and functional activities.^{6,14,51,105,107} Rehabilitation includes postoperative exercise; gait training with assistive devices; fabrication of foot orthoses; and patient education including information about shoe selection, fit, and modification and appropriate choices of recreational and activities of daily living (ADLs) as well.

Total Ankle Arthroplasty

Total ankle arthroplasty (TAA) is an option for carefully selected patients with disabling pain associated with advanced, symptomatic arthritis of the talocrural joint whose only surgical alternative is ankle arthrodesis. This procedure provides pain relief while preserving functional motion of the ankle and therefore reduces stresses on adja-

cent joints more effectively than does arthrodesis. TAA is most appropriate for individuals who are relatively sedentary and do not expect to participate in high-impact recreational activities or heavy labor after surgery.^{33,51,86,105}

Indications for Surgery

Although no consensus exists at this time, the following are frequently cited current-day indications for total ankle arthroplasty.^{14,33,41,51,86,105} These indications are far less liberal than those suggested when TAA was first introduced several decades ago.

- Severe, persistent pain, particularly during weight bearing, and compromised functional mobility as the result of advanced degenerative or inflammatory joint disease including post-traumatic arthritis; OA, RA, or JRA; or avascular necrosis of the dome of the talus
- Sufficient integrity of ligaments for ankle stability
- A flexible deformity that can be passively corrected to neutral or no more than 5° or hindfoot valgus
- Appropriate for an older patient with low physical demands
- An option when both ankles are involved and bilateral ankle fusions are impractical and would dramatically restrict functional mobility, such as ascending or descending stairs or rising from a chair.

Contraindications. There are numerous contraindications to TAA.^{14,33,51,86} Patient-related contraindications include active or chronic infection of the ankle, severe osteoporosis, impaired lower extremity vascular supply, and long-term use of corticosteroids. Young (less than 50 to 60 years of age), physically active patients or obese patients are not good candidates for TAA. Contraindications specific to the ankle include avascular necrosis of a significant portion of the body of the talus, marked ankle instability, a varus or valgus deformity of the hindfoot greater than 20°, less than a 20° total arc of dorsi- and plantarflexion, and peripheral neuropathy leading to decreased sensation, significant weakness, and imbalance of ankle and foot musculature.

Procedure

Implant designs, materials, and fixation. Introduced in the 1970s, the first total ankle arthroplasty designs were two-component, metal-to-polyethylene implants held in place with cement fixation.^{108,115} Short-term results of these “first generation” implants, although quite variable, seemed to hold promise. However, the early designs proved to have limited durability because many had highly constrained tibial and talar components and did not replicate the complex biomechanical characteristics of the ankle’s articulating surfaces.¹⁰⁸ Functional ROM of the ankle also was difficult to achieve with the more constrained designs. Other early designs were unconstrained, allowing multiplanar movements but providing no ankle stability.¹¹⁵ Consequently, a high rate of complications occurred, such as loosening at the bone–cement interface and premature component wear with the constrained implants, and ankle

dislocation with the unconstrained designs, leading to unsatisfactory long-term results.^{33,41,51,86,105}

Advances in prosthetic design, beginning in the late 1980s and early 1990s, based on a more thorough understanding of the biomechanics of the ankle and foot, have incorporated sliding and rotational motions into implant systems. Because contemporary prosthetic designs more closely mimic the characteristics of a normal ankle joint, ROM available in several of these systems now approaches that of a normal ankle.¹⁰⁹ Changes in design combined with improved surgical techniques, such as better soft tissue balancing and ligament reconstruction, and the availability of new implant materials and cementless fixation have led to current-day, “second generation” TAA (Fig. 22.6). These new implant designs, which are minimally constrained or semiconstrained, completely resurface the tibial, fibular, and talar articulating surfaces using either a two- or three-component system. Contemporary TAA also requires far less resection of bone than early replacements and often employs bioingrowth fixation.^{4,33,36,51,86,89,91,105} A hydroxyapatite coating on the outer surfaces of the metal implants is used to increase the rate of bone ingrowth.⁹¹ However, cement fixation continues to be used for patients with poor bone stock.⁵⁴

With a two-component system a porous or beaded metal-backed, high-density polyethylene tibial component articulates with a metal talar component that also has a beaded outer surface.⁵² A three-component design, sometimes referred to as a mobile bearing design, employs a flat (table-top) tibial component made of metal and a metal

talar dome distally with a mobile, polyethylene bearing interposed between the two metal components.^{4,36} All of these newer designs allow at least 5° to 10° of dorsiflexion and 20° to 25° of plantarflexion, sufficient for functional activities, and a small degree of rotation of the foot on the tibia to reduce stresses on the implants.^{33,51,86,105}

Operative procedure. Although there are numerous variations of operative procedures involved in a TAA, the following represent key components.^{4,33,51,91} An anterior longitudinal incision between the tibialis anterior and extensor hallucis longus tendons is the most widely used approach for TAA. The extensor retinaculum and capsule are incised to expose the joint. The joint is débrided and osteophytes are removed. An external distraction device is used to separate the joint surfaces and facilitate bone resection. Small portions of the distal tibia and talar dome are excised, followed by preparation of the joint surfaces. In some cases, the medial and lateral malleolar recesses also are resurfaced. Trial implants are inserted, and ROM is checked to be certain that at least 5° of dorsiflexion is possible. If limited by a contracture of the gastrocnemius–soleus muscle group, a percutaneous lengthening of the Achilles tendon is performed.

Sometimes a second incision is made along the distal fibula for fusion of the tibiofibular syndesmosis with screw fixation to provide a larger surface for fixation of the tibial prosthesis.^{51,52} If there is a significant varus or valgus hindfoot deformity, a subtalar arthrodesis may also be performed.⁹¹ After the permanent implants are inserted, soft tissues are balanced and repaired. Ligament reconstruction may be necessary if there is inadequate stability of the ankle and hindfoot. After the wound is closed, a bulky compression dressing and posterior splint are placed on the foot and ankle to control joint swelling and peripheral edema.

Complications

The incidence of complications after second generation ankle replacements appears to be lower than after first generation prostheses and surgical techniques. However, because few long-term follow-up studies have been reported, the full picture is not yet available. In addition, whether current-day TAA will prove to be as successful as total hip or knee arthroplasty has yet to be determined.⁵⁰

As with all types of joint arthroplasty, postoperative infection and wound healing are always potential complications. Postoperative edema in the ankle and foot also increases the likelihood of delayed wound healing. Wound healing complications, in turn, often prolong the immobilization period, thus delaying early ankle motion and potentially leading to poor ROM outcomes.^{33,50,74} Reflex sympathetic dystrophy (complex regional pain syndrome) occasionally develops and causes chronic foot or ankle pain.⁴ (Complex regional pain syndromes and interventions are described in Chapter 13.) Intraoperative (perioperative), early postoperative, and long-term complications unique to TAA are noted in Box 22.3.^{4,33,50,74} Intraoperative and early

FIGURE 22.6 Total ankle arthroplasty. Lateral view of a total ankle replacement in a 78-year-old woman 1 year following surgery for post-traumatic arthritis. (From Joint Replacement Arthroplasty, ed 3, Morrey, BF (ed), Chapter 85: Ankle replacement arthroplasty, Kitaoka, HB, Claridge, RJ, page 1148, 2003, with permission from The Mayo Clinic Foundation.)

BOX 22.3 Complications of Total Ankle Arthroplasty
Intraoperative Complications

- Fracture of the medial or lateral malleolus during implant insertion→the necessity for fracture stabilization with internal fixation.
- Malpositioning of an implant→chronic ankle instability, subluxation, dislocation, early mechanical loosening, or premature implant wear.
- Laceration of the posterior tibialis tendon during bone resection due to its close proximity to the medial malleolus→necessity for tendon repair.
- Nerve injury, usually the superficial or deep peroneal→impaired sensory or motor function.
- Insufficient soft tissue balancing or reconstruction→chronic ankle instability or deformity.

Postoperative: Early and Long-Term Complications

- Delayed union or nonunion of a tibiofibular syndesmosis fusion→an extended immobilization and nonweight-bearing period.
- Mechanical (aseptic) loosening (most often the talar component)→pain and impaired functional mobility
- Hindfoot arthritis (most often the subtalar joint)→pain and impaired weight-bearing abilities.

postoperative complications can adversely affect rehabilitation and outcomes of ankle replacement and may necessitate revision arthroplasty or arthrodesis.

Postoperative Management

There are few guidelines in the literature for postoperative management of patients who have undergone total ankle arthroplasty. Those that are available vary considerably with regard to immobilization, initiation of exercise, and weight bearing. Although opinions often are cited, there is a lack of evidence to support whether ROM exercises should be initiated a few days postoperatively or delayed for several weeks until there is evidence of bone ingrowth into the implants. It also is unclear whether early protected motion has a positive impact on ROM outcomes or if it is detrimental to implant fixation or wound healing.⁸⁶

Therefore, the following guidelines or precautions for postoperative management are a summary of those cited by several authors based on their experience and training.^{4,33,51,74,86}

Immobilization and Weight-Bearing considerations

Immobilization. The ankle is placed in a compression dressing and immobilized in a neutral position in a well-padded, short-leg, posterior splint. The duration of continuous immobilization varies depending on the type of implant fixation used and the types of surgical procedures performed during the arthroplasty. For example, if a tibiofibular syndesmosis or subtalar fusion was performed, no motion is allowed for 6 weeks or until there is evidence of bony union.^{51,52} If there was no bony fusion, at least 3

weeks of immobilization after cementless fixation is recommended if the prosthetic implants have a hydroxyapatite coating but approximately 6 weeks for beaded implants without a coating.⁸⁶

Weight-bearing considerations. A patient must always wear an ankle immobilizer when initiating weight bearing after TAA. Recommendations for the time at which weight bearing is permissible after cementless fixation range from a maximum of 40 pounds³³ or weight bearing as tolerated⁴ immediately after surgery to nonweight bearing for 3 weeks or more.⁸⁶ If a tibiofibular syndesmosis fusion was performed, weight bearing is not permitted for at least 6 weeks.^{51,52} After a period of restricted weight bearing, patients gradually progress from partial to full weight bearing over several weeks and then gradually discontinue wearing the immobilizer.

Exercise: Maximum Protection Phase

The first phase of postoperative rehabilitation, which extends for about 6 weeks, focuses on the patient becoming functionally mobile immediately after surgery with attention to protecting the operated ankle and controlling postoperative edema. *Goals* include maintaining ROM in the joints proximal to the ankle or any other arthritic joints, improving strength in the upper and nonoperated lower extremities, and minimizing atrophy of the ankle and foot muscles of the operated limb. If removal of the immobilization is allowed during the first few weeks after surgery, an additional goal is to prevent stiffness in the operated ankle and loss of extensibility of surrounding soft tissues.

To achieve these goals, the following exercise interventions are appropriate.

- Begin isometric (muscle-setting) exercises of the ankle musculature, gluteal, and quadriceps muscles and active-resistive exercises of hip and knee musculature on the operated side.⁹³
- Strengthen the nonoperated lower extremity and upper extremities using resisted exercises in preparation for ambulation.
- Regain active ROM of the operated ankle using gentle, nonforceful motions when it is permissible to remove the immobilization and if wound healing is sufficient. Include dorsiflexion and plantarflexion, inversion, eversion, and circumduction. Perform active ROM of the toes.

Exercise: Moderate and Minimum Protection Phases

By 6 weeks it usually is permissible to remove the immobilizer for exercise and gradually discontinue its use during weight-bearing activities except in cases of poor soft tissue healing or delayed bone ingrowth or union. *Goals* during the final phases of rehabilitation are to achieve 100% of the ROM observed intraoperatively⁸⁶; restore strength, muscular endurance, and balance in the lower extremities for unrestricted weight bearing; improve aerobic capacity and cardiopulmonary endurance; and help the patient perform necessary and desired functional activities safely. Patient education is a key to safe participation in recreational and work-related activities.

The following interventions are recommended to meet these goals. Refer to the last section of this chapter for detailed descriptions, progression, and illustrations of exercises. A progression of balance activities is described in Chapter 8.

- Continue or initiate active ROM exercises of the operated ankle and foot.
- Stretch the plantarflexors, if dorsiflexion is restricted, using towel stretches in a long-sitting position, or have the patient stand on a wedge for an extended period of time.
- Perform low-intensity, high-repetition resistance exercises in nonweight-bearing and weight-bearing positions.
- Initiate a stationary cycling program and progress the speed and distance of ambulation to increase cardiopulmonary fitness and lower extremity muscular endurance. The amount of dorsiflexion required during pedaling can be adjusted by raising or lowering the seat height.
- To the extent weight bearing allows, perform a progression of bilateral and unilateral balance activities.
- Through patient education and activity modification, prepare the patient to return to functional activities. Select nonimpact or low-impact activities, and for joint protection avoid activities that involve quick stop-and-go motions.¹¹⁰

Outcomes

As discussed previously, although early total ankle arthroplasty afforded pain relief for a period of time,^{89,108,115} there were unacceptably high rates of complications, leading to poor functional outcomes and patient dissatisfaction.^{14,51,86,105,108,115} Intermediate and long-term results of second generation systems and surgical techniques used for more judiciously selected surgical candidates are becoming available and are encouraging. However, long-term success is still in question.^{33,51,86} The outcomes discussed in this section are reported for contemporary TAA. Ongoing issues leading to complications were addressed in an earlier section. It is important to note that no studies were identified that compared early or late postoperative weight-bearing conditions or exercise programs.

Pain relief, functional improvement, and patient satisfaction. A variety of quantitative assessment instruments are used to measure pain relief, postoperative function, and patient satisfaction. Descriptors of outcomes, from “excellent” to “poor,” are based on data from these scales. The Ankle Osteoarthritis Scale and the American Orthopedic Foot and Ankle Society questionnaire are two examples.

There is evidence from prospective studies to suggest that the survival rates of implants are similar for patients with OA (primary or post-traumatic arthritis) and RA at a median follow-up of 14 years⁵⁴ and for patients older or younger than 50 years of age at a median follow-up of 6 years.⁵³ Survival rates (the percentage of prostheses not requiring removal) in the former study were 72.7% and 75.5% respectively in the patients with

OA and RA and in the latter study were 75% and 80.6% respectively in the younger and older patients.

Outcomes for a frequently used second generation, two-component system and more recently developed three-component (mobile-bearing) designs have been reported but not directly compared. Knecht⁵² reported positive outcomes (reduced pain and increased function) in 66 patients who had undergone a two-component ankle replacement a mean of 9 years earlier. The mean total arc of dorsi- and plantarflexion, measured in 33 patients, was 18°.

Buechel and colleagues⁴ followed 50 patients (mean age 49 years), who had undergone three-component, mobile-bearing, cementless TAA, and reported 48% excellent and 40% good results at a mean follow-up of 5 years (range 2 to 10 years). Of the 50 patients in the study, 26% reported no pain, 60% reported slight or mild pain, and 14% reported moderate or severe pain that interfered with functional activities. The mean total arc of dorsi- and plantarflexion was 28°. In a short-term follow-up study of 116 patients who had a different mobile-bearing prosthesis implanted in 122 ankles, 84% of patients were satisfied, with 82% reporting good or excellent results at an average of 19.9 months.³⁶ The mean total arc of ankle dorsi- and plantarflexion was 39°. Although postoperative gains in ROM reported in these studies were small (often as little as 5° to 10°), gains of even a few degrees have been reported to improve functional mobility.⁸⁶

Measurements of pain, ROM, general level of function, patient satisfaction, and postoperative complications are outcomes most often reported in follow-up studies. However, Valderrabano and co-investigators¹¹⁰ recently reported sport and recreational activities in which 147 patients (mean age 59.6 years, range 28 to 86 years) participated before and after TAA. Of these patients, 89% had a preoperative diagnosis of post-traumatic arthritis or primary OA and only 11% had a diagnosis of RA; 83% reported excellent or good results and 69% were pain-free postoperatively. Prior to surgery, 36% of patients were active in sports/recreational activities, and 56% were active after surgery. This change reflected an increase in the activity level of the patients with post-traumatic arthritis and primary OA, not of the patients with RA. The most frequently reported preoperative activities (in descending order) were cycling, swimming, hiking, and low-impact aerobics. After surgery, hiking was most frequently reported, followed by cycling, swimming, and aerobics. The only significant change before and after surgery was for hiking (from 25.5% to 52.8%). The authors recommended that before initiating any sport activity after ankle replacement, a patient should complete postoperative rehabilitation and be free of complications.

Arthrodesis at the Ankle and Foot

Arthrodesis is the most frequently used surgery for late-stage arthritis of the ankle or one or more of the joints of

the foot and toes. It typically is the procedure of choice for relatively young, active patients with post-traumatic arthritis and gross instability of the ankle and hindfoot.¹⁰⁵ Arthrodesis also is an option for patients with hindfoot or forefoot involvement as the result of RA or JRA.^{6,14} Deformities of the forefoot, such as hallux valgus or hallux rigidus, and severe deterioration of the MTP joint of the first toe also are managed with arthrodesis.^{1,6,14,17}

Indications for Surgery

The following are frequent indications for surgical fusion of selected joints of the ankle and foot.^{1,6,14,47,95,105}

- Debilitating pain, particularly during weight bearing, and severe articular degeneration secondary to post-traumatic arthritis, OA, RA, infection, or other inflammatory arthropathies
- Marked instability of one or more joints
- Deformity of the toes, foot, or ankle associated with chronic joint malalignment as the result of congenital anomalies, neuromuscular disorders, or arthritis
- Patients with high functional demands and pain-free compensatory movements in adjacent joints
- A salvage procedure after failed total ankle arthroplasty

Procedures

There are many types of arthrodesis; however, all involve the use of bone grafts coupled with internal fixation devices (see Fig. 12.2) or occasionally external skeletal fixation for bony ankylosis. Internal fixation can be achieved via multiple compression screws, pins, an intramedullary nail, or a plate. The type of fixation selected depends on the joints involved and types of deformity. For correction of severe deformity or tendon rupture, concomitant soft tissue procedures are required.

Arthrodesis at the ankle or foot almost always is performed through an open approach. Over the past decade, however, arthroscopic or arthroscopically assisted arthrodesis of the ankle has become an option for patients with severe pain at the tibiotalar joint but without significant fixed deformity.^{7,77,79,90,102} Specifically, an arthroscopic approach cannot be used if a varus or valgus deformity is greater than 5° to 10°.¹⁰² The most consistently suggested benefit of an arthroscopic approach is a reduced rate of wound healing complications because of less disruption of soft tissues during surgery.^{90,105}

There have been reports of a more rapid rate of fusion with an arthroscopic approach compared with an open approach. However, this potential benefit is based largely on data from nonrandomized, retrospective studies and therefore cannot yet be substantiated.^{77,79,102,105}

Common Types of Arthrodesis

Arthrodesis of the ankle. When the tibiotalar joint is fused, it is positioned in 0° of dorsiflexion, 5° of hindfoot valgus, and 5° to 10° of external rotation of the foot on the tibia to match the rotation of the opposite lower extremity.^{12,47,95,105} Although ankle arthrodesis provides pain relief and ankle stability, dorsiflexion and plantarflexion are lost, conse-

quently altering the biomechanics and speed of gait and increasing energy expenditure during ambulation.¹⁰⁵ Over time the hindfoot and forefoot compensate to a great extent for the loss of motion at the ankle. Nevertheless, an asymmetrical gait pattern is detectable in most patients after ankle arthrodesis.¹²

NOTE: For patients with RA involving both ankles, bilateral arthrodesis is rarely performed, because loss of dorsiflexion bilaterally makes it difficult to get up from a chair or to ascend or descend stairs.

Arthrodesis of the hindfoot. Severe instability or chronic malalignment and deformity of the hindfoot, such as pes valgus or pes planus, and pain as the result of advanced hindfoot arthritis may require a triple arthrodesis or a single-joint fusion, such as talonavicular or talocalcaneal (subtalar) arthrodesis. A triple arthrodesis, often indicated for a rigid hindfoot deformity, involves fusion of the talocalcaneal, talonavicular, and calcaneocuboid joints.⁶⁶ A single-joint fusion, such as a talonavicular arthrodesis, may be sufficient to correct a chronic but flexible hindfoot deformity.^{23,49,87} In most instances the hindfoot is positioned in 5° of valgus in each of these fusions.

Talonavicular, subtalar, or triple arthrodesis provides permanent medial-lateral stability and relief of pain in the hindfoot, but pronation and supination of the ankle are eliminated or substantially diminished. It is interesting to note that fusion of the talonavicular joint alone indirectly reduces motion at the subtalar and calcaneocuboid joints, thus providing added frontal plane stability without fusing additional joints.^{23,87}

Arthrodesis of the first toe. Fusion of the first MTP joint for hallux rigidus and hallux valgus provides relief of pain, most notably during ambulation.^{1,17,41} The position of fusion is neutral rotation, 10° to 15° of valgus, 15° to 30° of MTP extension. This allows adequate push-off during ambulation but also enables a patient to wear some types of commercially available shoes.^{14,17,41} If the lateral MTP joints also are involved, fusion of the great toe is performed after, not before, excision or implant arthroplasty of the lateral joints.^{6,14,107}

Arthrodesis of the IP joints of the toes. Fusion of the IP joints of the toes in a neutral position for hammer toes, usually occurring in the second and third toes, provides relief of pain for ambulation and correction of deformities of the toes to improve shoe fit.⁴¹

Complications

The overall rate of complications associated with arthrodesis is relatively low but varies with patient population, the joints involved, and surgical techniques.¹⁰⁵ The most common complication is nonunion, occurring in up to 10% of arthrodesis procedures.^{87,105} The smaller the area of the bony surfaces and the poorer their vascular supply, the higher the rate of nonunion. Factors that contribute to nonunion include postoperative infection, malalignment of the fused joint, and a patient's use of tobacco before

and after surgery.^{49,66} Delayed wound healing is a particular problem in patients with poor vascularity of the foot and ankle. Furthermore, nerve damage can occur during surgery or a neuroma can develop postoperatively, causing pain and limiting function. Occasionally a stress fracture of one of the fused bones or adjacent bones occurs.

Postoperative Management

Immobilization. The method and duration of immobilization of the fused joints are determined by the surgeon based on the site of the fusion, the type of fixation used, the quality of fixation achieved, the patient's bone quality, and the presence of factors that affect bone healing, such as systemic inflammatory disease and preoperative use of corticosteroids.

At the close of surgery, a compression dressing and splint are applied and worn for 48 to 72 hours for edema control. For an ankle or hindfoot arthrodesis, after the compression dressing has been removed, a short-leg cast is applied for an extended period of time, usually 4 to 8 weeks. During the first 6 weeks, frequent cast changes are necessary as swelling subsides. A short-leg walking cast or rigid boot is applied at about 4 to 8 weeks, and immobilization continues for an additional 4 to 6 weeks.^{23,49,66,79,87,95} After arthrodesis of the first MTP joint, a short-leg cast or surgical shoe with a flat, rigid sole is worn to protect the joint as it heals.^{1,17}

When there is evidence of fusion, the patient is weaned from the immobilizer over several weeks. After splint use is discontinued, the patient should be advised of proper shoe selection, modification, and fit. The use of custom-made foot orthoses may be necessary for support, relief of pressure, or shock absorption.¹⁴

Weight-bearing considerations. As with postoperative immobilization, published guidelines for the timing and extent of weight bearing permissible after arthrodesis vary considerably. The same considerations that influence decisions about immobilization also influence the progression of postoperative weight bearing on the operated extremity. The most prevalent practice is to substantially restrict weight bearing for many weeks after open or arthroscopic arthrodesis. Typically, patients must ambulate with crutches or a walker and are not allowed to bear weight on the operated side for 4 to 8 weeks.^{1,49,66,79,87,95,102} When there is radiographic evidence of bony healing, partial weight bearing is permitted while the patient wears a rigid short-leg boot or shoe. Full weight bearing without wearing an immobilizer usually is permitted by 12 to 16 weeks postoperatively.

In an effort to reduce recovery time and improve a patient's quality of life during recovery, the safety of early weight bearing is being investigated. To date, most studies have assessed the effects of early weight bearing only after arthroscopic ankle arthrodesis. In selected patient populations, early results are encouraging. However, randomized, prospective studies have not been done yet.

Focus on Evidence

Cannon and co-investigators⁷ conducted a nonrandomized, retrospective study of two comparable groups of patients who had undergone arthroscopic ankle arthrodesis. One group ($N = 16$; mean age 48) wore a short-leg cast and was not permitted to bear weight on the operated limb for 8 weeks. In contrast, the other group ($N = 23$; mean age 51) was encouraged to bear as much weight as was comfortable on the operated limb within the first few days after surgery while wearing a rigid boot that immobilized the ankle and foot.

At 8 weeks, all patients in both groups had radiographic evidence of bony union, and by 4 months all had achieved ankle fusion. There were no significant differences between groups in the rate of postoperative complications. The investigators concluded that an early weight-bearing regimen is safe after arthroscopic ankle arthrodesis provided the ankle is protected in a rigid splint. However, the investigators pointed out that early weight bearing after arthrodesis is not appropriate for patients with reduced sensation in the foot and ankle.

Postoperative exercises. Initially, postoperative exercises focus on ROM of the unoperated joints proximal or distal to the joints that are immobilized. If the patient is wearing a removable splint, ROM exercises of the unoperated joints confined by the immobilizer may be permissible early in the rehabilitation program as well.⁷ For example, after ankle or hindfoot arthrodesis, exercises to maintain toe mobility are indicated in addition to knee ROM. For a patient with RA, active ROM is essential in all involved joints not controlled by the immobilization device.

When bony fusion has occurred and use of the immobilizer has been discontinued, often there are signs of postimmobilization muscle weakness, hypomobility of joints adjacent to the arthrodesis, and impaired balance. In such instances, exercises described previously in this chapter for nonoperative management of chronic joint hypomobility are appropriate.

Outcomes

Short-term outcomes. When healing is complete after arthrodesis, pain relief and joint stability are predictable outcomes, resulting in improved functional mobility. Recent reports indicate that fusion is achieved greater than 90% of the time but varies with the number and location of joint(s) fused, the extent of preoperative deformity, and the underlying pathology.

Long-term outcomes. Although arthrodesis provides pain relief in the fused joint(s), it also imposes increased stresses on contiguous joints. Consequently, there are long-term adverse outcomes after arthrodesis. For example, Coester and colleagues¹² carried out a long-term follow-up study of 23 patients who had undergone isolated ankle arthrodesis for post-traumatic arthritis a mean of 22 years earlier. They found a substantial increase in

arthritis in the joints distal but not proximal to the fused tibiotalar joint compared with the same joints of the contralateral lower limb. In addition, ipsilateral foot pain interfered with the functional mobility of almost all patients, based on information from standardized, self-report functional assessment instruments.

OVERUSE (REPETITIVE TRAUMA) SYNDROMES: NONOPERATIVE MANAGEMENT

An overuse syndrome is a local inflammatory response to stresses from repetitive microtrauma, which may be from faulty alignment in the lower extremity, muscle imbalances or fatigue, changes in exercise or functional routines, training errors, improper footwear for the ground or functional demands placed on the feet, or a combination of several of these factors.²⁹ The syndrome occurs because continued demand is placed on the tissue before it has adequately healed, so the pain and inflammation continue. A common cause predisposing the foot to overuse syndromes is abnormal pronation of the subtalar joint. The abnormal pronation could be related to a variety of causes including excessive joint mobility, leg-length discrepancy, femoral anteversion, external tibial torsion, genu valgum, or muscle flexibility and strength imbalances.

Related Pathologies and Etiology of Symptoms

The extrinsic foot musculature may develop symptoms either at or near its proximal attachment in the leg (shin splints), or where coursing around bony prominences in the ankle, or at its distal attachment in the foot (tendinitis/tenosynovitis). Symptoms occur at the site of inflammation when the muscle is stressed. Symptoms may also develop in the intrinsic muscles as well as the plantar fascia (plantar fasciitis). Several common syndromes are described in this section; the principles of management may be used for any overuse syndrome.

Tendinitis and Tenosynovitis

Any of the tendons of the extrinsic muscles of the foot may become irritated as they approach and cross over the ankle or where they attach in the foot. Pain occurs during or after repetitive activity. When the foot and ankle are tested, pain is experienced at the site of the lesion as resistance is applied to the muscle action and also when the involved tendon is placed on a stretch or palpated.^{9,29,73} A common site for symptoms is proximal to the calcaneus in the Achilles tendon or its sheath (*Achilles tendinitis* or *peritendinitis*). Symptoms may develop when the person switches from high-heeled to low-heeled shoes and then does a lot of walking.^{29,58,60,83} Symptoms in the anterior or posterior tibialis tendons, or peroneus tendons, are also associated

with athletic activities such as running, tennis, and basketball.⁷³ Usually there is a hypomobile gastrocnemius–soleus complex and abnormal foot pronation.

Plantar Fasciitis

Pain is usually experienced along the plantar aspect of the heel where the plantar fascia inserts on the medial tubercle of the calcaneus. The site of the injury is very tender to palpation. Excessive pronation of the subtalar joint, which may be reinforced by hypomobile gastrocnemius–soleus muscles, predisposes the foot to abnormal forces and irritation of the plantar fascia. Conversely, stress forces on the fascia can also occur with an excessively high arch (cavus foot). Pressure transmitted to the irritated site with weight bearing or stretch forces to the fascia, as when extending the toes during push-off, causes pain.

A heel spur may develop at the site of irritation on the calcaneus causing pain whenever the heel is on the ground. The individual usually avoids heel-strike during the loading response of gait.

Shin Splints

This term is used to describe activity-induced leg pain along the posterior medial or anterior lateral aspects of the proximal two-thirds of the tibia. It may include different pathological conditions such as musculotendinitis, stress fractures of the tibia, periostitis, increased pressure in a muscular compartment, or irritation of the interosseous membrane.

Anterior shin splints. Most common is overuse of the anterior tibialis muscle. A hypomobile gastrocnemius–soleus complex and a weak anterior tibialis muscle, as well as foot pronation, are associated with anterior shin splints. Pain increases with active dorsiflexion and when the muscle is stretched into plantarflexion.

Posterior shin splints. A tight gastrocnemius–soleus complex and a weak or inflamed posterior tibialis muscle, along with foot pronation, are associated with posterior medial shin splints. Pain is experienced when the foot is passively dorsiflexed with eversion and with active supination. Muscle fatigue with vigorous exercise, such as running or aerobic dancing, may precipitate the problem.

Common Impairments and Functional Limitations/Disabilities

- Pain with repetitive activity, on palpation of the involved site, when the involved musculotendinous unit is stretched, and with resistance to the involved muscle
- Pain with weight-bearing activities and gait
- Muscle length–strength imbalances, especially tight gastrocnemius–soleus muscle group
- Abnormal foot posture (may be from faulty footwear)
- Functional limitations resulting from the impairments include decreased length of time the individual can stand, decreased distance or speed of ambulation, and restriction of sport or recreational activities

Overuse Syndromes: Management—Protection Phase

While tissues are inflamed, leg or foot symptoms should be treated as an acute condition, with rest and appropriate modalities (see Chapter 10 for general principles and guidelines). Immobilization in a cast or splint with the foot slightly plantarflexed or a heel lift inside the shoe may be used to relieve stress.^{60,83}

- Apply cross-friction massage to the site of the lesion.
- Initiate gentle muscle-setting contractions or electrical stimulation to the involved muscle in pain-free positions.
- Teach active ROM within the pain-free ranges.
- Instruct the patient to avoid the activity that provokes the pain.
- Use supportive taping to provide relief of symptoms.⁴⁰

Overuse Syndromes: Management—Controlled Motion and Return to Function Phases

When symptoms become subacute, the entire lower extremity as well as the foot should be examined for abnormal alignment or muscle flexibility and strength imbalances. Eliminating or modifying the cause is important to prevent recurrences. Orthotic devices may be necessary to correct alignment.^{19,60,62,83} Therapeutic exercises may be helpful to increase flexibility, and, in general, improve muscle performance. Detailed descriptions of stretching and strengthening exercises for the ankle and foot are in the last section of this chapter.

Educate the Patient and Provide Home Exercises

- Help the patient incorporate home exercises within his or her daily routine.
- With plantar fasciitis the patient experiences the greatest pain when first bearing weight, especially in the morning and after prolonged sitting. Teach the patient to do ROM exercises (especially dorsiflexion) or alphabet writing with the foot for several minutes before standing.
- Teach prevention, including the following principles:
 - Before intense exercise, use gentle repetitive warm-up activities followed by stretching of tight muscles.
 - Use proper foot support for the ground conditions (this cannot be overemphasized).
 - Allow time for recovery from microtrauma after high-intensity workouts

Stretch Range-Limiting Structures

- The gastrocnemius–soleus muscle complex is frequently hypomobile in cases of foot problems and should be stretched. Restricted mobility causes the foot to pronate when the ankle dorsiflexes.
- With plantar fasciitis and heel spurs, apply deep massage and stretching exercises to the plantar fascia.

Improve Muscle Performance

- Begin with resistive isometric and progress to resistive dynamic (including isokinetic) exercises to the foot and ankle in open- and closed-chain activities. Develop a balance in strength between the muscle groups, especially the invertors and evertors, for medial and lateral support.
- With plantar fasciitis, the intrinsic muscles need to be strengthened. Include exercises that require toe control such as scrunching tissue paper or a towel and picking up marbles and other small objects with the toes.
- In addition to general strengthening of the extrinsic and intrinsic muscles of the foot, place emphasis on muscular endurance, and train the muscles to respond to eccentric loading.

LIGAMENTOUS INJURIES: NONOPERATIVE MANAGEMENT

After trauma, the ligaments of the ankle may be stressed or torn. First- and second-degree (grades 1 and 2) sprains are usually treated conservatively. The most common type of ankle sprain is caused by an *inversion stress* and can result in a partial or complete tear of the anterior talofibular (ATF) ligament and often the calcaneofibular (CF) ligament.^{38,85} The posterior talofibular (PTF) ligament, the strongest of the lateral ligaments, is torn only with *massive* inversion stresses. If the inferior tibiofibular ligaments are torn after stress to the ankle, the mortise becomes unstable. Rarely do the components of the deltoid ligament become stressed; there is greater likelihood of an avulsion from or fracture of the medial malleolus with an eversion stress. Depending on the severity of injury, the joint capsule may also be involved, and intra-articular pathology, including articular cartilage lesions, may also occur,⁵⁵ resulting in symptoms of acute (traumatic) arthritis.

Common Impairments and Functional Limitations/Disabilities

- Pain when the injured tissue is stressed in mild to moderate injuries
- Excessive motion or instability of the related joint in the case of complete tears
- Proprioceptive deficit manifested as decreased ability to perceive passive motion and development of balance impairments²⁵
- Related joint symptoms and reflex muscle inhibition
- Possible decreased ROM in the talocrural joint in recurrent lateral ankle sprains due to anterior subluxation and impaired tracking of the talus in the mortise.¹¹³
- Functional limitations resulting from the impairments include restricted ambulation (requiring assistance) during the acute and subacute phases. With chronic instability the individual may have difficulty walking or running on uneven surfaces or making quick changes in direc-

tion, may not be able to land safely when jumping, or may fall more frequently.

Management: Protection Phase

See Chapter 10 for principles of treatment during stages of inflammation and repair.

- If possible, examine the ankle before joint effusion occurs. To minimize the swelling, use compression, elevation, and ice. The ankle should be immobilized in neutral or in slight dorsiflexion and eversion.
- Use gentle joint mobilization techniques to maintain mobility and inhibit pain.
- Educate the patient.
 - Teach the patient the importance of RICE (rest, ice, compression, and elevation) and to apply the ice every 2 hours during the first 24 to 48 hours.
 - Teach partial weight bearing with crutches to decrease the stress of ambulation.²⁷
 - Teach muscle-setting techniques and active toe curls to help maintain muscle integrity and assist with circulation.

Focus on Evidence

Green and associates²⁸ studied 38 individuals following acute ankle sprain (within 72 hours of injury and requiring partial weight bearing). All subjects received RICE intervention. Those randomly assigned to the experimental group ($N = 19$) also received gentle anterior-posterior (AP) joint mobilization techniques to the talocrural joint with the foot positioned in dorsiflexion. Range of pain-free ankle dorsiflexion, gait speed, step length, and single support time were measured. The majority of those in the experimental group were discharged after fewer treatments (13/19 subjects by the fourth treatment), having gained full range of dorsiflexion, whereas only three subjects in the control group met this criterion and required additional treatment. Also, subjects in the experimental group demonstrated improved stride speed compared to the control group.

Management: Controlled Motion Phase

- As the acute symptoms subside, continue to provide protection for the involved ligament with a splint during weight bearing. Fabricating a stirrup out of thermoplastic material and holding it in place with an elastic wrap or Velcro straps provides stability to the joint structures while allowing for the stimulus of weight bearing for proprioceptive feedback and proper healing. Commercial splints such as an air splint are also available to provide medial-lateral stability while allowing dorsiflexion and plantarflexion.^{30,48}
- Apply cross-fiber massage to the ligaments as tolerated.
- Use grade II joint mobilization techniques to maintain mobility of the joint.
- Teach the patient exercises to be done within tissue tolerance at least three times per day. Suggestions include:

- Nonweight-bearing AROM into dorsiflexion and plantarflexion, inversion and eversion, toe curls and writing the alphabet in the air with the foot.
- Sitting with the heel on floor and scrunching paper or a towel and picking up marbles with the toes.
- If adhesions are developing in the healing ligament, have the patient actively move the foot in the direction opposite the line of pull of the ligament. For the anterior talofibular ligament, the motion is plantarflexion and inversion. Also stretch the gastrocnemius-soleus muscle group for adequate dorsiflexion. Progress to weight-bearing stretches when the patient's recovery allows.
- As swelling decreases and weight-bearing tolerance increases, progress to strengthening, endurance, and stabilization exercises; include isometric resistance to the peroneals, bicycle ergometry, and partial to full weight-bearing balance board exercises. Have the patient wear a brace or splint that restricts end-range motion to control the range and prevent excessive stress on the healing ligament.²⁷

Management: Return to Function Phase

- Progress strengthening exercises by adding elastic resistance to foot movements in long-sitting (open-chain) and sitting with the heel on the floor for partial weight bearing. Use isokinetic resistance if a unit is available.
- Progress stabilization and proprioceptive/balance training for ankle stability, coordination, and reflex response with full weight-bearing activities on a rocker, wobble, or BAPS board.^{26,84,116} Depending on the final goals of rehabilitation, train the ankle with weight-bearing activities such as walking, jogging, and running and with agility activities such as controlled twisting, turning, and lateral weight shifting.
- When the patient is involved in sports activities, the ankle should be splinted, taped, or wrapped, and proper shoes should be worn to protect the ligament from reinjury.¹⁷

Focus on Evidence

Twenty-five individuals with post-acute (3 to 4 weeks) lateral ankle sprain (unilateral grade I or II), who exhibited postural sway instability in their sprained ankle (modified Rhomberg Test), were tested under two conditions (with a commercial air splint and nonbraced control) with two dependent variables (shuttle-run and vertical-jump). The tests were repeated after 5 to 7 days of wearing the splint during ADLs to determine if acclimation to the brace affected performance. Results demonstrated immediate performance enhancement while wearing the air splint for the shuttle-run test (mean 9.43 ± 0.72 seconds) compared with the nonbraced condition (mean 9.57 ± 0.75 seconds) in sessions 1 and 2, demonstrating that an acclimation period was not necessary for the stabilizing benefit. The vertical jump did not show improvement when the splint was worn.³⁰

TRAUMATIC SOFT TISSUE INJURIES: SURGICAL AND POSTOPERATIVE MANAGEMENT

Repair of Complete Lateral Ligament Tears

A third-degree (grade 3) sprain of the lateral ankle, which usually occurs as the result of a severe inversion injury, causes a complete tear or rupture of the anterior talofibular (ATF) ligament, often the calcaneofibular (CF) ligament, and only occasionally the posterior tibiofibular (PTF) ligament (Fig. 22.7).^{24,99} When the ATF and CF ligaments are both torn, it leads to combined instability of the tibiotalar and subtalar joints. The ATF ligament is most likely to tear when forceful inversion occurs while the ankle is plantarflexed.¹⁰¹ Associated injuries that occur include a transverse fracture of the lateral malleolus or an avulsion fracture of the base of the fifth metatarsal.^{24,73,85}

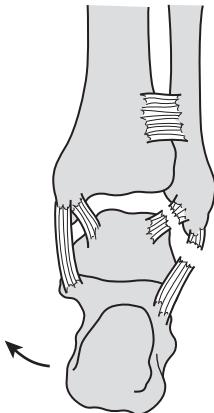

FIGURE 22.7 A complete tear of the lateral collateral ligament complex as the result of a severe (grade 3) inversion injury of the ankle. (From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed 2. FA Davis, Philadelphia, 2005, p 389, with permission.)

In addition to significant pain, swelling, and tenderness, a complete tear of one or more lateral ligaments causes marked mechanical instability and functional instability of the ankle during weight-bearing activities. Mechanical instability is defined as ankle mobility beyond the physiological ROM, increased talar tilt, and an anterior drawer sign. Functional instability is characterized by the sensation of the ankle “giving way” experienced by the patient.¹⁰³ As many as 20% of patients without evidence of mechanical instability complain of the ankle “giving way” after a severe lateral ankle sprain, thus significantly impairing functional activities.¹³

After an acute, grade 3 inversion injury, nonoperative treatment is successful for most patients. However, some patients sustain recurrent inversion injuries after the acute injury has healed and develop chronic, symptomatic instability. For patients with demonstrated mechanical instability who do not respond to nonoperative management and

for selected patients with acute lateral ankle injuries who regularly engage in high-impact activities, surgical repair or reconstruction may be required to manage the instability and return the patient to a desired level of function.^{13,24,81} The goal of surgery and postoperative management is to restore joint stability while retaining pain-free, functional ROM of the ankle and subtalar joints.^{13,24,31,32,85,96,99}

Indications for Surgery

The following are frequently cited indications for surgical repair or reconstruction of the soft tissues of the lateral aspect of the ankle.^{24,31,32,81,96,99}

- Chronic mechanical and functional instability of the ankle during activity, which remains unresolved after conservative management.
- Acute, third-degree lateral ankle sprain resulting in a complete tear of the ATF and/or CF ligaments.

Procedures

Types of Procedures

There are numerous surgical procedures that may be used for repair and reconstruction of the lateral ligaments and associated structures of the ankle.^{24,39,81,99} Arthroscopy, for the most part, is reserved for preoperative examination to assist the surgeon in identifying pathologies associated with ankle instability that may not be readily evident through physical examination or during surgery.⁸ The various repair and reconstruction procedures are performed almost exclusively through an open approach. However, arthroscopic repair of ATF ligament tears by means of staples or bone anchors has been reported.⁹⁸

Open procedures may be classified into two broad categories: those that primarily involve a direct (anatomic) repair of the torn or attenuated (overstretched) ligaments and those that involve tenodesis (tendon graft and transposition) to reconstruct the lateral ankle complex and augment joint stability.⁵⁷ Recently an arthroscopic, thermally assisted capsular shift has been introduced as an alternative to open repair for selected patients.³⁹

The type of procedure selected depends on the severity and chronicity of the instability, the presence of comorbidities, the age of the patient, and the patient's anticipated postoperative activity level. Some procedures are used predominantly for a primary repair, whereas others are reserved for revision surgery.

Direct repair. The surgery used most commonly for a primary repair is an open procedure called the *modified Bröstrom procedure*, also known as the *Bröstrom-Gould procedure*.^{31,32,35} This procedure involves an anatomic repair with direct suturing of the torn ATF and CF ligament ends, imbrication (plication) of lax ligaments to tighten the ligament and provide a double layer of reinforcement, or reinsertion of an avulsed ligament to bone. The lateral aspect of the ankle is reinforced by pulling the lateral portion of the extensor retinaculum proximally over the repaired structures and suturing it to the anterior aspect of the distal fibula. The advantages of the modified Bröstrom

procedure are that it provides stability (without the need to harvest a soft tissue graft) while retaining full ROM of the tibiotalar and subtalar joints, an outcome particularly important to individuals who wish to return to activities that require full ankle mobility, such as gymnastics and ballet.

Reconstruction with augmentation. The other broad grouping of procedures are those that use a tenodesis, usually a tendon autograft and transposition of the peroneus brevis tendon, to reconstruct the lateral ankle complex with or without ligament repair. Examples include various modifications of the *Evans*, *Chrisman-Snook*, and *Watson-Jones* procedures.^{13,24,35,81,96,99} These procedures all provide additional reinforcement to the joint to augment stability but sacrifice a portion of the ankle evertors and often limit the range of inversion available after surgery.⁵⁷ To maintain the integrity of the peroneal tendons, a bone–patellar tendon graft has been proposed as an alternative to a peroneal tendon autograft.¹⁰⁴ These procedures typically are used as revision procedures when previous direct repair has failed to prevent recurrence of lateral instability. Reconstruction with augmentation is used occasionally during a primary repair for large patients, specifically those weighing more than 200 to 250 pounds.³¹

Arthroscopic thermally assisted capsular shift. Similar to its use for glenohumeral joint instability, arthroscopic, thermally assisted capsular shift (capsulorrhaphy) is a relatively new type of repair for the unstable ankle. The procedure shrinks and tightens attenuated lateral ligaments and joint capsule by means of radiofrequency or laser energy for the purpose of improving joint stability. The long-term success of this procedure at the ankle has not yet been determined. (Refer to Chapters 12 and 17 for additional discussions of thermally assisted capsular shift.)

Operative Overview

Prior to an open repair or reconstruction for lateral ankle instability, arthroscopy is performed to assess the extent of intra-articular pathology, because a high percentage (93%) of patients with complete tears of one or more lateral ligaments also exhibit associated joint pathology, including articular cartilage lesions.⁵⁵ After arthroscopy, an oblique or vertical incision is made beginning at the anterior aspect of the distal fibula and extending distally along the lateral aspect of the ankle and foot. Torn or ruptured structures are identified, repaired, and reinforced with the extensor retinaculum.

If a peroneus brevis tendon graft is to be used to reinforce the ankle, the tendon is split longitudinally. One-half of the tendon is harvested by detaching it proximally at its musculotendinous junction and weaving it through drill holes in the fibula, talus, and/or calcaneus. Then it is doubled back and sutured to itself.

Prior to wound closure, the stability and ROM of the ankle are checked. The foot and ankle are placed in a compression dressing and well-padded, short-leg, posterior splint with the ankle in 0° of dorsiflexion and slight eversion. The leg is elevated for control of joint swelling and peripheral edema.

Postoperative Management

In the past decade there has been a trend to allow early postoperative weight bearing while the ankle is immobilized, and in selected patients, early but protected ROM after lateral ligament reconstruction. The exercise progression after surgery is similar to that used for nonoperative management of lateral ankle sprains. Postoperative management is geared toward not only returning a patient to a pre-injury level of function, but also toward preventing re-injury.

Immobilization and Weight-Bearing Considerations

Immobilization. After some degree of swelling has subsided, usually within 3 to 5 postoperative days or as late as a week to 10 days, the compression dressing is removed and a short-leg walking cast is applied that immobilizes the ankle in a neutral position. If a short-leg cast is used initially, it may be removed at 4 to 6 weeks and replaced with an air-stirrup type splint,³¹ a removable cast-boot, or a controlled active motion (CAM) walking brace, worn for several additional weeks.^{24,73,101,103}

By 8 to 12 weeks the patient gradually discontinues use of the immobilizer during ambulation. However, patients returning to athletic activities that involve jumping, running, and quick changes of direction are advised to wear a protective orthotic device or to tape the ankle for at least 3 to 6 months or even indefinitely to prevent re-injury.

Weight-bearing considerations. Immediately after surgery the patient must remain nonweight bearing on the operated extremity while the ankle is in the compression dressing and posterior splint. When the compression dressing is removed and the short-leg walking cast applied, protected weight bearing is initiated and gradually progressed to full weight bearing by 6 weeks.^{24,31,101,103}

NOTE: After an arthroscopic thermally assisted capsular shift, the nonweight-bearing period is longer than after an open repair, usually extending for 5 to 6 weeks.³⁹

Exercise: Maximum Protection Phase

The primary goal of the first phase of rehabilitation, which extends for 4 to 6 weeks, is to regain independent mobility for functional activities while protecting the repaired or reconstructed lateral ankle structures. Ambulation with crutches, nonweight bearing on the operated extremity, is initiated directly after surgery. Elevation of the operated foot is essential when the patient is resting to control peripheral edema and reduce pain. ROM of the operated ankle is not permitted during this period. The following treatment goals and exercises are appropriate during the first postoperative phase.

Maintain strength of nonimmobilized muscle groups.

Perform active or gentle resisted exercises of the hip and knee of the operated lower extremity and resistance exercises of the upper extremities and sound lower extremity. If the immobilizer, such as a splint or boot, allows a small degree of dorsi- and plantarflexion, perform mini-squats in bilateral stance when partial weight bearing is permissible.

Prevent reflex inhibition of immobilized muscle groups.

While the ankle is immobilized, begin gentle, pain-free muscle-setting exercises of the ankle musculature including isometric contractions of the peroneal muscles.

Exercise: Moderate and Minimum Protection Phases

By 4 to 6 weeks postoperatively only moderate protection of healing structures is necessary as joint symptoms subside. Most patients are allowed to bear full weight on the operated extremity by 6 weeks. The goals of the intermediate and final phases of rehabilitation are to restore full ROM and strength of the operated ankle and to improve balance reactions, and neuromuscular control and reaction times in the operated extremity. All activities are directed toward enabling the patient to return to functional activities safely and preventing recurrence of ankle injuries.^{21,73,96,101,103}

With proper precautions a return to functional activities, including selected sports, may be possible by 3 to 4 months postoperatively^{31,103} or when peroneal muscle strength is normal (compared to the contralateral ankle) and when multiple, pain-free single-leg hops on the operated lower extremity are possible.¹⁰¹

The following exercises and activities are appropriate at this stage to achieve the stated goals.

Restore ROM. Begin with pain-free, assisted or active dorsiflexion and plantarflexion of the operated ankle as soon as the immobilizer may be removed for exercise as determined by the surgeon, usually by 4 to 6 weeks postoperatively. Postpone inversion and supination movements until 6 to 8 weeks postoperatively. Progress to multiplanar motions such as figure-of-eight movements.

- If joint restriction limits dorsi- or plantarflexion, perform grade II or III joint mobilization procedures, but avoid stretch mobilization of the subtalar joint.
- If full ankle motion is not achieved with active ROM, add gentle self-stretching exercises to improve flexibility of specific muscle groups, most frequently the gastrocnemius–soleus complex.

PRECAUTION: It is advisable to begin with open-chain stretching, such as a towel stretch or closed-chain stretching in a seated position, because closed-chain stretching with the patient standing imposes significant ground reaction forces on the repaired ligaments.

Increase strength of ankle and foot musculature. Perform low-intensity resistance exercises of all ankle muscles in open- and closed-chain positions. After surgical repair of the lateral ligaments, improving strength of the evertors is particularly important for dynamic stability of the ankle.

- Isometric strengthening of the evertors can be achieved by having the patient cross the ankles and press the lateral borders of the feet together. Dynamic strengthening of the evertors against elastic resistance is also appropriate (see Fig. 22.12).
- Progress to dynamic exercises using elastic resistance and isokinetic training, if available.

- In the final phase of rehabilitation initiate plyometric training.

NOTE: The extent of strength loss in the ankle musculature has been shown to be associated with the chronicity of the instability.⁴²

Improve neuromuscular control, balance reactions, dynamic stability, and agility. Initiate proprioceptive/balance training at about 6 weeks postoperatively or when the patient is able to bear full weight on the operated lower extremity without ankle pain. Emphasize a progression of bilateral to unilateral balance activities first on a level, firm surface, then on a soft surface, such as dense foam, and then on a balance board. Progress to jumping, then hopping forward, diagonally, backward, and side-to-side on the floor or a mini-trampoline. Other balance activities are described in the final section of this chapter.

Focus on Evidence

For patients with a functionally unstable ankle proprioceptive training, using rocker or wobble boards has been shown to be an effective method of improving joint proprioception (joint position sense) and single-leg standing ability and reducing postural sway and muscle reaction times during balance activities.^{22,26,84,116}

In a prospective study by Verhagen and co-investigators,¹¹¹ 1127 male and female professional volleyball players from 116 teams were randomly assigned by team to a training group or a control group. Throughout the 36-week volleyball season, the training groups participated in a proprioceptive training program consisting of a variety of balance activities, some on balance boards. The control groups were not given any training program. The training and control groups kept track of injuries sustained during the season. Among players who had a history of a lateral ankle sprain prior to the beginning of the study, those who participated in the balance training program had a significantly lower incidence of acute lateral ankle sprains during the season than those in the control group. Among training and control group players who did not have a history of lateral ankle sprains, there was no significant difference in the incidence of ankle injury during the season. The authors concluded that proprioceptive training was effective in preventing recurrence of lateral ankle injury in adult volleyball players.

Although these studies did not involve patients undergoing rehabilitation after reconstruction of the lateral ankle ligaments, proprioceptive training programs such as these may be beneficial for the postoperative patient.

Improve muscular endurance and cardiopulmonary fitness. Begin with swimming, stationary bicycling, treadmill walking, or using a cross-country ski machine. Progress to outdoor walking, jogging or running, being certain the ankle is appropriately supported.

Safely return to functional activities and prevent re-injury. Sport-specific training, beginning with low-intensity simu-

BOX 22.4 Activity-Related Precautions to Reduce the Risk of Re-injury After Lateral Ligament Reconstruction of the Ankle

- Modify activities, if possible, by participating in low-impact sports, such as swimming, cycling, low-impact aerobics, or cross country skiing.
- Minimize or avoid participation in activities that involve high-impact (basketball, volleyball), rapid stopping and starting and changes of direction (tennis, soccer), or moving on uneven surfaces
- If involved in activities associated with high risk of ankle injury
 - Participate in a pre-season injury prevention program that includes progressive proprioceptive and plyometric training and continue the program throughout a sport season.¹¹¹
 - Wear a prescribed orthotic device to provide medial-lateral stability of the ankle, such as functional stirrup brace or splint.¹⁰¹
 - Tape the ankle or insert a slight lateral lift in the shoe.^{65,73}

lated movements, usually is permissible by 8 to 12 weeks postoperatively.^{31,101,103} Precautions to reduce the risk of re-injury when returning to sports or high-demand activities after reconstruction of lateral ankle ligaments are summarized in Box 22.4.

Outcomes

A successful postoperative outcome after lateral ankle repair or reconstruction is an ankle that has full mobility but remains stable and pain-free during functional activities. At this time, an open approach for primary repair or reconstruction provides more predictable long-term results than arthroscopic procedures.¹³ In some instances, although not an optimal result, a slight loss of ankle motion, possibly 5° to 10° of eversion, occurs most often after tenodesis procedures.⁹⁶

A review of the literature of studies involving patients with chronic lateral ankle instability indicated that 87% to 95% of patients report good to excellent results after surgery.⁸¹ Similar results were reported in a postoperative follow-up study of ballet dancers who had undergone a modified Bröstrom procedure.³² Several studies have compared the results of an anatomic (direct) repair with reconstruction with a tendon graft (tenodesis). Hennrikus et al.³⁵ compared two types of lateral ankle reconstruction, one using anatomic repair (modified Bröstrom procedure) and the other involving augmentation with a peroneus brevis tendon graft (Chrisman-Snook procedure). Both procedures yielded good to excellent results in 80% of patients, but the latter was associated with a higher rate of complications.

In a multicenter, retrospective nonrandomized study, Krips and colleagues⁵⁷ evaluated two groups of athletes

($N = 77$) who had undergone an anatomic (direct) repair or reconstruction with a tenodesis procedure for chronic lateral ankle instability 2 to 10 (mean 5.4) years earlier. There were no significant differences in preoperative characteristics of the athletes in the two groups. All had participated in a nonoperative treatment program for at least 6 months before surgery. Physical examination at follow-up revealed significantly more patients (15/36) in the tenodesis group had limited ankle ROM than patients (3/41) in the anatomic repair group. Functional abilities reported by patients on a quantitative questionnaire were rated as excellent and good by 21/36 subjects in the tenodesis group and by 36/41 in the anatomic repair group. Those in the tenodesis group reported a noticeably diminished push-off power on the operated side during running. They also reported a lower activity level and a perception of less ankle stability than those in the anatomic repair group. The authors concluded that an anatomic repair was a better choice than tenodesis for primary repair of chronic ankle instability in an athletic population.⁵⁷

Repair of a Ruptured Achilles Tendon

Acute rupture of the Achilles tendon is a common soft tissue injury, occurring more frequently in men than in women, 30 to 50 years old, who intermittently participate in exercise or athletic activities.^{3,46,117} The rupture usually is associated with a forceful concentric or eccentric contraction of the gastrocnemius–soleus muscles (triceps surae) during sudden acceleration or abrupt deceleration, such as jumping or landing.⁵ Degenerative and mechanical factors appear to increase the risk of acute rupture, including decreased strength or flexibility of the plantarflexors, excessive body weight, pre-existing tendinosis, corticosteroid injections into the tendon, and decreased vascularity of the tendon.⁵

The tendon often ruptures proximal to the distal insertion of the tendon on the calcaneus.³⁴ At the time of injury a complete rupture leads to pain, swelling, a palpable defect, and significant weakness in plantarflexion. It also is associated with a positive Thompson test (absence of reflexive plantarflexion when the patient is prone-lying with the foot over the edge of a table and the calf is squeezed).¹⁰⁶

A complete rupture of the Achilles tendon can be managed conservatively with extended cast immobilization or functional bracing; or it can be managed surgically. There is general agreement in the literature and in clinical practice that surgical intervention is routinely recommended for the young, active patient less than 30 years of age but that nonoperative management is the better option for the sedentary patient older than 50 to 60 years of age.^{3,46,117} Furthermore, surgery is considered the only option for the symptomatic patient with a chronic rupture in which the diagnosis or treatment was delayed for 4 weeks or more.^{71,114} However, there is lack of agreement in the literature and in practice as to which is the better option for the middle-aged population.

Several recently reported systematic reviews and meta-analyses of the literature that included only prospective, randomized and quasi-randomized studies have revealed there is insufficient evidence to indicate which option is the better treatment strategy or yields better outcomes.^{3,46,117} Both options have advantages and disadvantages. With surgical repair there is a lower rate of re-rupture of the tendon than with nonoperative management, but there also is a risk of wound closure problems, infection, and nerve injury with surgery. Nonoperative management requires a longer immobilization and recuperative time and is associated with a higher rate of deep vein thrombosis (DVT).^{3,11,46,117} Both patient and surgeon must weigh the different advantages and disadvantages in the decision-making process.

Indications for Surgery

The following are frequently cited indications for surgical repair or reconstruction of an acute or chronic rupture of the Achilles tendon.

- Acute, complete rupture of the Achilles tendon^{5,10,11}
- Chronic, previously undiagnosed or untreated complete rupture in which end-to-end apposition cannot be achieved by conservative means.^{72,114}
- Typically indicated for the active individual who wishes to return to high-demand functional activities.^{3,11,117}

Procedures

There are a considerable number of surgical procedures and techniques for repair or reconstruction of a ruptured Achilles tendon.^{5,10,11,68,69,114,117} An open or percutaneous approach can be used for a primary repair.^{15,61,100}

Primary repair of an acute rupture is performed within a few days to a week after the injury and usually is carried out with a direct, end-to-end repair in which the ends of the torn tendon are reopposed and sutured together.⁵ The repair site may or may not be reinforced by some method of tissue augmentation. Delayed repair of a chronic rupture requires reconstruction and augmentation of the tendon most often by an autograft, or tendon transfer, or possibly an allograft.^{71,114} Structures that may serve as a donor graft are the flexor hallucis longus, plantaris, or peroneus brevis tendons or a flap of fascia from the gastrocnemius muscle.

In an open primary repair, a posterior incision is made at the distal leg just medial to the Achilles tendon. Placing the incision medial of the tendon avoids possible damage to the sural nerve. The tendon ends are identified, frayed fibers are removed, and the ends reopposed and sutured together while the ankle is maintained in a neutral to slightly plantarflexed position.⁵ With a tendon reconstruction a second incision is made to harvest the donor graft. If, for example, the flexor hallucis longus (FHL) tendon is selected, an incision is made along medial aspect of the sole of the foot at the mid-metatarsal level. A sufficient portion of the FHL tendon is left distally so the remaining portion can be sutured to the flexor digitorum longus tendon to retain active flexion of the first toe.¹¹⁴ The har-

vested portion of the FHL tendon then is woven into and sutured to bridge the gap of the Achilles tendon ends.

Before closure, the ankle is moved through the ROM to assess the stability of the repair or reconstruction. A compression dressing and below-knee posterior splint are applied after closure with the ankle usually positioned in 15° to 20° of plantarflexion.^{5,114} If immediate or very early postoperative weight bearing is to be allowed by the surgeon, the ankle is placed in a neutral (0° of dorsiflexion), if possible, and stabilized with a rigid anterior splint.⁴³

NOTE: An above-knee cast is applied (and later replaced with a below-knee cast) if the rupture occurred at the myotendinous junction or the quality of the repair is tenuous.⁵

Postoperative Management

Although guidelines for postoperative rehabilitation after an open repair of an acute Achilles tendon rupture vary considerably in the literature and in clinical practice, these guidelines tend to fall within two categories—use of a conventional (traditional) management strategy or an early remobilization approach. The use of immobilization and the initiation of weight bearing distinguish one approach from the other. Guidelines for management after percutaneous repair are not addressed in the following sections but can be found in other resources.^{15,61,100}

Immobilization and Weight Bearing Considerations

Conventional approach. After an open primary repair of an acute Achilles tendon rupture, conventional postoperative management, a widely used practice for many years, involves approximately 6 weeks of continuous immobilization with the ankle held in plantarflexion at least a portion of that period of time.^{3,5,11,63,67} The patient remains non-weight bearing on the operated extremity during this time. After a delayed tendon reconstruction with graft augmentation for a chronic rupture, the time before motion and weight bearing are permissible is longer, usually an additional 2 weeks or more.¹¹⁴

Table 22.2 summarizes immobilization and weight-bearing guidelines associated with conventional management after primary Achilles tendon repair.^{3,5,11,63,67,68} Although this approach is safe and associated with low risk of rerupture, extended immobilization, traditionally thought to be necessary to protect the healing tendon, has been shown in some studies to lead to deficits in strength, particularly in the plantarflexors, and loss of ROM of the ankle.^{9,68,100}

Early remobilization approach. For the past two decades or more there has been a trend to decrease the period of continuous postoperative immobilization and to initiate early ankle ROM in a protected range and early weight bearing in a functional orthosis.^{9,34,43,63,64,67–69,82,97} This approach, sometimes termed “functional rehabilitation,” is an option after primary repair of an acute rupture, not a delayed reconstruction. Early motion and weight bearing are possible because of advances in surgical procedures, such as stronger suturing techniques and sometimes the

TABLE 22.2 Conventional Postoperative Management After Achilles Tendon Repair or Reconstruction with Graft*

Postoperative Time Period	Type and Position of Ankle Immobilization	Weight-bearing Guidelines
At 0–4 weeks	<ul style="list-style-type: none"> Compression dressing removed a few days to a week postoperatively When compression dressing removed, below-knee cast applied; foot in 15° to 30° plantarflexion At 2–3 weeks new cast applied in less plantarflexion 	<ul style="list-style-type: none"> Nonweight bearing Ambulation with crutches
At 4 weeks	<ul style="list-style-type: none"> Cast set in equines removed and walking cast applied with ankle positioned in neutral or replaced with a controlled ankle motion (CAM) brace that limits dorsiflexion to 0°; cast or brace worn an additional 2–4 weeks 	<ul style="list-style-type: none"> Weight bearing initiated while wearing immobilizer Progressed as tolerated
At 6–8 weeks	<ul style="list-style-type: none"> If walking cast used; replaced with CAM brace allowing dorsiflexion beyond neutral. Active ROM exercises initiated 	<ul style="list-style-type: none"> Full weight bearing wearing functional brace; transition to shoe with 1.0- to 1.5-cm heel lift for an additional 2 to 4 weeks or more
Beyond 12 weeks	<ul style="list-style-type: none"> Functional brace gradually discontinued** 	<ul style="list-style-type: none"> Full weight bearing in regular shoes without lift, if ankle is pain-free and 10° dorsiflexion attained

*All time periods are approximately 2 weeks longer after reconstruction with tendon graft.

** Immobilizer may be worn during ambulation for a longer period of time if wound healing is delayed or the quality of the repair is tenuous.

use of soft tissue augmentation to reinforce the primary repair.^{10,43,64,68,69,97}

Although published recommendations for early protected motion and weight bearing vary widely, use of a below-knee (boot-like) *dorsal* functional brace or splint is a consistent feature of early remobilization approaches. If bracing is prescribed, it is a hinged, controlled ankle motion (CAM) orthosis that can be locked in various positions.⁸² When ankle motion is permissible, the orthosis is adjusted to allow movement but only in a protected range, typically limiting dorsiflexion beyond neutral.^{9,34,67} If a rigid splint is used, its dorsal configuration limits dorsiflexion to 0° but allows plantarflexion.^{43,63}

Initially, the brace or splint holds the ankle in slight plantarflexion but is adjusted (or refabricated in the case of a splint) to neutral by 2 weeks postoperatively.^{13,34,63} During the first 6 weeks of rehabilitation the protective orthosis is worn during ambulation and at all other times except when removed for wound care and selected exercises.

When the patient is able to ambulate on level surfaces without pain while bearing full weight on the operated extremity, the protective boot or splint is discontinued (usually by 8 to 10 weeks postoperatively). As with a conventional approach, after discontinuing the functional brace or splint, many surgeons prescribe a 1.0- or 1.5-cm heel lift for both shoes that are worn for several weeks to decrease ground reaction forces during functional activities.⁶⁸

The guidelines for initiating and progressing weight bearing and ROM exercises recommended in published

programs differ from study to study. A summary of these guidelines is presented in Box 22.5.^{43,63,67,82} Common to all early remobilization programs is the use of safe levels of applied stress while protecting the healing tendon. Close communication among the surgeon, therapist, and patient is essential for success with this approach to postoperative management.

Focus on Evidence

Although there have been few randomized studies directly comparing a functional bracing or splinting and early motion program after acute Achilles tendon repair with a program of extended cast immobilization (usually 6 weeks) followed by ROM exercises, a recent meta-analysis of these studies demonstrated that patients managed with an early motion/functional bracing program had a significantly lower rate of adhesion formation and limited ankle ROM. However, the investigators noted that the pooled data from the available studies must be interpreted with caution because of the variety of postoperative regimens used.⁴⁶

Exercise

After open, primary repair of an acute Achilles tendon rupture, the types of exercise included in a postoperative program are similar regardless of whether an early motion/early weight-bearing approach or a conventional (extended immobilization/delayed motion and weight bearing)

BOX 22.5 Features of Early Remobilization Programs After Repair of Acute Achilles Tendon Rupture*

Weight-bearing Guidelines

- Initiated as tolerated while using crutches immediately after surgery^{43,63} or after 2 weeks^{67,82} in a below-knee orthosis with the ankle immobilized most often in plantarflexion or possibly neutral
- Progress gradually to full weight-bearing status between 3 to 6 weeks postoperatively^{43,82}
- Orthosis worn during all weight-bearing activities for 6 to 8 weeks after surgery⁸²
- Full weight bearing without the functional orthosis but wearing regular shoes with bilateral heel lifts when orthosis discontinued beginning at about 6 to 8 weeks postoperatively^{43,101}

ROM Exercises

- Immediately^{43,63,64,97} or by 1 to 2 weeks^{67,82,101} after surgery, active plantarflexion and dorsiflexion of the ankle initiated while wearing a dorsal functional brace or splint to prevent dorsiflexion beyond 15° to 30° of equines or to no more than a neutral position while seated or supine
- By 6 to 8 weeks dorsiflexion to 10° permitted in the orthosis and inversion/eversion out of the orthosis^{43,67}

*Beyond 6 to 8 weeks postoperatively guidelines are similar for early remobilization and conventional programs.

approach is employed. What is different is the timing and progression of the exercises based on when ROM and weight bearing are permissible.

In the sections that follow a progression of exercises designed to assist a patient achieve a number of treatment goals and ultimately function at the pre-injury level is presented.

Exercise: Maximum Protection Phase

Achilles tendon repair frequently is performed on an outpatient basis. Therefore, patient education is essential before surgery or prior to discharge. It focuses on wound care (if the immobilizer is removable), controlling peripheral edema by elevating the operated leg, gait training, and a home exercise program. The following treatment goals and exercises are appropriate during the first 4 to 6 weeks after surgery.

- **Maintain ROM of nonimmobilized joints.** Perform active ROM of the hip, knee, and toes of the operated lower extremity while the patient is wearing the immobilizer.
- **Prevent reflex inhibition of immobilized muscle groups.** If early ROM is not permitted, begin submaximal, pain-free muscle-setting exercises of the ankle in the immobilizer within the first few days after surgery. Start with setting exercises of the dorsiflexors, invertors, and evertors. At 2 weeks, add setting exercises of the plantarflexors.

- **Prevent joint stiffness and soft tissue adhesions in the operated ankle and foot.** If an early motion and weight-bearing approach was planned, begin the ROM exercises described in Box 22.5 within a few days to 2 weeks after surgery. The time frame is determined by the surgeon.

- **Maintain cardiopulmonary endurance.** Use an upper extremity ergometry for endurance training, if available.

Exercise: Moderate Protection Phase

By 6 weeks postoperatively the patient may be permitted to bear weight as tolerated on the operated extremity regardless of whether an early weight-bearing program or conventional program was implemented. However, a functional CAM orthosis is required during progressive weight-bearing activities for several weeks.

During this phase of rehabilitation, which usually extends from 6 to 12 weeks postoperatively, gradually increasing stress is placed on the operated tendon and surrounding structures. Patients typically begin a supervised exercise program at this time.

PRECAUTIONS: Progress all exercises very cautiously that place resistance or a stretch on the gastrocnemius–soleus muscle group. Postpone closed-chain exercises until the patient is able to bear full weight on the operated side without pain. Avoid any high-impact, high-velocity activities to minimize the risk of re-rupture of the Achilles tendon.

- **Increase ROM of the operated ankle.** Begin gentle self-stretching exercises in nonweight-bearing and weight-bearing positions. Stretch the gastrocnemius–soleus muscle group with the knee extended and flexed. Examples of stretching activities are:

- Grade III joint mobilization techniques if ankle or foot joints are restricted
- Gentle manual stretching to increase inversion/eversion and dorsiflexion/plantarflexion
- A towel stretch to increase dorsiflexion
- While seated, active ankle ROM with the foot resting on a small rocker or wobble board
- Standing stretch to increase dorsiflexion with the knee flexed and extended
- Descend stairs step over step as ROM improves

- **Improve strength of the operated lower extremity.** Initiate open- and closed-chain, low-intensity resistance exercises at 6 to 8 weeks. Examples include:

- Open-chain resistance exercises of the ankle against a light grade of elastic resistance.
- Bilateral, progressing to unilateral closed-chain activities, such as heel and toe raises while seated, mini-squats alternating heel raises and toe raises, and partial lunges using body weight as resistance.

- **Re-establish balance reactions.** Initiate proprioceptive training and balance exercises in double-leg stance on a firm surface. Progress to single-leg stance on a soft surface.

- **Improve muscular and cardiopulmonary endurance.** Begin and gradually progress level-surface treadmill walking or stationary cycling (recumbent or upright)

while wearing the functional, hinged orthosis, if required, or regular shoes with a heel lift. Raise the seat height of the upright bicycle to accommodate for limited dorsiflexion. Progress to treadmill walking on an incline.

Exercise: Minimum Protection/ Return to Function Phase

The final phase of rehabilitation, which begins around 12 to 16 weeks postoperatively, is directed toward returning a patient to a pre-injury level of function for expected work-related demands and desired recreational/athletic activities. Stretching exercises continue until full ROM is achieved, and then the patient transitions to a maintenance program. Eccentric resistance exercises of the gastrocnemius–soleus muscle group in weight-bearing positions and eventually plyometric training are added to the strengthening program. More challenging proprioceptive training is added. Jogging, running, agility drills, and sport-specific training usually can be initiated at 16 weeks. Patient education focuses on ways to reduce the risk of rerupture of the repaired tendon, such as warming up before strenuous activity and daily stretching. Most patients are permitted to resume sports gradually at 5 to 6 months if the strength of the operated extremity is relatively comparable to that of the contralateral extremity.^{5,63,67}

Outcomes

The ideal outcome is for a patient to return to a pre-injury level of physical activity without pain or re-rupture of the repaired Achilles tendon. Patients undergoing primary repair of an acute rupture have consistently better outcomes than those who undergo a delayed repair for a chronic rupture. The longer the delay between injury and repair, the poorer the results.¹¹⁴ The patient population with the highest risk of re-rupture after primary repair of an acute rupture are active individuals 30 years of age or younger.⁸²

Comparison of methods of management. The results of numerous studies comparing methods of management of acute tendon ruptures have been reported. Methods compared include operative and nonoperative management, open and percutaneous procedures, and conventional and early motion/early weight bearing approaches to postoperative treatment. Outcomes typically reported are rate of rerupture, ROM, strength, functional or sport-related activity level, and patient satisfaction. Some generalizations can be drawn from systematic reviews of the literature and individual studies.

When comparing outcomes of nonoperative (cast immobilization) with operative management of acute ruptures, three systematic reviews and meta-analyses of the literature have revealed that there is a significantly higher rate of re-rupture associated with nonoperative management than with surgical repair.^{3,46,117} The authors of one of these reviews of randomized trials concluded that there is a three times higher risk of re-rupture after nonoperative treatment than after surgery. However, excluding re-rupture, operative management is associated with a substantially higher rate of complications than

nonoperative treatment, including infection, adhesions, and nerve injury.⁴⁶ The authors of another one of the reviews noted that when patients who sustain a re-rupture are excluded from an analysis of outcomes of nonoperative and operative management, long-term results, including activity level, ROM and strength, are similar.³

Comparison of open repair with percutaneous repair indicates no significant difference in the rate of re-rupture between the two techniques, but a higher rate of infection occurs with open repair⁶¹ and a higher rate of sural nerve damage occurs with a percutaneous approach.¹¹⁷

Rehabilitation using early motion and weight bearing appears to be as safe as management with prolonged cast immobilization and delayed weight bearing. Early follow-up studies have indicated no increased incidence of tendon rerupture with early postoperative motion.^{9,44,64,68} Although early reports are promising, no determination can yet be made on whether early motion and weight bearing enables a patient to return to a full level of functional activity sooner than if managed with a conventional postoperative approach.^{44,64,68} However, authors of a systematic review of the available studies concluded that open repair followed by early motion and weight bearing is probably the treatment of choice and leads to better outcomes for active patients.¹¹⁷

EXERCISE INTERVENTIONS FOR THE ANKLE AND FOOT

EXERCISE TECHNIQUES TO INCREASE FLEXIBILITY AND RANGE OF MOTION

Loss of flexibility in the ankle and foot can result from a variety of causes. Restoration of motion may be necessary to correct alignment or for normal biomechanics during walking and running. Joint mobilization techniques are used to increase accessory motion of the joint surfaces. These techniques are described in detail in Chapter 5. Manual passive stretching and neuromuscular inhibition techniques are described in Chapter 4. Self-stretching techniques to improve flexibility and ROM are the emphasis of this section.

Flexibility Exercises for the Ankle Region

Increase Dorsiflexion of the Ankle

The muscles that restrict dorsiflexion of the ankle are the one-joint soleus and the two-joint gastrocnemius. To effectively stretch the gastrocnemius, the knee must be extended while dorsiflexing the ankle. To isolate stretch to the soleus, the knee must be flexed during dorsiflexion to take tension off the gastrocnemius. Most of the follow-

ing stretching exercises can be adapted with the knee in flexion or extension so that both of the plantarflexor muscles can be stretched.

PRECAUTION: When a patient uses weight-bearing exercises to stretch the plantarflexor muscles, shoes with arch supports should be worn or a folded washcloth can be placed under the medial border of the foot to minimize the stress to the arches of the foot.

- **Patient position and procedure:** Long-sitting (knees extended) or with the knees partially flexed. Have the patient strongly dorsiflex the feet, attempting to keep the toes relaxed.
- **Patient position and procedure:** Long-sitting or with the knee partially flexed and with a towel or belt under the forefoot. Have the patient pull the foot into dorsiflexion.
- **Patient position and procedure:** Sitting with the foot flat on the floor. Have the patient slide the foot backward, keeping the heel on the floor.
- **Patient position and procedure:** Standing. Have the patient stride forward with one foot, keeping the heel of the back foot flat on the floor (the back foot is the one being stretched). If necessary, have the patient brace his or her hands against a wall. To provide stability to the foot, the patient partially rotates the back leg inward so the foot assumes a supinated position and locks the joints. The patient then shifts body weight forward onto the front foot. To stretch the gastrocnemius muscle, the knee of the back leg is kept extended; to stretch the soleus, the knee of the back leg is flexed.
- **Patient position and procedure:** Standing on an inclined board with feet pointing upward and heels downward (Fig. 22.8). Greater stretch occurs if the patient leans forward. Because the body weight is on the heels, there is little stretch on the long arches of the feet. Little effort is required to maintain this position for extended periods.

FIGURE 22.8 Self-stretching the ankle into dorsiflexion (stretching the gastrocnemius muscle).

● **Patient position and procedure:** Standing, with the forefoot on the edge of a step or stool and heel over the edge. Have the patient slowly lower the heel over the edge (heel drop).

PRECAUTION: This stretch may create muscle soreness because it requires that the patient control an eccentric contraction of the plantarflexors.

Increase Inversion

- **Patient position and procedure:** Sitting, with the foot to be stretched placed across the opposite knee. Have the patient grasp the mid- and hindfoot with the opposite hand and lift the foot into inversion. Emphasize turning the heel inward, not just twisting the forefoot.
- **Patient position and procedure:** Long-sitting with a towel or belt under the foot. Have the patient pull on the medial side of the towel to cause the heel and foot to turn inward (Fig. 22.9). This technique can also be used to turn the foot outward by pulling on the lateral side of the towel. It is important that the motion includes the heel, not just the forefoot.
- **Patient position and procedure:** Sitting or standing, with feet pointing forward. Have the patient roll to the lateral border of each foot so the soles are turned inward.
- **Patient position and procedure:** Standing or walking, with the involved foot on a slanted board, placing the lateral aspect of the foot to be stretched on the lower side of the board. Bilateral stretching can be accomplished if hinged planks are placed in an inverted-V position and the patient stands or walks on them.

Increase Ankle Plantarflexion and Eversion

It is not common for plantarflexion and eversion to be restricted because in the supine position gravity plantarflexes the foot and in the standing position the body's weight everts the foot. Eversion, which is a component of pronation, is the loose-packed position of the foot and is perpetuated with weight bearing. The exception for restricted talocrural plantarflexion is when there is a capsular pattern at the joint as a result of arthritis. If the restriction is from joint hypomobility, it is treated with joint mobilization techniques. If there is restriction of

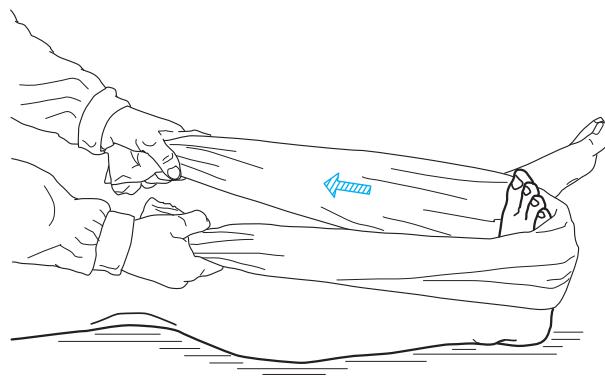

FIGURE 22.9 Self-stretching the foot into inversion using a towel by pulling on the towel on the medial side of the foot.

eversion, a stretching technique was described previously with use of a towel or belt around the foot.

Flexibility Exercises for Limited Mobility of the Toes

Tight extrinsic muscles of the toes occur with claw toes and hammer toes, causing the MTP joints to extend and IP joints to flex. There is often weakness in the intrinsic muscles. To stretch the intrinsic muscles, emphasize *MTP flexion* and *IP extension*.

Passive MTP Flexion

Patient position and procedure: Sitting with the foot crossed onto the opposite knee. Show the patient how to stabilize the foot under the metatarsal heads (MTP joints) with the thumbs, and passively *flex* the MTP joints by applying pressure against the proximal phalanges. Or have the patient attempt active flexion of the MTP joints, assisting the motion if necessary.

Passive IP Extension

Patient position and procedure: Sitting with the foot crossed onto the opposite knee. Teach the patient to stabilize the proximal phalanx of the involved toe and passively stretch the long flexors across each joint by moving the middle and/or distal phalanx into *extension*.

Active MTP Flexion

Patient position and procedure: Standing with the toes over the edge of a stool or book and the MTP joints at the edge. Have the patient attempt to flex the MTP joints over the edge of the stool. Ideally the patient should try to keep the IP joints of the toes extended, but many individuals cannot do this.

Great Toe Extension

Extension of the great toe at the MTP joint is critical during the push-off phase of gait. In addition to joint mobilization techniques, passive stretching and self-stretching techniques should be used.

- *Patient position and procedure:* Sitting with the foot resting on the opposite knee. Show the patient how to stabilize the foot around the head of the first metatarsal with one hand, and passively *extend* the MTP joint by applying pressure against the proximal phalanx.
- *Patient position and procedure:* Standing with the involved foot in a backward stride position. The patient may lean his or her hands against a wall for support. Have the patient keep the toes on the ground and rock forward lifting the heel until a stretch is felt under the first toe. A sustained stretch or a gentle rocking stretch can be used.

Stretching the Plantar Fascia of the Foot

- *Patient position and procedure:* Sitting with the foot placed across the opposite knee. Teach the patient to use his or her thumbs to apply deep massage horizontally and longitudinally across the plantar surface of the foot.

- *Patient position and procedure:* Sitting with a ball or small roller (or bottle) under the foot. Have the patient roll the foot forward and backward across the curved surface, using as much pressure as is comfortable. Pressing down on the knee with one or both hands can exert additional force.

EXERCISES TO DEVELOP AND IMPROVE MUSCLE PERFORMANCE AND FUNCTIONAL CONTROL

Causes of strength and flexibility imbalances in the ankle and foot include disuse, immobilization, nerve injury, and progressive joint degeneration. In addition, imbalances occur from the weight-bearing stresses that are imposed on the feet. Imbalances can be the cause or the effect of faulty lower extremity mechanics. Because the lower extremities bear weight, realignment by strengthening exercises alone is of limited value. Strengthening exercises undertaken in conjunction with conscious correction, appropriate stretching, balance training, and other necessary measures (such as using orthotic inserts or adaptations for shoes, bracing, splinting, or surgery) improve alignment so that structurally safe weight bearing is possible. In addition, observation of the types of shoes and surfaces that the person uses for walking or sports activities may be a lead to the source of faulty mechanics, which then can be adjusted. (Techniques of orthopedic adaptations for shoes, bracing, and splinting are beyond the scope of this text.)

Most functional demands on the ankle and foot occur in weight-bearing postures. Kinesthetic input from skin, joint, and muscle receptors and the resulting joint and muscle responses are different in open- and closed-chain activities.^{25,59} Therefore, whenever possible, use of progressive weight-bearing exercises is important to simulate functional activities. In addition to the exercises described in this section, refer to Chapter 20 for total lower extremity functional exercises performed in the standing position that influence muscle control at the hip, knee, and ankle.

Activities to Develop Dynamic Neuromuscular Control

- *Patient position and procedure:* Long-sitting or with the knees partially flexed. Have the patient practice contracting each of the major muscles while concentrating on his or her actions, for example, dorsiflexion with inversion (anterior tibialis), plantarflexion with inversion (posterior tibialis), and eversion (peroneus muscles).
- *Patient position and procedure:* Long-sitting or with the knee partially flexed. Instruct the patient to “draw” the alphabet in space leading with the toes but moving at the ankle. For variety have the patient “print” using capital letters, then with lower case letters, or “write” words such as his or her name or address.

- **Patient position and procedure:** Sitting on a chair or low mat table with feet on the floor. Place a number of small objects, such as marbles or dice, to one side of the involved foot. Have the patient pick up one object at a time by curling the toes around it and then placing it in a container on the other side of the foot. This emphasizes the plantar muscles as well as inversion and eversion.
- **Patient position and procedure:** Sitting with feet on the floor or standing. Have the patient curl the toes against the resistance of the floor. Place a towel or tissue paper under the feet, and have the patient attempt to wrinkle it up by keeping the heel on the floor and flexing the toes.
- **Patient position and procedure:** Sitting, with the feet on the floor. Have the patient attempt to raise the medial longitudinal arch while keeping the forefoot and hindfoot on the floor. External rotation of the tibia should occur but not abduction of the hips. The activity is repeated until the patient has consistent control, then it is performed while standing as a progression.
- **Patient position and procedure:** Sitting with a tennis ball placed between the soles of the feet. Instruct the patient to roll the tennis ball back and forth from heel to forefoot.
- **Patient position and procedure:** Sitting with both feet or just the involved foot on a rocker or balance board. Have patient perform controlled ankle and foot motions (with or without the assistance of the normal foot) into dorsiflexion and plantarflexion and inversion and eversion (Fig. 22.10). If the equipment permits, the patient also can perform circumduction in each direction. Progress this activity to the standing position to further develop control and to develop balance.
- **Patient position and procedure:** Standing. Have the patient practice walking while concentrating on place-

FIGURE 22.10 Using a rocker board to develop control of ankle motions with the patient sitting. When both feet are on the board, the normal foot can assist the involved side. With only the involved foot on the board, the activity is more difficult.

ment of the feet and shifting body weight with each step. The patient begins by accepting body weight on the heel, then shifting the weight along the lateral border of the foot to the fifth metatarsal head and across to the first metatarsal head and great toe for push-off.

Open-Chain Strengthening Exercises

All of the following exercises in this section are performed without bearing weight through the foot and ankle.

Plantarflexion

Patient position and procedure: Long-sitting with the leg resting on a rolled towel to slightly elevate the heel off the treatment table. Have the patient hold onto the ends of elasticized material that is looped under the forefoot and then plantarflex the foot against the resistance (Fig. 22.11).

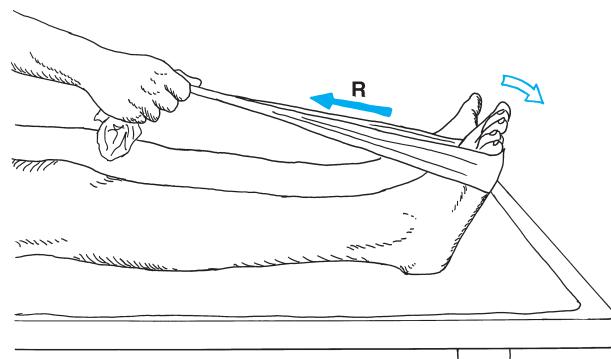

FIGURE 22.11 Resisting the ankle plantarflexor muscles with an elasticized material.

Isometric Eversion and Inversion

Patient position and procedure: Long-sitting or sitting in a chair with knees flexed.

- To resist *eversion*, the ankles are crossed; instruct the patient to press the lateral borders of both feet together against each other.
- To resist *inversion*, the medial borders of the feet are placed beside each other; instruct the patient to press the medial borders of the feet against each other.

Eversion and Inversion with Elastic Resistance

Patient position and procedure: Long-sitting, supine, or sitting with the feet resting on the floor.

- To resist *eversion*, place a loop of elastic tubing around both feet and have the patient evert one or both feet against the resistance (Fig. 22.12). Instruct the patient to keep the knees still and just turn the foot outward, not allowing the thigh and leg to abduct or externally rotate.
- To resist *inversion*, tie the elastic band or tubing to a structure on the lateral side of the foot. Again, have the patient keep the legs stationary and only turn the foot inward without allowing the hip to adduct and internally rotate.

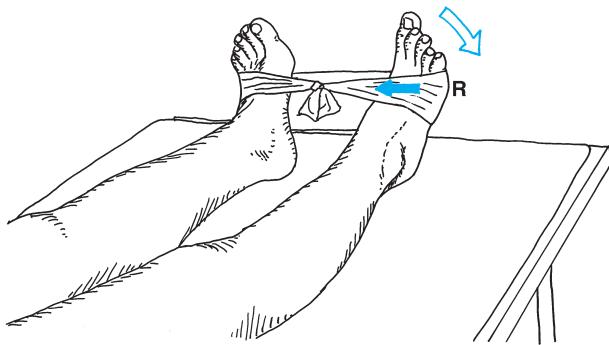

FIGURE 22.12 Resisting the evertor muscles of the foot with an elasticized material.

Adduction with Inversion and Abduction with Eversion Using Weights

Patient position and procedure: Sitting with the foot on the floor. Place a towel under the forefoot and a weight on the end of the towel (Fig. 22.13). Have the patient pull the weighted towel along the floor with the forefoot by keeping the heel fixed on the floor and swinging the foot either inward or outward.

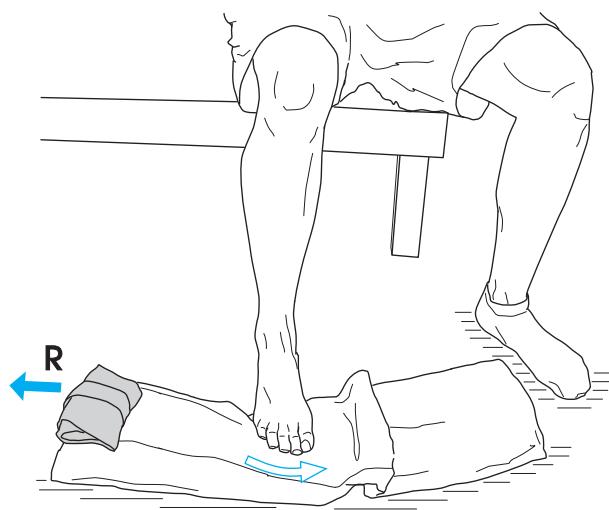

FIGURE 22.13 Resisting adduction and inversion with a weight on the end of the towel. The heel is kept stationary while a windshield wiper motion of the foot is used to pull the towel along the floor. Abduction with eversion is resisted by placing the weight on the towel on the medial side of the foot.

Dorsiflexion

Patient position and procedure: Long-sitting or supine with a rolled towel under the distal leg to elevate the heel slightly. Tie an elastic band or tubing to the foot end of the bed (or other object), and place a loop over the dorsum of the foot. Have the patient dorsiflex against the resistance (Fig. 22.14).

All Ankle Motions

Position of patient: Sitting in a chair or standing with one or both feet in a box filled with sand, foam, dry peas, dry

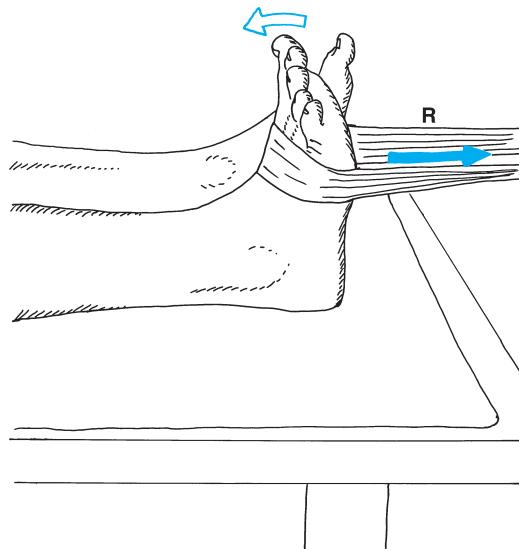

FIGURE 22.14 Resisting the ankle dorsiflexor muscles with an elasticized material.

beans, or other similar type material to offer resistance to various foot motions. Have the patient plantarflex, dorsiflex, invert and evert the foot and ankle, and curl the toes either with the foot on top or with the foot dug into the medium.

Weight-Bearing Exercises for Strength, Balance, and Function

For these exercises, the patient position is standing. If the patient does not initially tolerate full weight bearing without reproduction of symptoms, begin by standing in the parallel bars or in a pool to reduce weight-bearing forces. Refer to Table 6.8 for general guidelines for progression of closed-chain exercises.

Stabilization Exercises

- Apply resistance to the patient's pelvis in various directions while he or she attempts to maintain control. At first, use verbal cues, then resist without warning. Also increase the speed and intensity of the perturbation forces.
- Have the patient hold onto a wooden dowel rod or cane with both hands. Apply the resistance through the rod in various directions and with varying intensities and speeds as the patient attempts to remain stable (Fig. 22.15).
- Progress to standing only on the involved foot.

Dynamic Strength Training

Have the patient perform bilateral toe raises, heel raises, and rocking outward to the lateral borders of the feet. Progress to unilateral toe raises, heel raises, and lateral border standing. When tolerated, resistance is added with a weight belt or handheld weights.

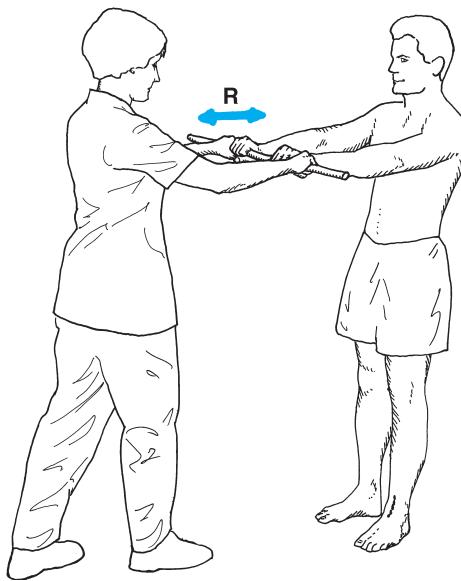

FIGURE 22.15 Stabilization exercises with the patient standing and maintaining balance against the alternating resistance forces from the therapist. The therapist applies force through the rod in backward/forward, side-to-side, and rotation directions.

Resisted Walking

- Have the patient walk on heels and on toes against resistance.
- Apply resistance against the patient's pelvis, or have the patient walk against a pulley weight or elastic resistance fixed around the pelvis (see Fig. 20.25).

Balance Activities

Exercises and functional activities to improve balance are described in detail in Chapter 8. Additional balance activities are described in Chapter 20. Begin with partial weight-bearing activities in the parallel bars if necessary; progress to full, bilateral weight bearing, then unilateral weight bearing. Have the patient shift body weight, stand and balance while performing various arm motions, march in place, walk, and progress to walking on uneven surfaces.

A rocker or balance board can be used several different ways to stimulate balance reactions. If necessary, begin with the patient supporting himself or herself with both hands in the parallel bars or by holding onto a stable object. Initially, both feet are on the board. Increasing the size of the half sphere or rocker under the board increases the difficulty of the balance activity. Progress to unilateral stance on the board.

- Have the patient rock the feet forward and backward, then side-to-side while attempting to control the motion and maintain balance.
- Instruct the patient to maintain balance and not let the edges of the board hit the ground (Fig. 22.16). As the patient learns to control the board, impose various challenges while he or she maintains balance on the board. Examples:

FIGURE 22.16 Advanced training for balance and coordination on a balance board requires that the patient not hold on while balancing with one leg.

- Have the patient move the arms forward, backward, and overhead.
- Perform various arm motions against elastic resistance, with free weights, or while controlling a BodyBlade® (see Fig. 6.55).
- Toss a ball (unweighted or weighted) back and forth to the patient.
- Have the patient hold onto elastic resistance while you pull the resistance in various directions.

Simulation and Practice of Functional Activities

Using the principle of specificity of training, replicate whatever functional activity the individual requires, first in controlled patterns, then with increased velocity and decreased control.

Functional strengthening. Lifting, pushing, and pulling heavy objects requires ankle strength as well as hip, knee, and trunk strength. Develop exercises that involve the total body to develop safe body mechanics. Include squatting and lunging to lift objects from the floor, pushing or pulling weighted carts, and climbing and descending steps and ladders while carrying weights. Modify techniques if substitute motions occur.

Endurance. Develop endurance by increasing the amount of time spent performing various drills.

Power. Develop power with plyometric drills such as jumping and hopping. Progress to jumping off and back onto boxes of various heights.

Agility and skill. Develop an obstacle course and have the patient maneuver around or up and over the obstacles, first walking, then running, skipping, or jumping. Include forward, backward, and side-to-side maneuvers.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Observe how the foot and ankle function as a unit in several activities such as walking up steps, walking on uneven surfaces, and walking in high-heeled shoes versus low-heeled shoes.
 - What motions occur in the talocrural, subtalar, transverse tarsal, and metatarsophalangeal joints? Describe the mechanics.
 - What muscles are functioning and what level of strength is needed to move or control each joint?
2. Describe the role of the ankle and foot during the gait cycle.
 - What ROM is needed at the ankle and what muscles are acting to cause or control the motion? What other forces are causing or controlling motion at the ankle?
 - What gait deviations occur if there is muscle shortening or weakness at the ankle?
 - After a unilateral arthrodesis of the talocrural joint (ankle fused in neutral) what deviations will occur in the gait cycle?
 - Describe the mechanics and function of pronation and supination in the foot during the gait cycle. Explain how the gait cycle would be affected if a patient had flexible flat feet versus rigid supinated feet.
3. Compare and contrast an exercise program for a patient who has had a repair or reconstruction of torn lateral ligaments of the ankle versus a patient who has had a repair of a ruptured Achilles tendon. How will precautions and selection of exercises differ after these two types of surgical repairs?
4. Discuss the benefits and limitations of total ankle arthroplasty versus arthrodesis of the ankle for the patient with RA.

● Laboratory Practice

1. Review all the joint mobilization techniques for the leg, ankle, and foot; include basic glides, accessory motions, and mobilization with movement techniques.
 - Identify and practice techniques that you could use to increase ankle plantarflexion; begin with the ankle at zero, and progress at 15° increments until full plantarflexion is reached.
 - Do the same for ankle dorsiflexion, subtalar inversion and subtalar eversion, and metatarsophalangeal extension.
2. Set up a circuit-training course for the foot and ankle musculature to increase strength, muscular endurance, stability, and balance. Sequence the activities from basic to advanced, and observe accuracy and safety with each exercise. Identify other muscles in the lower extremity, trunk, or arms that are also being affected by the exercises.

● Case Studies

1. Mr. C. has a 10-year history of rheumatoid arthritis. Currently, medication is managing his acute symptoms so that he is able to walk with a cane. His complaints are increased pain after walking 15 minutes and considerable stiffness along with generalized weakness. You observe his gait: he walks with a short step and has no push-off. Ankle ROM: dorsiflexion 10°, plantarflexion 15°, inversion 0°, eversion 8°. He stands with a pronated foot, has dorsal migration of the first phalanges and moderate hammer toes. He tolerates moderate resistance in all his musculature within the limited range, although he is unable to demonstrate toe walking or do bilateral toe raises even one time.
 - List his impairments and functional limitations and state goals.
 - Develop a program of intervention to meet the goals. How will you initiate the intervention? What techniques will you use and how will you progress them?
 - Describe the rationale for each manual technique you would use, and for each exercise you would teach the patient.
 - Identify any precautions you will use and that you will teach the patient.
2. Sally S., a college student, sustained a bootline fracture of the tibia and fibula as the result of a fall while snow skiing. She was immobilized in a long-leg cast for 6 weeks, followed by a short-leg cast for 4 weeks. She was allowed partial weight bearing while wearing the short-leg cast. The cast was removed this morning. She described significant stiffness and discomfort when attempting to move her foot. Observation reveals atrophy in the calf, no edema or joint swelling. ROM in the ankle and foot is minimal, and there is no gliding of the fibula at the proximal or distal tibiofibular joints. Strength could not be tested, although the patient can activate all muscles.
 - Answer the same questions as in Case 1.
 - Even though both patients have restricted motion and demonstrate weakness, what are the differences in your intervention strategies and in the precautions you will follow?
 - How will you determine the progression of weight-bearing activities?
3. Ron W. is a 35-year-old computer programmer who plays basketball at the local recreation center. He sustained a massive inversion strain of his right ankle when landing on the foot of an opponent after jumping to rebound the basketball. He wrapped the ankle and iced it for 2 days. On the third day he went for a radiograph. No fractures were detected, but he does have a grade 2 instability of the anterior talofibular ligament. Observation reveals swelling and discoloration in the anterior and lateral ankle region. He experiences a marked increase in pain with inversion and plantarflexion

- tests, with anterior gliding of the talus, and with palpation over the involved ligament. Because of muscle guarding, strength was not tested.
- Identify impairments, goals, and an intervention strategy for this patient.

Throughout a woman's life cycle, specific gender differences need to be recognized for their relevance to rehabilitation. Recent research has shown *repeatedly* that women have specific and distinct physiological processes that extend beyond the obvious considerations of anatomy and

hormones, including differences in symptoms of heart attack and metabolism of medications.⁴² Clearly, the pregnant or postpartum patient presents a unique gender-based clinical challenge for the physical therapist. Although pregnancy is a time of tremendous musculoskeletal, physio-

logical, and emotional change, it is nonetheless a state of wellness. Pregnant women are typically well motivated, willing to learn, and highly responsive to treatment suggestions. For many women, the therapist is able to assess and monitor the physical changes with the primary focus on maintaining wellness. The ability to educate women about the role of exercise and health promotion during this key life transition provides a significant professional opportunity and responsibility.

In cases of musculoskeletal impairment related to pregnancy, the therapist is able to examine and treat the patient by incorporating knowledge of injury and tissue healing with knowledge of the changes during pregnancy. By considering a broader perspective, it is recognized that all female patients can benefit from education regarding the role of the pelvic floor muscles in musculoskeletal health, specifically in trunk stabilization. Specialized treatment of pelvic floor dysfunction is critical to quality of life for women experiencing incontinence, pelvic organ prolapse, and a variety of pelvic pain syndromes. Although all physical therapists can fairly easily incorporate activation of the pelvic floor muscles as a key component of trunk stabilization exercises, true expertise can come only with further training and mentoring. Advanced study of pelvic floor anatomy, evaluation, and treatment is highly recommended for therapists who wish to specialize in this area.

This chapter provides readers with basic information about the systemic changes of pregnancy as a foundation for the development of safe and effective exercise programs. In addition, a review of pelvic floor anatomy, function, and dysfunction serves as an introduction to the treatment of pelvic floor disorders. The chapter emphasizes modification of general exercises to meet the needs of the obstetric patient, and provides information to assist in the development of an exercise program for an uncomplicated pregnancy. Cesarean delivery, high-risk pregnancy, and the special needs of patients with these conditions are also discussed.

OVERVIEW OF PREGNANCY, LABOR, AND RELATED CONDITIONS

CHARACTERISTICS OF PREGNANCY AND LABOR

Pregnancy

Pregnancy, which spans 40 weeks from conception to delivery, is divided into three trimesters, with characteristic changes during each.^{27,36,54,58}

Changes During the First Trimester

During the first trimester (weeks 0 through 12) the following occur:

- Implantation of the fertilized ovum in the uterus occurs 7 to 10 days after fertilization.

- The mother is very fatigued, urinates more frequently, and may experience nausea and/or vomiting (“morning” sickness).
- Breast size may increase.
- There is a relatively small weight gain of 0 to 1455 g (0 to 3 lb is normal).
- Emotional changes may occur.
- By the end of the 12th week, the fetus is 6 to 7 cm long and weighs approximately 20 g (2 oz). The fetus now can kick, turn its head, and swallow and has a beating heart, but these movements are not yet felt by the mother.

Changes During the Second Trimester

During the second trimester (weeks 13 through 26) the following occur:

- The pregnancy becomes visible to others.
- The mother begins to feel movement at around 20 weeks.
- Most women now feel very good. Nausea and fatigue have usually disappeared.
- By the end of the second trimester, the fetus is 19 to 23 cm (14 inches) in length and weighs approximately 600 g (1 to 2 lb).
- The fetus now has eyebrows, eyelashes, and fingernails.

Changes During the Third Trimester

From week 27 through 40 weeks the following occur:

- The uterus is now very large and has regular contractions, although these may be felt only occasionally.
- Common complaints during the third trimester are frequent urination, back pain, leg edema and fatigue, round ligament pain, shortness of breath, and constipation.
- By the time of birth, the baby will be 33 to 39 cm long (16 to 19 inches) and will weigh approximately 3400 g (7 lb, although a range of 5 to 10 lb is normal).

NOTE: Although pregnancy typically lasts 40 weeks, the range of 38 to 42 weeks is considered full term.

Labor

Labor is divided into three stages, each containing specific events.^{7,36,56,58} The exact mechanism that initiates labor is not known. Regular and strong involuntary contractions of the smooth muscles of the uterus are the primary symptom of labor. True labor produces palpable changes in the cervix, which are known as effacement and dilation (Fig. 23.1).⁵⁸

- **Effacement** is the shortening or thinning of the cervix from a thickness of 5 cm (2 inches) before onset of labor to the thickness of a piece of paper.
- **Dilation** is the opening of the cervix from the diameter of a fingertip to approximately 10 cm (4 inches).

Labor—Stage 1

Some women experience initial cervical dilation and effacement before they are in true labor. However, by the end of this stage, the cervix is fully dilated and there is no doubt that a baby is about to be delivered. Stage 1 of labor is divided into three major phases.

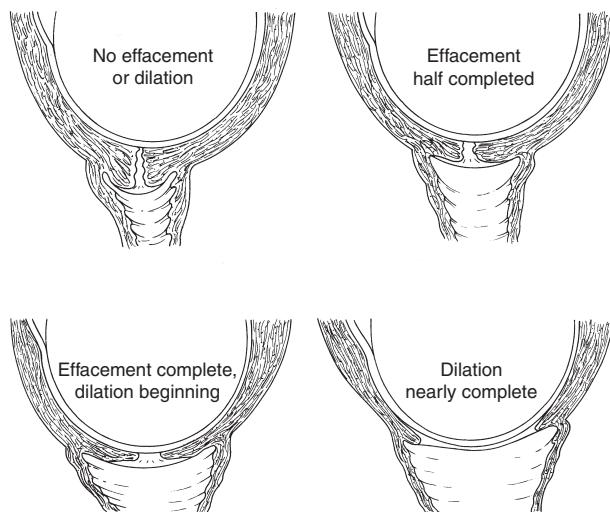

FIGURE 23.1 Effacement and dilation of the cervix. (From Sandberg,⁵⁸ with permission.)

Cervical dilation phase. The cervix dilates from 0 to 3 cm (0 to 1 inch) and will almost completely efface. Uterine contractions occur from the top down, causing the cervix to open and pushing the fetus downward.

Middle phase. The cervix dilates from 4 to 7 cm (1 to 3 inches). Contractions are stronger and more regular.

Transition phase. The cervix dilates from 8 to 10 cm (3 to 4 inches) and dilation is complete. Uterine contractions are very strong and close together.

Labor—Stage 2

Stage 2 involves “*pushing*” and *expulsion* of the fetus. Intra-abdominal pressure is the primary force expelling the fetus; it is produced by voluntary contraction of the abdominal muscles and diaphragm. Relaxation and stretching of the pelvic floor during stage 2 are also necessary for successful vaginal delivery. Uterine contractions may last as long as 90 seconds during this stage.

Fetal descent. Position changes (cardinal movements) by the fetus allow it to pass through the pelvis and be born (Fig. 23.2).⁵⁶ The position changes are described as:

- **Engagement.** The greatest transverse diameter of the fetal head passes through the pelvic inlet (the superior opening of the minor pelvis).
- **Descent.** Continued downward progression of the fetus occurs.
- **Flexion.** The fetal chin is brought closer to its thorax; this occurs when the descending head meets resistance from the walls and floor of the pelvis and the cervix.
- **Internal rotation.** The fetus turns its occiput toward the mother’s symphysis pubis when the fetal head reaches the level of the ischial spines.
- **Extension.** The flexed fetal head reaches the vulva; the fetus extends its head, bringing the base of the occiput in direct contact with the inferior margin of the maternal

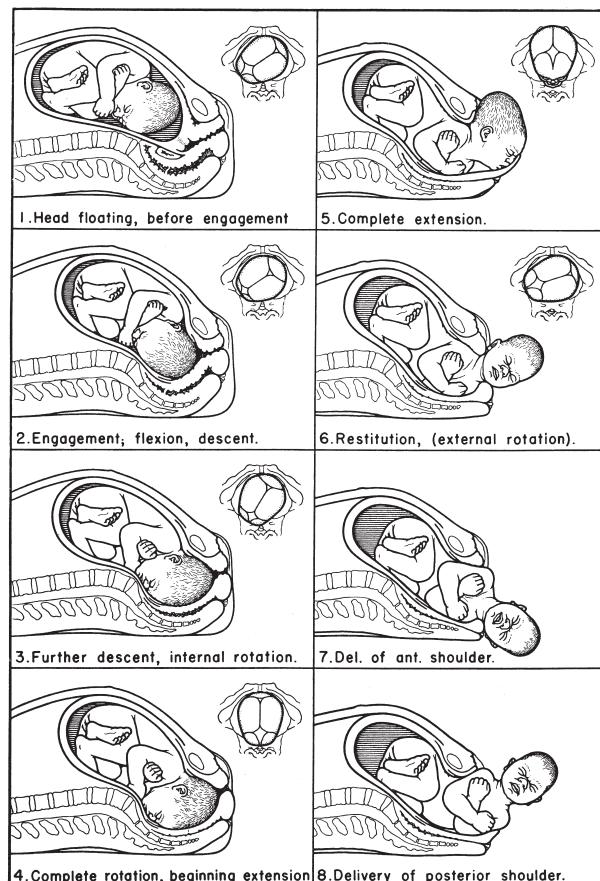

FIGURE 23.2 Principal movements in the mechanism of labor and delivery, left occiput anterior position. (From Pritchard, J, MacDonald, P,⁵⁶ with permission.)

symphysis pubis; this phase ends when the fetal head is delivered.

- **External rotation.** The fetus rotates its occiput toward the mother’s sacrum to allow the fetal shoulders to pass through the pelvis.

Expulsion. The fetal anterior shoulder passes under the symphysis pubis, and the rest of the body follows.

Labor—Stage 3

Placental stage (expulsion of the placenta). After delivery, the uterus continues to contract and shrink, causing the placenta to detach and be expelled.

- As the uterus decreases in size, the placenta detaches from the uterine wall, blood vessels are constricted, and bleeding slows. This can occur 5 to 30 minutes after the baby is delivered.
- A hematoma forms over the uterine placental site to prevent further significant blood loss; mild bleeding persists for 3 to 6 weeks after delivery.

Uterine involution. The uterus continues to contract and decrease in size for 3 to 6 weeks after delivery; the uterus always remains slightly enlarged over its pre-pregnant size.

BOX 23.1 Total Weight Gain (Ranges) for Single Fetus

• Fetus	3.36–3.88 kg	(7.5–8.0 lb)
• Placenta	0.48–0.72 kg	(1.0–1.5 lb)
• Amniotic fluid	0.72–0.97 kg	(1.5–2.0 lb)
• Uterus and breasts	2.42–2.66 kg	(5.0–5.5 lb)
• Blood and fluid	1.94–3.99 kg	(4.0–7.0 lb)
• Muscle and fat	0.48–2.91 kg	(1.0–6.0 lb)
• Total:	9.70–14.55 kg	(20.0–30.0 lb)

ANATOMICAL AND PHYSIOLOGICAL CHANGES OF PREGNANCY

Considerable changes occur in the woman's body as the pregnancy progresses.^{7,36,54,56,58,62,66}

Weight Gain During Pregnancy

Current recommendations for weight gain during pregnancy are an average of 25 to 27 lbs.⁶² with a distribution as shown in Box 23.1.

Changes in Organ Systems

Uterus and Related Connective Tissue

Uterus. The uterus increases from a prepregnant size of 5 by 10 cm (2 by 4 inches) to 25 by 36 cm (10 by 14 inches). It increases five to six times in size, 3000 to 4000 times in capacity, and 20 times in weight by the end of pregnancy. By the end of pregnancy, each muscle cell in the uterus has increased approximately 10 times over its pre-pregnancy length.⁶⁶ Once the uterus expands upward and leaves the pelvis, it becomes an abdominal rather than a pelvic organ.

Connective tissues. Ligaments connected to the pelvic organs are more fibroelastic than ligaments supporting joint structures. The fascial tissues, which surround and enclose the organs in a continuous sheet, also include a significant amount of smooth muscle fibers.¹⁷ The round, broad, and uterosacral ligaments in particular provide suspensory support for the uterus.

Urinary System

Kidneys. The kidneys increase in length by 1 cm (0.5 inch).

Ureters. The ureters enter the bladder at a perpendicular angle because of uterine enlargement. This may result in a reflux of urine out of the bladder and back into the ureter; therefore, during pregnancy there is an increased chance of developing urinary tract infections because of urinary stasis.

Pulmonary System

Hormonal influences. Hormone changes affect pulmonary secretions and rib cage position.

- Edema and tissue congestion of the upper respiratory tract begin early in pregnancy because of hormonal changes. Hormonally stimulated upper respiratory hypersecretion also occurs.
- Changes in rib position are hormonally stimulated and occur prior to uterine enlargement. The subcostal angle progressively increases; the ribs flare up and out. The anteroposterior and transverse chest diameters each increase by 2 cm (1 inch). Total chest circumference increases by 5 to 7 cm (2 to 3 inches) and does not always return to the pre-pregnant state.
- The diaphragm is elevated by 4 cm (1.5 inch); this is a passive change caused by the change in rib position.

Respiration. Respiration rate is unchanged, but depth of respiration increases.⁵⁶

- Tidal volume and minute ventilation increase, but total lung capacity is unchanged or slightly decreased.^{56,66}
- There is a 15% to 20% increase in oxygen consumption; a natural state of hyperventilation exists throughout pregnancy to meet the oxygen demands of pregnancy.^{56,66}
- The work of breathing increases because of hyperventilation; dyspnea is present with mild exercise as early as 20 weeks into the pregnancy.^{56,66}

Cardiovascular System

Blood volume and pressure. Blood volume progressively increases 35% to 50% (1.5 to 2 liters) throughout pregnancy and returns to normal by 6 to 8 weeks after delivery.

- Plasma increase is greater than red blood cell increase, leading to the “physiologic anemia” of pregnancy, which is not a true anemia but is representative of the greater increase of plasma volume. The increase in plasma volume occurs as a result of hormonal stimulation to meet the oxygen demands of pregnancy.
- Venous pressure in the lower extremities increases during standing as a result of increased uterine size and increased venous distensibility.
- Pressure in the inferior vena cava rises in late pregnancy, especially in the supine position, because of compression by the uterus just below the diaphragm. In some women, the decline in venous return and resulting decrease in cardiac output may lead to symptomatic supine hypotensive syndrome. The aorta is partially occluded in the supine position.
- Blood pressure decreases early in the first trimester. There is a slight decrease of systolic pressure and a greater decrease of diastolic pressure. Blood pressure reaches its lowest level approximately midway through pregnancy, then rises gradually from mid-pregnancy to reach the pre-pregnant level approximately 6 weeks after delivery. Although cardiac output increases, blood pressure decreases because of venous distensibility.

Heart. Heart size increases, and the heart is elevated because of the movement of the diaphragm.

- Heart rhythm disturbances are more common during pregnancy.

- Heart rate usually increases 10 to 20 beats per minute by full term and returns to normal levels within 6 weeks after delivery.
- Cardiac output increases 30% to 60% during pregnancy and is most significantly increased when a woman is in the left side-lying position, in which the uterus places the least pressure on the aorta.

Musculoskeletal System

Abdominal muscles. The abdominal muscles, particularly both sides of the rectus, are stretched to the point of their elastic limit by the end of pregnancy. This greatly decreases the muscles' ability to generate a strong contraction, and thus decreases their efficiency of contraction. The shift in the center of gravity also decreases the mechanical advantage of the abdominal muscles.⁶⁶

Pelvic floor muscles. The pelvic floor muscles, in their anti-gravity position, must withstand the total change in weight; the pelvic floor drops as much as 2.5 cm (1 inch) as a result of pregnancy.⁶²

Connective tissues and joints. The hormonal influence on the ligaments is profound, producing a systemic decrease in ligamentous tensile strength. This change is primarily a result of an increase in relaxin and progesterone levels.⁶²

- The thoracolumbar fascia is put in a position of extreme length, which diminishes its ability to stabilize the trunk effectively.¹⁸
- Joint hypermobility occurs as a result of ligamentous laxity and may predispose the patient to injury, especially in the weight-bearing joints of the back, pelvis, and lower extremities.

Thermoregulatory System

Metabolic rate. During pregnancy, basal metabolic rate and heat production increase.²⁰

- An additional intake of 300 calories per day is needed to meet the basic metabolic needs of pregnancy.
- In pregnant women, normal fasting blood glucose levels are lower than in nonpregnant women.²⁰

Changes in Posture and Balance

Center of Gravity

The center of gravity shifts upward and forward because of the enlargement of the uterus and breasts. This requires postural compensations to maintain balance and stability.^{54,66}

- The *lumbar and cervical lordoses* increase to compensate for the shift in the center of gravity, and the knees hyperextend, probably because of the change in the center of gravity.
- The *shoulder girdle and upper back* become rounded with scapular protraction and upper extremity internal rotation because of breast enlargement; this postural tendency persists with postpartum positioning for

infant care. Tightness of the pectoralis muscles and weakness of the scapular stabilizers may be pre-existing to or perpetuated by the pregnancy postural change.

- The *suboccipital muscles* respond in an effort to maintain appropriate eye level (optical righting reflex), and to moderate forward head posture along with the change in shoulder alignment.
- *Weight shifts* toward the heels to bring the center of gravity to a more posterior position. This contributes to the "waddling" gait that is typically seen in pregnancy.
- Changes in posture do not automatically correct after childbirth, and the pregnant posture may become habitual. In addition, many child-care activities contribute to persistent postural faults and asymmetry.

Balance

With the increased weight and redistribution of body mass there are compensations to maintain balance.^{54,66}

- The pregnant woman usually walks with a wider base of support and increased external rotation at the hips.
- This change in stance along with growth of the baby makes some activities such as walking, stooping, stair climbing, lifting, reaching, and other activities of daily living (ADLs) progressively more challenging.
- Activities requiring fine balance and rapid changes in direction, such as aerobic dancing and bicycle riding, may become inadvisable, especially during the third trimester.

OVERVIEW OF PELVIC FLOOR ANATOMY, FUNCTION, AND DYSFUNCTION

Treatment of pelvic floor impairment has become more visible and accepted in the physical therapy community over the last 5 to 10 years. However, advanced and in-depth study of anatomy, physiology, evaluation, and treatment continues to be highly recommended for therapists who wish to specialize in this area.^{2-4,9,10,12,17,19,22,26,28,33-35,37,38,41,43-45,48,51,53-55,57,59,61,62,64-67,70}

Pelvic Floor Musculature

The pelvic floor musculature is composed of several layers with bony attachments to the pubic bone and the coccyx. The anterior-posterior fibers are oriented almost horizontally and form the inferior support for the trunk. Laterally, the tissues blend into a fascial layer overlying the obturator internus. Both right and left sides of the muscles contribute fibers to the perineal body located between the vagina and rectum (Fig. 23.3). The structure and action of the muscles of each layer are summarized in Table 23.1. Fibers that run anterior-posterior create a superior force toward the heart, while the more superficial fibers surround the sphincters and produce a puckering motion.

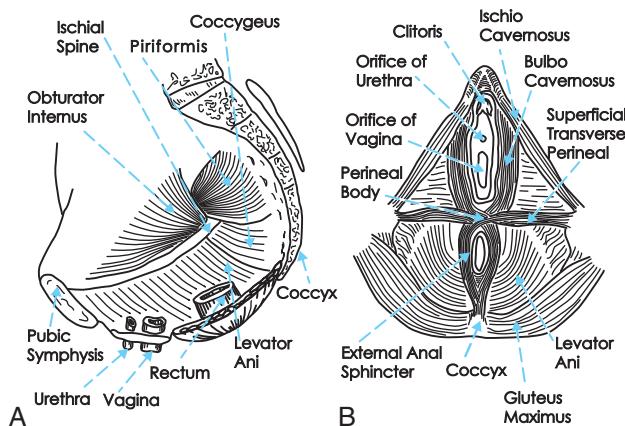

FIGURE 23.3 Pelvic floor muscles. (A) Sagittal section; note sling/hammock orientation and (B) viewed from below; note figure-eight orientation of the muscles around the orifice of the urethra/vagina and the anal sphincter.

Female Pelvic Floor

The female pelvic floor allows for passage of the urethra, vagina, and rectum. This creates less inherent stability when compared to the male anatomy.

Innervation

The pudendal nerve arises from ventral divisions of S2 to S4 in the sacral plexus, as well as direct branches from S3 and S4, and supplies the pelvic floor complex. This dual innervation provides a safeguard against direct damage to the pudendal nerve. The terminal branches are the perineal branch and the inferior rectal nerve, which ends in the external anal sphincter.

Function

The pelvic floor musculature has the following essential roles:

- Provide support for the pelvic organs and their contents
- Withstand increases in intra-abdominal pressure
- Maintain continence (through sympathetic nerve fibers) to the urethral and anal sphincters
- Sexual response and reproductive function

Effect of Childbirth on the Pelvic Floor

Neurological Compromise

Stretch and compression of the pudendal nerve occurs during labor as the baby's head travels through the birth canal; this stretch can be as much as 20% of the total length of the nerve.^{3,61} This compromise to the pudendal nerve is most intense during pushing (the second stage of labor), through the completion of vaginal delivery.

Muscular Impairment

Extreme stretching of the pelvic floor tissues is inherent in the process of labor and vaginal delivery. The pelvic floor musculature may also be torn or incised during the birth process. An episiotomy is an incision made in the perineal body (see Fig. 23.3). It is automatically considered a second-degree laceration according to the following classification of perineal lacerations⁵⁶:

First degree—only skin

Second degree—includes underlying muscle

Third degree—extends to anal sphincter

Fourth degree—tears through the sphincter and into the rectum

Additional trauma can occur as a result of forceps use, necessitating suturing throughout the musculature and into the vaginal vault.

Episiotomy

Although episiotomy is common, occurring in 33% to 51% of vaginal deliveries (with some studies reporting a figure as high as 75%), there is no strong medical evidence supporting its use. In fact, outcomes with episiotomy are worse in some cases, including pain with intercourse and extension of the episiotomy into the sphincter or rectum.^{33,41} Pregnant women have many questions about labor in general and episiotomy in particular; the clinician is able to provide education and support for the patient as she explores her options.

TABLE 23.1 Pelvic Floor Anatomy—From Superficial to Deep

Muscle Layer	Structure	Action
Superficial (outlet)	Ischiocavernosus	Clitoral erection
	Bulbocavernosus	"Drawing in" of the introitus, clitoral erection
	Superficial transverse perineal	Fixes perineal body
	External anal sphincter	Compression of anal canal
Urogenital diaphragm (perineal membrane)	Deep transverse perineal • Compressor urethrae • Urethrovaginal sphincter	Compression of urethra and ventral wall of vagina Support of the perineal body and introitus
Pelvic diaphragm (primary muscular support)	Levator ani • Pubococcygeus • Puborectalis • Iliococcygeus Coccygeus	Prime mover of the pelvic floor Puborectalis aids in closure of the rectum Flexes coccyx

Focus on Evidence

A randomized controlled trial of 459 Canadian women during their first pregnancy found a significant protective effect against third- and fourth-degree tears (extensions following episiotomy) in women who participated in “strenuous” exercise three or more times per week. The researchers defined “strenuous” exercise as bicycling, jogging, tennis, skiing, and weight training as opposed to “non-strenuous” exercise such as walking, swimming, prenatal classes, and yoga. Data were collected regarding type, frequency, and duration of exercise for a 12-month period including prepregnancy and postpartum time frames. In the “strenuous” exercise group, 200 of the women did *not* have third- or fourth-degree tears as compared to only 25 women who did experience this tearing. In addition, this study helped dispel the theory that serious exercisers may have overdeveloped perineal musculature; these women were *not* at increased risk for episiotomy when compared to casual exercisers.⁴¹

Classification of Pelvic Floor Dysfunction

Prolapse

A prolapse is a supportive impairment. It refers to the descent of any of the pelvic viscera out of their normal alignment because of muscular, fascial, and/or ligamentous deficits, and increased abdominal pressure (Fig. 23.4). A prolapse often worsens over time and with subsequent pregnancies and can be aggravated by constipation and straining with elimination.

- A recent cross-sectional study found stage I prolapse in 33% of the subjects, and stage II descent in 62.9%. The sample included 270 women with a mean age of 68.3 years and median parity of three vaginal births.⁵¹ This is critically important information for all clinicians prescribing trunk stabilization programs for female patients, regardless of diagnosis.
- From a biomechanical aspect, activation of the pelvic floor is necessary in coordination with core muscle activation and trunk strengthening activities to prevent excessive downward forces. Otherwise, trunk strengthening will likely increase a previously undetected prolapse, or aggravate an existing condition.

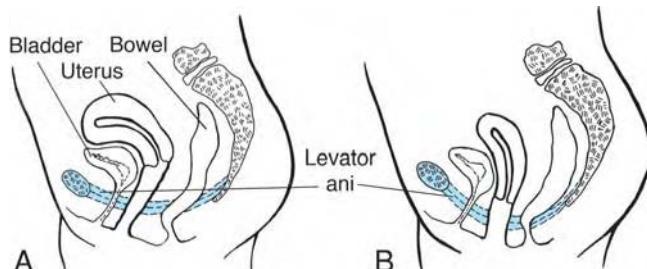

FIGURE 23.4 (A) Good pelvic floor support with a firm base, organs in normal position. (B) Inadequate support, pelvic organs descend.

- As prolapse progresses, functional changes occur as a result of perineal pressure and heaviness, low back pain, abdominal pressure or pain, and voiding difficulties. Currently, there is very limited evidence regarding prevention or treatment of pelvic organ prolapse.

Focus on Evidence

Involuntary loss of bladder or bowel contents, often a result of both neuromuscular and musculoskeletal impairments, often occurs in combination with prolapse. A conservative estimate of persons affected with urinary incontinence is 15 million in the United States alone (approximately 1 in 20 persons); women are twice as likely to have these symptoms as men.²² These patients often have significant social discomfort and anxiety regarding leakage and hygiene concerns.

Focus on Evidence

Statistically significant improvements in urinary leakage were demonstrated as a result of a program of pelvic floor strengthening in three different studies.^{44,45,57} Both pregnant and postpartum women were studied in these trials, with follow-up until 1 year after delivery in two of the studies.^{44,57} Morkved et al.⁴⁵ determined that pelvic floor muscle training prevented incontinence in about one in six women during pregnancy and one in eight women after delivery ($N = 301$).

Pain and Hypertonus

The broad category that encompasses pain and hypertonus includes a variety of causes. Pain and hypertonus may be related to delayed healing of perineal lacerations, trauma to the soft tissues or the sacro-coccygeal joint during delivery, pelvic obliquity, multiple gynecologic/visceral diagnoses, cauda equina involvement, scar tissue adhesions, or muscle spasm/guarding throughout the pelvis.

- Accurate statistics are lacking; however, in one study with a total sample of 581 women (age 18 to 45), the following prevalence was found: pelvic pain, 39%; dyspareunia, 46%; and dysmenorrhea, 90%.³⁷
- Functional limitations may include pain with ADLs, decreased sitting tolerance, dyspareunia (pain with intercourse), and difficulty with elimination of bladder and bowel contents. In patients with pelvic pain impairments, often referred to as chronic pelvic pain (CPP), persistent tightness of the lumbar paraspinals and hip flexors is typically present.²
- Because of the breadth of this topic, treatment recommendations are conflicting. Recent guidelines stress the importance of multidisciplinary assessment and consideration of myofascial dysfunction for successful outcomes.³⁸

Risk Factors for Dysfunction

Childbirth

Childbirth is obviously the most significant risk factor for pelvic floor impairments. The process of labor, particularly

with vaginal delivery and current medical management, can produce significant trauma to the structures of the pelvic floor.

- A longitudinal cohort study with follow-up 15 years after delivery ($N = 55$) showed that stress incontinence during the first pregnancy doubled the risk of re-occurrence 15 years later.¹⁹
- Other potential obstetric risk factors include multiple deliveries, prolonged second stage of labor, use of forceps or oxytocin, third-degree perineal tears, and birth weight greater than 8 lb.^{51,61,65}

Other Causes

Women who have never been pregnant may also present with pelvic floor dysfunction. Excessive straining because of chronic constipation, smoking, chronic cough, obesity, and hysterectomy can contribute to these impairments in any woman.^{3,22,35,65} The role of estrogen in the development of incontinence is still unclear, with some studies citing estrogen depletion as a risk factor²² and others that found a connection between incontinence and estrogen replacement therapy.^{35,65} High caffeine intake (more than 400 mg/day) is a specific risk factor for urge incontinence.³⁵

Interventions for Pelvic Floor Impairments

Visual Aids

Visual aids are critical in teaching patients about pelvic floor function. Emphasis should be placed on both the sling/hammock fibers and the figure-eight orientation of the musculature (see Fig. 23.3). Help the patient to visualize the fibers that run anterior–posterior (to create a “lifting” motion toward the heart) as well as the circumferential fibers (which produce a drawstring or “pucker” effect). Successful strengthening is unlikely without this educational component; in fact, instructing women in pelvic floor exercises by verbal or written instruction alone caused increased pressures to the bladder in 25% of women, rather than producing an appropriate superiorly directed force.⁹

Neuromuscular Re-education

Neuromuscular re-education is essential, as many women have significant disuse and proprioceptive deficits of the pelvic floor muscles. Internal techniques of assessment and treatment are often indicated for optimal patient outcomes. For example, manual stretch facilitation (a Proprioceptive Neuromuscular Facilitation technique) to the levator ani can be a very effective treatment option. Initially, emphasis on *isolated* contractions of the pelvic floor is needed⁴ because many patients will exhibit excessive accessory muscle recruitment such as the gluteals, hip adductors, and abdominals. Once coordination has improved, the patient progresses to integration of pelvic floor activity with ADLs, lumbar stabilization, and other functional exercises.

Exercise and Biofeedback

The use of exercise and biofeedback, including surface electromyography (SEMG) for treatment of pelvic floor dysfunction in a female population is well supported.^{10,22}

^{53,67} SEMG allows for immediate visual and/or auditory feedback to the patient, enhancing motor learning and proprioceptive improvements. It is particularly invaluable for *pelvic floor* re-education owing to lack of knowledge of the muscles’ existence, let alone their function and importance.

Specific exercises to address pelvic floor impairments are listed in the exercise section of the chapter.

Manual Treatment and Modalities

Manual treatment and modalities, including intravaginal and intrarectal techniques, also play a role in the treatment of pelvic floor symptoms, particularly pelvic pain syndromes. Advanced training is necessary for true expertise with internal techniques.

PREGNANCY-INDUCED PATHOLOGY

The combined influence of hormones, weight gain, and postural changes of pregnancy contributes to a variety of impairments (in addition to pelvic floor dysfunction that was described in the previous section) that can be addressed with physical therapy.

Diastasis Recti

Diastasis recti is separation of the rectus abdominis muscles in the midline at the linea alba. The etiology of this separation is unknown; however, the continuity and integrity of the abdominal musculature are disrupted (Fig. 23.5). Any separation larger than 2 cm or two fingerwidths is considered significant.^{5,11,48}

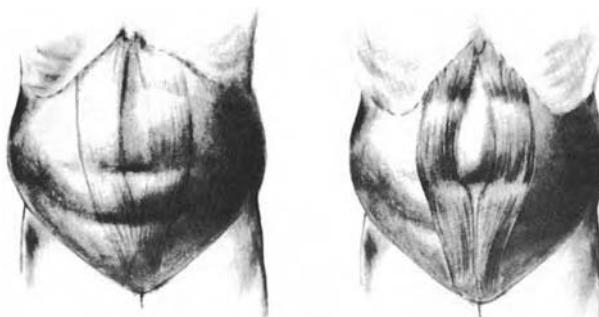

FIGURE 23.5 Diagrammatic representations of diastasis recti. (From Boissonnault, JS, Kotarinos, RK: Diastasis recti. In Wilder, E [ed]: Obstetric and Gynecologic Physical Therapy,⁶⁶ with permission.)

Incidence

The condition is not exclusive to childbearing women but is seen frequently in this population. In one study, Boissonnault and Blaschak tested 89 women for separation of the rectus abdominis muscles.⁵ The sample included women who were not pregnant, one group for each trimester of pregnancy, and two postpartum groups. The incidence in this study ranged from 0 in the nonpregnant and first trimester women, to 27% in the second trimester, to a high of 66% in the third trimester. Also of interest is that 36% of the women between 5 weeks and 3 months postpartum

continued to display a separation. A second study, done by Bursch, found a significant diastasis in 62.5% of postpartum women tested within 92 hours of delivery.¹¹

- Diastasis recti may occur in pregnancy as a result of hormonal effects on the connective tissue and the biomechanical changes of pregnancy; it may also develop during labor, especially with excessive breath-holding during the second stage.⁶² It causes no discomfort.
- It can occur above, below, or at the level of the umbilicus but appears to be less common below the umbilicus.
- It appears to be less common in women with good abdominal tone before pregnancy.⁵
- Clinically, a diastasis may be found in women well past their childbearing years and also in men. Routine assessment for this condition is highly recommended and can easily be done in conjunction with abdominal strength testing.

Significance

The condition of diastasis recti may produce musculoskeletal complaints, such as low back pain, possibly as a result of decreased ability of the abdominal musculature to stabilize the pelvis and lumbar spine.

Functional limitations. Functional limitations can also occur, such as inability to perform independent supine to sitting transitions because of extreme loss of the mechanical alignment and function of the rectus muscle. Again, this finding is not exclusive to childbearing patients.

Decreased fetal protection. In severe separations, the remaining midline layers of abdominal wall tissue are skin, fascia, subcutaneous fat, and peritoneum.^{5,11,62} The lack of muscular support provides less protection for the fetus.

Potential for herniation. Severe cases of diastasis recti may progress to herniation of the abdominal viscera through the separation at the linea alba. This degree of separation requires surgical repair. Rehabilitation following this type of repair may include components of C-section rehabilitation, with specific precautions and input from the referring surgeon. There may be a need for very slow progression depending on the severity of the diastasis and how it was repaired.

Examination for Diastasis Recti

Test all pregnant patients for the presence of diastasis recti before performing any abdominal exercises. This test should be repeated throughout the pregnancy and appropriate modifications made to existing exercises.

Instruct patients to perform a self-test on or after the third postpartum day for optimal accuracy. Until 3 days after delivery, the abdominal musculature has inadequate tone for valid test results.^{48,62}

Patient position and procedure: Hook-lying. Have the patient slowly raise her head and shoulders off the floor, reaching her hands toward the knees, until the spines of the scapulae leave the floor. Place the fingers of one hand horizontally across the midline of the abdomen at the umbilicus (Fig. 23.6). If a separation exists, the fingers will sink into the gap between the rectus muscles. The number of

FIGURE 23.6 Diastasis recti test.

fingers that can be placed between the muscle bellies is then documented. A diastasis recti can also present as a longitudinal bulge along the midline. Because this condition can occur above, below, or at the level of the umbilicus, test for it at all three areas.

Intervention for Diastasis Recti

Teach the patient to perform the corrective exercise for diastasis recti (see Fig. 23.8 and accompanying text later in this chapter) exclusive of other abdominal exercise until the separation is decreased to 2 cm or less.⁴⁸ The rationale for this is that, due to the angle of attachment of the obliques into the linea alba, there is a possibility that trunk rotation exercises will perpetuate the separation.⁶² Once the correction has been obtained, strengthening of the obliques and more advanced abdominal work can be resumed.

Postural Back Pain

Back pain commonly occurs because of the postural changes of pregnancy, increased ligamentous laxity, and decreased abdominal muscle function.^{1,18,48,52,54,55,66}

Incidence

Back pain is reported by 50% to 70% of pregnant women at some point during pregnancy^{30,47}; this condition contributes to lost work days and decreased functional ability. In addition, symptoms may continue in the postpartum period, with a prevalence in up to 68% of women, for as long as 12 months after delivery.⁴⁷

Characteristics

The symptoms of low back pain usually worsen with muscle fatigue from static postures or as the day progresses; symptoms are usually relieved with rest or change of position. Women who are physically fit generally have less back pain during pregnancy.⁵²

Interventions

Low back pain symptoms can be treated effectively with many traditional low back exercises, proper body mechan-

ics, posture instructions, improvement in work techniques, along with superficial modality application.^{48,62} The use of deep-heating agents, electrical stimulation, and traction is generally *contraindicated* during pregnancy.

Focus on Evidence

Garshasbi and Faghish Zadeh³⁰ studied more than 200 primigravid women (pregnant for the first time) in a prospective randomized study of the effect of exercise on the intensity of low back pain during pregnancy. Subjects were excluded if they had a history of exercise before pregnancy or history of orthopedic conditions. The exercise group were in a supervised exercise program for 3 hours/week for 12 weeks in the second and early third trimesters; the control group were women who were homemakers, and had no significant change in activity level. The groups were statistically equal in maternal and neonatal weight gain as well as length of pregnancy. The exercise group experienced significant decrease in intensity of low back pain by the end of the study, while intensity was increased in the control group. The study did not describe the nature of the symptoms or differentiate between postural pain versus sacroiliac pain. Interestingly, there was no significant difference in the change in lordosis between the two groups.

Sacroiliac/Pelvic Girdle Pain

Characteristics

Sacroiliac pain is localized to the posterior pelvis and is described as stabbing deep into the buttocks distal and lateral to L5/S1. Pain may radiate into the posterior thigh or knee but not into the foot. Symptoms include pain with prolonged sitting, standing or walking, climbing stairs, turning in bed, unilateral standing, or torsion activities. Symptoms may not be relieved by rest and frequently worsen with activity. Pubic symphysis dysfunction may occur alone or in combination with sacroiliac symptoms, and includes significant tenderness to palpation at the symphysis, radiating pain into the groin and medial thigh, and pain with weight bearing. In addition, excessive separation and translation of the bone may occur.^{18,62} One study reported a four times greater incidence of posterior pelvic pain than low back pain in pregnant women.⁵²

Interventions

Pelvic girdle and sacroiliac symptoms are treated via modification or elimination of activities that may further aggravate sensitive tissue, stabilization exercises, and the use of belts and corsets to provide external support to the pelvis.

● **Activity modification.** Daily activities should be adapted to minimize asymmetrical forces acting on the trunk and pelvis. For example, getting into a car is done by sitting down first, then pivoting both legs and the trunk into the car, keeping the knees together; side-lying is made more symmetrical by placing a pillow between the knees and under the abdomen, and sexual positions are altered to avoid full range of hip abduction. Single-leg weight bearing, excessive abduction and sitting on very soft surfaces should be avoided. In addition, caution patients

to avoid climbing more than one step at a time, swinging one leg out of bed at a time when getting up, or crossing the legs when sitting.^{18,62}

● **Exercise modification.** Exercise must be modified so as not to aggravate the condition. Avoid exercises that require single-leg weight bearing and excessive hip abduction or hyperextension. Teach the patient to activate the pelvic floor and transverse abdominals when transitioning from one position to another in order to stabilize the pelvis.

Focus on Evidence

A randomized clinical trial with 2-year follow-up looked at long-term effects of physical therapy for pelvic girdle pain in the postpartum period.⁶³ Each group had 20 weeks of treatment, with the control group focusing on modalities, manual therapy, and general exercises. In addition, the second group had specific focus on trunk/hip stabilizing exercises, with particular attention to the transverse abdominals. All participants received individual instruction from an experienced physical therapist. Outcome measures included the Oswestry Disability Questionnaire, pain scales, and a health-related quality of life (QOL) tool that measured eight subscales. At 1 year postpartum, the group with specific stabilizing exercises showed significantly better scores on all measures of those three tools, except for the social functioning subscale of the QOL tool. The same measurements were collected at 2 years post-delivery, and the benefit for the stabilization group persisted, with significant differences in functional status and morning and evening pain. The specific exercise group had scores on QOL comparable to those of a representative group of the general population.

● **External stabilization.** Use of external stabilization such as belts or corsets designed for use during pregnancy helps reduce posterior pelvic pain, especially when walking.

Focus on Evidence

Ostgaard et al.⁵² found that the use of nonelastic external stabilization designed for use during pregnancy helped reduce posterior pelvic pain in 82% of women. This was a large, randomized, controlled study ($N = 407$). More recent studies have validated the use of external stabilization for pelvic girdle pain ($N = 118$)⁴⁷ but found no effect with a support belt in cases of pubic symphysis pain ($N = 87$).¹⁸

Varicose Veins

Varicosities are aggravated in pregnancy by the increased uterine weight, venous stasis in the legs, and increased venous distensibility.

Characteristics

Varicosities can present in the first trimester, and are more prevalent with repeated pregnancies. They can occur in the

lower extremities, the rectum (hemorrhoids), or vulva. Symptoms usually include heaviness or aching discomfort, especially with dependent leg positions; intensity may become severe as the pregnancy progresses. In addition, pregnant women are more susceptible to deep vein thrombosis.⁶²

Interventions

- **Exercise modification.** If there is discomfort, exercises may need to be modified so that minimal dependent positioning of the legs occurs.
- **External support.** Elastic support stockings should be worn to provide an external pressure gradient against the distended veins, and the woman should be encouraged to perform lower extremity exercises and to elevate the lower extremities as often as possible (see Box 24.8 and accompanying text in Chapter 24). Vulvar varicosities may benefit from use of a perineal pad or belt that provides counter-pressure and support to the tissues.⁴⁸

Joint Laxity

Significance

All joint structures are at increased risk of injury during pregnancy and during the immediate postpartum period. The tensile quality of the ligamentous support is decreased, and therefore injury can occur if women are not educated regarding joint protection. There is much controversy regarding the impact of postpartum hormone levels; however, elevated levels have been found 3 to 5 months after delivery.⁶² This may persist even longer if the woman is nursing. Many patients are aware of persistent symptoms in conjunction with the menstrual cycle.

Interventions

- **Exercise modification.** Teach the woman safe exercises to perform during the childbearing year, including modification of exercises to decrease excessive joint stress (see exercises described in the management section of this chapter).
- **Aerobic exercise.** Suggest nonweight-bearing or less stressful aerobic activities such as swimming, walking, or biking, particularly for women who were relatively sedentary before pregnancy.

Nerve Compression Syndromes

Causes

Impairments from conditions such as thoracic outlet syndrome (TOS) or carpal tunnel syndrome (CTS) may be caused by one or more of the following in pregnancy: postural changes in the neck and upper quarter, fluid retention, hormonal changes, or circulatory compromise. Overall, women are three times as likely as men to experience carpal tunnel syndrome. Occurrence in pregnancy can be as high as 41%⁵³ (see Chapter 13 for discussion on CTS and TOS and Chapter 14 for discussion on posture).

Nerve compression syndromes may also occur in the lower extremities because of the weight of the fetus, fluid retention, hormonal changes, or circulatory compromise.

Interventions

Typical protocols include postural correction exercises, manual techniques, ergonomic assessment, and modalities (see Chapter 13 for management of nerve compression syndromes). Splints may be used in the treatment of carpal tunnel syndrome. Carpal tunnel surgery in the pregnant population is rare, as symptoms generally resolve soon after delivery; a longer course of the problem has been noted in women who breastfeed.⁶²

EXERCISE INTERVENTIONS FOR PREGNANCY, LABOR, AND RELATED CONDITIONS

PHYSIOLOGICAL EFFECTS OF AEROBIC EXERCISE DURING PREGNANCY

Many women who have been doing aerobic exercises choose to continue exercising during pregnancy to maintain their cardiopulmonary fitness. Maternal^{1,13,15,39,66} and fetal^{13,14,16,20,21,29,39,66} responses have been well studied; therefore this information is used to guide both the therapist and the patient in determining necessary modifications to an existing exercise program.

Maternal Response to Aerobic Exercise

Blood Flow

Aerobic exercise does not reduce blood flow to the brain and heart. It does, however, cause a redistribution of blood flow away from the internal organs (and possibly the uterus) and toward the working muscles. This raises two concerns: that the reduction in blood flow may decrease the oxygen and nutrient availability to the fetus and that uterine contractions and preterm labor may be stimulated.¹³ Stroke volume and cardiac output both increase with steady-state exercise. This, coupled with increased blood volume and reduction in systemic vascular resistance during pregnancy, may help offset the effects of the vascular shunting.

Respiratory Rate

The maternal respiration rate appears to adapt to mild exercise but does not increase proportionately with moderate and severe exercise when compared with a nonpregnant state. The pregnant woman reaches a maximum exercise capacity at a lower work level than a nonpregnant woman because of the increased oxygen requirements of exercise.

Hematocrit Level

The maternal hematocrit level during pregnancy is lowered; however, it rises up to 10 percentage points within 15 minutes of beginning vigorous exercise. This condition continues for up to 4 weeks postpartum. As a result, cardiac reserve is decreased during exercise.

Inferior Vena Cava Compression

Compression of the inferior vena cava by the uterus can occur after the fourth month of pregnancy, with relative obstruction of venous return. This leads to decreased cardiac output and orthostatic hypotension. It occurs most often in supine or static standing positions, and therefore prolonged time in these positions should be avoided.²⁰

Energy Needs

Hypoglycemia occurs more readily during pregnancy; therefore, adequate carbohydrate intake is important for the pregnant woman who exercises.¹⁵ A caloric intake of an additional 500 calories per day is suggested to support the energy needs of pregnancy *and* exercise, dependent on the intensity and duration of the exercise. In comparison, a sedentary pregnant woman requires a 300 calorie per day increase.¹

Core Temperature

Vigorous physical activity and dehydration through perspiration leads to increased core temperature in anyone who exercises. Concern has been expressed over this occurring in the pregnant woman because of the relationship of elevated core temperature to neural tube defects of the fetus. Studies report that during pregnancy the core temperature of physically fit women actually decreases during exercise. These women appeared to be more efficient in regulating their core temperature, and thus the thermal stress on the embryo and fetus is reduced.^{14,15}

Uterine Contractions

Norepinephrine and epinephrine levels increase with exercise. Norepinephrine increases the strength and frequency of uterine contractions. This may pose a problem for the woman at risk of developing premature labor.

Healthy Woman Response

Studies have shown that healthy women who continue to run throughout pregnancy deliver on the average of 5 to 7 days sooner compared with controls.^{13,14} Clapp^{13–15} found that exercise, including weight bearing (even with ballistic motions such as during aerobic dancing), can be performed in mid- and late pregnancy without risk of preterm labor or premature rupture of the membranes. Women who wish to continue strenuous or competitive exercise or participate in specific athletic training require close supervision by a specialist during pregnancy.^{20,21}

Fetal Response to Maternal Aerobic Exercise

No human research has conclusively proven a detrimental fetal response to mild- or moderate-intensity maternal exercise. Recent studies suggest that even vigorous exercise does not have the detrimental effects on the fetus that once were feared, and therefore restrictions on exercise because of concerns for the effects on the embryo and fetus have been lessened. In fact, fit women who maintained their volume of exercise after 20 weeks' gestation delivered babies with lower fat mass than those who

decreased exercise intensity mid-way through the pregnancy.^{13–15} Given the epidemic of obesity in the United States, the need for future research to define further the connections between fetal nutrition and adult disease is imperative.¹⁶

Blood Flow

A 50% or greater reduction of uterine blood flow is necessary before fetal well-being is affected (based on animal research). No studies have documented such decreases in pregnant women who exercise, even vigorously. It is suggested that the cardiovascular adaptations in exercising women offset any redistribution of blood to muscles during exercise.¹³

Fetal Heart Rate

Brief submaximal maternal exercise (up to 70% maternal aerobic power) does not adversely affect fetal heart rate (FHR).²⁰ The FHR usually increases 10 to 30 beats per minute at the onset of maternal exercise. After mild to moderate maternal exercise, the FHR usually returns to normal levels within 15 minutes, but in some cases of strenuous maternal exercise the FHR may remain elevated as long as 30 minutes. Fetal bradycardia (indicating fetal asphyxia) during maternal exercise has been reported in the literature, with the return to pre-exercise FHR levels within 3 minutes after maternal exercise, followed by a brief period of fetal tachycardia.²⁹ The healthy fetus appears to be able to tolerate brief episodes of asphyxia with no detrimental results.

Heat Dissipation

The fetus has no mechanism such as perspiration or respiration by which to dissipate heat. However, physically fit women are able to dissipate heat and regulate their core temperature more efficiently, thus reducing risk.¹³

Newborn Status

Newborn children of women who continue endurance exercises into the third trimester of pregnancy are reported to have an average decrease in birth weight of 310 g. There is no change in head circumference or heel–crown length. Further study of these children (up to 5 years of age) has shown slightly better neurodevelopmental status in addition to higher percentage of lean body mass.¹⁵

EXERCISE FOR THE UNCOMPLICATED PREGNANCY AND POSTPARTUM

Exercise programs during pregnancy and after childbirth are designed to minimize impairments and help the woman maintain or regain function while she is preparing for the arrival of the baby and then caring for the infant.^{1,20,21,23,29,39,40,45,46,48,53,54,57,60,62,66} The potential impairments, functional limitations, and management guidelines related to uncomplicated pregnancies are summarized in Box 23.2, and a suggested

BOX 23.2**MANAGEMENT GUIDELINES—Pregnancy and Postpartum****Potential Impairments and Functional Limitations**

Stress, pain, and muscle imbalances from faulty postures

Poor body mechanics; related to lack of knowledge, changing body size and caring for growing child

Lower extremity edema and discomfort from altered circulation, varicose veins

Pelvic floor dysfunction

- urinary or fecal incontinence
- organ prolapse
- hypertonus
- poor episiotomy healing
- poor proprioceptive awareness and disuse atrophy

Abdominal muscle stretch, trauma, and diastasis recti

Potential decrease in cardiovascular fitness

Lack of knowledge of body changes and safe exercises to use during and after pregnancy

Changing body image

Lack of physical preparation (strength, endurance, relaxation) necessary for labor and delivery

Lack of knowledge of appropriate positioning for optimal comfort in labor and delivery

Lack of adequate postpartum rehabilitation

Plan of Care

1. Develop awareness and control of posture during and after pregnancy
2. Learn safe body mechanics.

3. Develop upper extremity strength for the demands of infant care.
4. Promote increased body awareness and a positive body image.
5. Prepare the lower extremities for the demands of increased weight bearing and circulatory compromise.
6. Develop awareness and control of the pelvic floor musculature.

7. Maintain abdominal function and prevent or correct diastasis recti.
8. Promote or maintain safe cardiovascular fitness.
9. Learn about the changes of pregnancy and birth.

10. Learn relaxation skills.
11. Prevent impairments associated with pregnancy

12. Prepare physically for labor, delivery, and postpartum activities.
13. Provide education on safe postpartum exercise progression.
14. Develop awareness of treatment options for pelvic floor dysfunction.

Interventions

1. Stretch, train, and strengthen postural muscles. Posture awareness training.
2. Body mechanics in sitting, standing, lifting, and lying as well as transitions from one position to another. Body mechanics with baby equipment and childcare activities. Positioning options for labor and delivery.
3. Resistive exercises to appropriate muscles.

4. Body awareness and proprioception activities. Posture reinforcement.
5. Use of elastic support stockings. Stretching exercises. Toning and resistive exercises to appropriate muscles.
6. Awareness of isolated pelvic floor muscle contraction and relaxation. Train and strengthen for muscle control, integration with ADLs.
7. Monitor diastasis recti. Diastasis recti exercises. Safe abdominal-strengthening exercises with diastasis recti protection.
8. Safe progression of aerobic exercises.
9. Patient/family instruction. Refer to other disciplines as indicated.
10. Relaxation and breathing techniques.
11. Education about potential problems of pregnancy. Teach prevention techniques and appropriate exercises.
12. Strengthen muscles needed in labor and delivery, and train responses. Teach comfort measures for labor and delivery.
13. Postpartum exercise instruction.

14. Comprehensive approach for prolapse, incontinence, or hypertonus.

BOX 23.3 Suggested Sequence for Exercises Classes

1. General rhythmic activities to “warm up”
2. Gentle selective stretching for postural alignment and for perineum and adductor flexibility
3. Aerobic activity for cardiovascular conditioning (duration/intensity may need to be individualized)
4. Postural exercises; upper/lower extremity strengthening and individualized abdominal exercises
5. Cool-down activities
6. Pelvic floor exercises
7. Relaxation techniques
8. Labor and delivery techniques
9. Educational information
10. Postpartum exercise instruction (e.g., when to begin exercises, how to safely progress, precautions) because the patient may not be attending a postpartum class. Include education regarding body mechanics relative to child care.

sequence for teaching an exercise class is listed in Box 23.3.^{1,54,62,66}

Guidelines and techniques for exercise instruction are included in this section.^{1,20,21,23,40,46,48,54,62,66} Interventions for special situations such as cesarean childbirth and high-risk pregnancy are described in the following sections.

Guidelines for Managing the Pregnant Woman

Suggest that your patients discuss with their physicians any guidelines or restrictions to exercise before engaging in an exercise program, either in a class or on a one-to-one basis. As always, follow your state practice act for physical therapy regarding referral, evaluation, and treatment.

Examination. Individually examine each woman before participation to screen for pre-existing musculoskeletal problems, posture, and fitness level.

Education. Educate your patients that increased uterine cramping *may* occur with moderate activity; this is acceptable as long as the cramping stops when the activity is completed. Teach your patient all exercise guidelines and precautions so that exercises may be carried out safely at home. Include the following:

- Do not exceed 5 minutes of supine positioning at any one time after the first trimester of pregnancy to avoid vena cava compression by the uterus. Educate your patients that compression of the vena cava also occurs with motionless standing. For supine exercise, place a small wedge or rolled towel under the right hip to lessen the effects of uterine compression on abdominal vessels and improve cardiac output. The wedge turns the patient slightly toward the left (Fig. 23.7).¹ This modification is

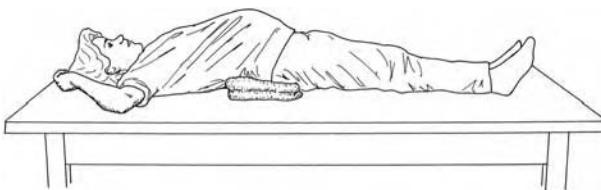

FIGURE 23.7 To prevent inferior vena cava compression when the patient is lying supine, a folded towel can be placed under the right side of the pelvis so the patient is tipped slightly to the left.

also helpful during examination and treatment when the patient is positioned supine.

- To avoid the effects of orthostatic hypotension, instruct the woman to always rise slowly when moving from lying down or sitting to standing positions.
- Discourage breath-holding and avoid activities that tend to elicit the Valsalva maneuver because this may lead to undesirable downward forces on the uterus and pelvic floor. In addition, breath-holding causes stress to the cardiovascular system in terms of blood pressure and heart rate.
- Break frequently for fluid replenishment. The risk of dehydration during exercise is increased in pregnancy.
- Encourage complete bladder emptying before exercise. A full bladder places increased stress on an already weakened pelvic floor.
- Include appropriate warm-up and cool-down activities.
- Modify or discontinue any exercise that causes pain.
- Limit activities in which single-leg weight bearing is required, such as standing leg kicks. Besides possible loss of balance, these activities can promote sacroiliac or pubic symphysis discomfort.

Stretching/flexibility. Choose stretching exercises that are specific to a single muscle or muscle group; do not involve several groups at once. Asymmetric stretching or stretching multiple muscle groups can promote joint instability.

- Avoid ballistic movements.
- Do not allow any joint to be taken beyond its normal physiologic range.
- Use caution with hamstring and adductor stretches. Overstretching of these muscle groups can increase pelvic instability or hypermobility.

Muscle performance. Recommendations and adaptations for pelvic floor training, general strengthening, and cardiopulmonary conditioning during pregnancy and postpartum are described in the exercise section of this chapter. Exercises to prepare for labor and delivery are also described in the exercise section.

Overexertion or complications. Observe participants closely for signs of overexertion or complications. The following signs are reasons to *discontinue exercise* and *contact a physician*^{20,21}:

- Persistent pain, especially in the chest, pelvic girdle, or low back

- Leakage of amniotic fluid
- Uterine contractions that persist beyond the exercise session
- Vaginal bleeding
- Decreased fetal movements
- Persistent shortness of breath
- Irregular heartbeat
- Tachycardia
- Dizziness/faintness
- Swelling/pain in the calf (rule out phlebitis)
- Difficulty in walking

NOTE: Keep in mind when developing intervention programs that most modalities are *contraindicated* in pregnancy. Superficial heat or ice may be beneficial along with manual techniques prenatally to relieve pain/spasm and improve circulation. Muscle energy techniques, with *light* resistance, are often indicated for pelvic instability. Electric stimulation may be added postpartum to modulate pain and to stimulate muscle contractions, respectively. Ultrasound may be helpful in cases of poor episiotomy healing and painful scar tissue.

Recommendations for Fitness Exercise

NOTE: These recommendations are for pregnant women with no maternal or fetal risk factors.^{1,6,13–16,20,21,23,29,39,44,45,48,53,54,57,60,62,66}

- It is strongly recommended for all women to participate in mild to moderate exercise, for both strength and cardiopulmonary benefits, 15 to 30 minutes/session, most days of the week. Individualized programs, based on pre-pregnancy fitness level, are preferable.^{20,21}
- Currently, there are no data in humans suggesting that pregnant women need to decrease their intensity of exercise or lower their target heart rates, but because of decreased oxygen supply, they should modify exercise intensity according to their tolerance. Conventional (age-based) target heart rate zones may be too aggressive for the average pregnant patient. Use of the Borg scale of perceived exertion (Box 23.4) is more appropriate in this population, with exertion between 12 and 14 suggested during pregnancy.^{6,21} When fatigued, a woman should stop exercising and never exercise to exhaustion.
- Activities to avoid include contact sports, anything with a high risk of abdominal trauma or falling, high-altitude activities (greater than 6000 ft), and scuba diving. The fetus is at increased risk of decompression sickness during scuba diving.²¹
- Nonweight-bearing aerobic exercises such as stationary cycling, swimming, or water aerobics will minimize the risk of injury throughout pregnancy and the postpartum period.
- If the woman cannot safely maintain balance because of the shifting and increasing weight, have her modify exercises that could result in falling and injury to herself or the fetus.

BOX 23.4 Borg Rating Scale for Perceived Exertion⁶

| 17—Very hard |
| 18 |
| 19—Very, very hard |
| 20—Exhaustion |

- Adequate caloric intake for nutrition, adequate fluid intake, and appropriate clothing for heat dissipation are critical.
- Resumption of prepregnancy exercise routines during the postpartum period should be gradual. Initiation of pelvic floor exercises immediately postpartum may reduce symptoms and duration of incontinence.^{44,45,57}
- Physiologic and morphologic changes of pregnancy continue for a minimum of 4 to 6 weeks postpartum. Encourage continued joint protection if the woman is nursing. Breastfeeding women can be reassured that moderate exercise does not impair quantity of breast milk or infant growth. There may be a short-term increase in lactic acid secreted in breast milk after exercise; if the baby appears to eat less after an exercise session, this can easily be remedied by nursing before exercise.^{20,21}

Precautions and Contraindications to Exercise

There are some circumstances where exercise is contraindicated or requires very specific restrictions and precautions.^{1,8,20,21,31,48–50,54,60,62,66} Discussion of interventions for patients with high-risk pregnancy are described later in this chapter.

Absolute Contraindications

- Incompetent cervix: early dilation of the cervix before the pregnancy is full term
- Vaginal bleeding, especially second or third trimester
- Placenta previa: placenta is located on the uterus in a position where it may detach before the baby is delivered.
- Multiple gestation with risk of premature labor.^{20,49}
- Pre-eclampsia: pregnancy-induced hypertension
- Rupture of membranes: loss of amniotic fluid before the onset of labor.

- Premature labor: labor beginning before the 37th week of pregnancy
- Maternal heart disease, thyroid disease or serious respiratory disorder
- Maternal type 1 diabetes
- Intrauterine growth retardation

Precautions to Exercise

The woman with one or more of the following conditions may participate in an exercise program under close observation by a physician^{1,8,48} and a therapist as long as no further complications arise. Exercises may require modification.^{20,21}

- Gestational diabetes
- Severe anemia
- Systemic infection
- Extreme fatigue
- Musculoskeletal complaints and/or pain
- Overheating
- Extreme obesity or extreme underweight/eating disorder
- Diastasis recti

Critical Areas of Emphasis and Selected Exercise Techniques

Posture Exercises

The growing fetus places added stress on postural muscles as the center of gravity shifts forward and upward and the spine shifts to compensate and maintain stability. In addition, after delivery, activities involving holding and caring for the baby stress postural muscles. Muscles that require emphasis for strengthening and stretching are listed. General exercise descriptions are listed in respective chapters. Subsequent sections describe adaptations of exercises specific for the pregnant woman.

Stretching (with Caution)

Flexibility and stretching exercises are implemented with caution. Remember that connective tissues and supporting joint structures are at increased risk of injury from forceful stresses during pregnancy and the immediate postpartum period because of hormonal changes.

- Upper neck extensors and scalenes (Chapter 16)
- Scapular protractors, shoulder internal rotators, and levator scapulae (Chapter 17)
- Low back extensors (Chapter 16)
- Hip flexors, adductors, and hamstrings (Chapter 20). Caution: women with pelvic instabilities should not overstretch.
- Ankle plantarflexors (Chapter 22)

Strengthening (Low Intensity)

- Upper neck flexors, lower neck and upper thoracic extensors (Chapter 16)
- Scapular retractors and depressors (Chapter 17)
- Shoulder external rotators (Chapter 17)
- Trunk flexors (abdominals), particularly lower abdominals, with modifications noted below (Chapter 16)

- Hip extensors (Chapter 20)
- Knee extensors (Chapter 21)
- Ankle dorsiflexors (Chapter 22)

Corrective Exercises for Diastasis Recti

A check for diastasis recti must always be performed before initiating abdominal exercise. Only the corrective exercises (head lift or head lift with pelvic tilt) should be used until the separation is corrected to 2 cm (two finger-widths) or less.⁴⁸

Head lift

Patient position and procedure: Hook-lying with her hands crossed over midline at the level of the diastasis for support. Have the woman exhale and lift only her head off the floor or until the point just before a bulge appears. At the same time, her hands should gently approximate the rectus muscles toward midline (Fig. 23.8). Then have the woman lower her head slowly and relax. This exercise emphasizes the rectus abdominis muscle and minimizes the obliques. Some women may not be able to successfully reach over their abdomen. In this case, the use of a sheet wrapped around the trunk at the level of the separation can be used to provide support and approximation.⁴⁸

FIGURE 23.8 Corrective exercise for diastasis recti. The patient gently approximates the rectus muscle toward the midline by pulling with the crossed arms.

Head Lift with Pelvic Tilt

Patient position and procedure: Hook-lying. The arms are crossed over the diastasis for support as above. Have the patient slowly lift her head off the floor while approximating the rectus muscles and performing a posterior pelvic tilt, then slowly lower her head and relax. All abdominal contractions should be performed with an exhalation so that intra-abdominal pressure is minimized.

Abdominal Muscle Exercises

As pregnancy progresses, the abdominals will undergo extreme overstretching. Therefore, exercise must be adapted to meet the needs of each individual, and periodic re-assessment must be done (approximately every 4 weeks during pregnancy). The following exercises progress from least to most strenuous.

NOTE: Keep in mind the 5-minute time limit for supine positioning when prescribing abdominal exercises after 13 weeks' gestation.

Pelvic Tilt Exercise

Patient position and procedure: Quadruped (on hands and knees). Instruct the patient to perform a posterior pelvic tilt. While the patient keeps her back straight, have her isometrically tighten (imagine drawing in) the lower abdominals and hold, then release and perform an anterior tilt through very small range.

- For additional exercise, while holding the abdominals in and the back straight, have the woman laterally flex the trunk to the right (side-bend to the right), looking at the right hip, then reverse to the left.
- Have the woman practice pelvic tilt exercises in a variety of positions, including side-lying and standing.

Leg Sliding

Patient position and procedure: Hook-lying with pelvis in a posterior tilt. Instruct the woman to hold the pelvic tilt as she slides one foot along the floor until the leg is straight or to the point at which she is unable to maintain the pelvic tilt. Have her slowly slide the leg back to the starting position, then repeat with the other leg. Breathing should be coordinated with the exercise so that abdominal contractions occur with exhalation.

Trunk Curls

- Curl-downs and curl-ups are classic abdominal exercises for rectus abdominis strengthening and can be used if tolerated and no diastasis recti is present. Have a pregnant patient protect the linea alba with crossed hands (see Fig. 23.8) while performing trunk curls.
- Diagonal curls are carried out to strengthen the oblique muscles. Have the woman lift one shoulder toward the outside of the opposite knee as she curls up and down and protects the linea alba with crossed hands.

Modified Bicycle

Patient position and procedure: The woman is supine with one lower extremity flexed and the other partially extended. The lower abdominals stabilize the pelvis as the lower extremities flex and extend in an alternating pattern as if cycling. The further the lower extremities extend, the greater the resistance. In order to not strain the back, the woman must keep it flat against the floor by controlling the arc of the cycling pattern.

PRECAUTION: Leg-lowering exercises cause excessive strain on the low back and should not be performed during pregnancy; they may be resumed postpartum with the following precautions and modifications. The legs should be lowered only through the range in which control of the posterior pelvic tilt and flattening of the low back is maintained. If low back strain is felt or if the lumbar spine begins to arch, this exercise should not be performed. The pull of the psoas major may cause a shear force on the lumbar vertebrae, and the supporting ligaments may be strained.

Stabilization Exercises

Exercises for activating the abdominal and low back muscles and developing control of their stabilizing function in

the lumbar spine and pelvis are described in Chapter 16. They should be initiated and progressed at the intensity that the woman is able to safely control. Slow, controlled breathing is emphasized while developing the stabilizing function of the muscles.

Precautions

- Because the trunk muscles are contracting isometrically in many of these abdominal exercises, there is a tendency to hold the breath; this is detrimental to the blood pressure and heart rate. Caution the woman to maintain a relaxed breathing pattern and exhale during the exertion phase of each exercise.
- If diastasis recti is present, adapt the stabilization exercises to protect the linea alba as described for the corrective curl-up. Any progression of postpartum abdominal strengthening exercises should be postponed until the diastasis has been corrected to two fingerwidths or less.

Pelvic Motion Training

These exercises are helpful in cases of postural back pain; they are beneficial for improving proprioceptive awareness as well as lumbar, pelvic, and hip mobility.²⁴

“The Pelvic Clock”

Patient position and procedure: Hook lying. The patient's legs may move slightly while performing this exercise. Ask the woman to visualize the face of a clock on her lower abdomen. The umbilicus is 12 o'clock and the pubic symphysis is 6 o'clock.

- Have her begin with gentle movements from 12 to 6 o'clock (the basic pelvic tilt exercise).
- Then ask her to move from 3 o'clock (weight shifted to left hip) to 9 o'clock (weight shifted to the right hip).
- Then move in a clockwise manner from 12 to 3 to 6 to 9 and then back to 12 o'clock.

With practice, this will become a very smooth and rhythmical movement and will not require such concentration on each number of the clock. Continue relaxed breathing throughout the exercise and do not force any part of the movement. If the patient has difficulty with the motion, make the clock “smaller” until coordination improves.²⁴

Pelvic Clock Progressions

- Use the visual imagery of cutting the face of the clock in half so that there is a right side and a left side, or a top half and a bottom half. Have the woman move her pelvis through the arc on the one side and back through the middle of the clock, and then move the pelvis through the opposite side and back through the middle. Initially, the woman may notice asymmetry when comparing the halves; this will improve with time.
- Once the patient understands and is able to perform the clockwise pattern have her do counterclockwise motions with all of the above activities, and then progress the exercises to the sitting position.²⁴

Modified Upper and Lower Extremity Strengthening

As the abdomen enlarges, it becomes impossible to comfortably assume the prone position. Exercises that are usually performed in the prone position must be modified.

Standing Push-Ups

Patient position and procedure: Standing, facing a wall, feet pointing straight forward, shoulder-width apart, and approximately an arm-length away from the wall. The palms are placed on the wall at shoulder height. Have the woman slowly bend the elbows, bringing her upper body close to the wall, maintaining a stable pelvic tilt, and keeping the heels on the floor. Her elbows should be shoulder height. She then slowly pushes with her arms, bringing the body back to the original position.

Supine Bridging

Patient position and procedure: Supine in the hook-lying position. Have the patient perform a posterior pelvic tilt and then lift her pelvis off the floor. She can do repetitive bridges, or hold the bridge position and alternately flex and extend her upper extremities to emphasize the stabilization function of the hip extensors and trunk musculature (see Fig. 20.21).

Quadruped Leg Raising

Patient position and procedure: On hands and knees (hands may be in fists or palms open and flat). Instruct the woman to first perform a posterior pelvic tilt, and then slowly lift one leg, extending the hip to a level no higher than the pelvis while maintaining the posterior pelvic tilt (Fig. 23.9). She then slowly lowers the leg and repeats with the opposite side. The knee may remain flexed or can be straightened throughout the exercise. Monitor this exercise and discontinue if there is stress on the sacroiliac joints or

ligaments. If the woman cannot stabilize the pelvis while lifting the leg, have her just slide one leg posteriorly along the floor and return (see Fig. 16.29A).

Modified Squatting

Wall slides and supported squatting exercises are used to strengthen the hip and knee extensors for good body mechanics and also to help stretch the perineal area for flexibility during the delivery process. In addition, if the woman wishes to use squatting for labor and delivery, the muscles *must* be strengthened and endurance trained in advance.

- *Patient position and procedure:* Standing with back against a wall and her feet shoulder-width apart. Have the woman slide her back down the wall as her hips and knees flex only as far as is comfortable, then slides back up (see Fig. 20.24).

- *Patient position and procedure:* Standing with feet shoulder-width apart or wider, facing a counter, chair, or wall on which the woman can rest her hands and/or forearms for support. Have the woman slowly squat as far as is comfortable, keeping knees apart and over the feet and keeping the back straight. To protect her feet, she should wear shoes with good arch support. A woman with knee problems should perform only partial range of the squat. For optimal success with squatting during stage 2 of labor (pushing), increase the duration of the squat gradually to 60 to 90 seconds as tolerated.

Scapular Retraction

When scapular retraction exercises become difficult in the prone position, the woman should continue strengthening in the sitting or standing position (see Figs. 17.45 and 17.46).

Perineum and Adductor Flexibility

In addition to the modified squatting exercises described in the preceding text, these flexibility exercises prepare the legs and pelvis for childbirth.^{48,54,62}

Self-Stretching

- *Patient position and procedure:* Supine or side-lying. Instruct the patient to abduct the hips and pull the knees toward the sides of her chest and hold the position for as long as is comfortable (at least to the count of 10).

- *Patient position and procedure:* Sitting on a short stool with the hips abducted as far as possible and feet flat on the floor. Have her flex forward slightly at the hips (keeping the back straight), or have her gently press her knees outward with her hands for an additional stretch.

Pelvic Floor Awareness, Training, and Strengthening

Pelvic floor muscle training is a valuable modality regardless of a patient's presentation or cause of symptoms.^{3,9,34,44,45,57,62,66} The majority of women are unfamiliar with the presence of the pelvic floor muscles, and even less aware of their function and role in daily activities. Inter-

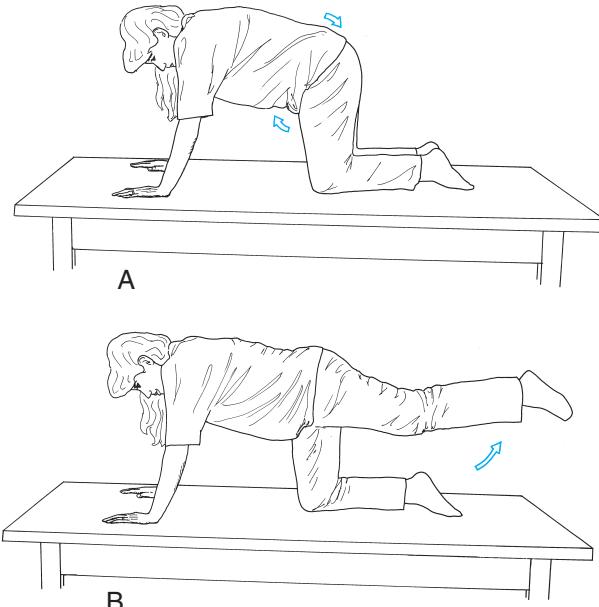

FIGURE 23.9 All-fours leg-raising. (A) Patient assumes quadruped position with posterior pelvic tilt. (B) Leg is raised only until it is in line with the trunk.

vention is slowly becoming more common during the childbearing years owing to the stress of pregnancy, labor, and delivery on the pelvic floor. Pelvic floor anatomy, function, and dysfunction are described in the first section of this chapter.

Focus on Evidence

A Cochrane review of 43 randomized trials concluded that pelvic floor muscle training is an effective treatment for stress or mixed urinary incontinence, and is better than no treatment or placebo.³⁴ Functional improvements (decreased urinary incontinence and improved pelvic floor strength) have been noted in late pregnancy and from 3 to 12 months postpartum in a number of studies.^{44,45,57} For optimal outcomes, pelvic floor contractions should be incorporated into routine ADLs, particularly activities that are “triggers” for leakage due to increased intra-abdominal pressure; used for stabilization prior to coughing or sneezing; and continued for life-long health benefits.³⁴

Begin pelvic floor exercise training with an empty bladder. Gravity-assisted positioning (hips higher than the heart, such as supported bridge or elbows/knees position) may be indicated initially for some women with extreme weakness and proprioceptive deficits. Positional changes are introduced as strength and awareness improve (supine, side-lying, quadruped, sitting, standing).

Contract–Relax

Instruct the woman to tighten the pelvic floor as if attempting to stop urine flow or hold back gas. Hold for 3 to 5 seconds and relax for at least the same length of time. Repeat up to 10 times (if performed with proper technique). With significant coordination dysfunction or fatigue, substitution with the gluteals, abdominals, or hip adductors may occur. To maximize proprioception and motor learning, it is important to emphasize isolation of the pelvic floor and avoid the substitute muscle actions. In addition, watch for Valsalva; if necessary, have the woman count out loud to encourage normal breathing patterns.

Quick Contractions

Have the woman perform quick, repeated contractions of the pelvic floor muscles while maintaining a normal breathing rate and keeping accessory muscles relaxed. Try for 15 to 20 repetitions per set. This type II fiber response is important to develop in order to withstand pressure from above, especially with coughing or sneezing.

“Elevator” Exercise

Instruct the woman to imagine riding in an elevator. As the elevator goes up from one floor to the next, she contracts the pelvic floor muscles a little more. As strength and awareness improve, add more “floors” to the sequence of the contraction. Another way to increase difficulty is by asking the woman to relax the muscles gradually, as if the elevator were descending one floor at a time. This component requires an eccentric contraction and is very challenging.

Pelvic Floor Relaxation

- Instruct the woman to contract the pelvic floor as in the strengthening exercise, then allow total voluntary release and relaxation of the pelvic floor. Use of the “elevator” imagery should also be emphasized, with particular attention to taking the elevator to the “basement.”
- Pelvic floor relaxation is closely linked with effective breathing and relaxation of the facial muscles. Instruct the woman to concentrate on a slow, deep breath and allow the pelvic floor to completely relax. Relaxation of the pelvic floor is extremely important during stage 2 of labor and vaginal delivery.^{28,48,62}
- Chronic inability to relax the pelvic floor muscles may lead to impairments such as hypertonus, pain with intercourse, or voiding dysfunction. Please refer to the earlier information on pelvic pain syndromes. If the patient presents with these symptoms, increase the rest time between pelvic floor contractions and sets; also use submaximal contractions to improve awareness of tension vs relaxation. Use of surface EMG for muscle re-education is invaluable with these impairments for increasing awareness of holding patterns, pain inhibition, and resting tone.

Relaxation and Breathing Exercises for Use During Labor

Developing the ability to relax requires awareness of stress and muscle tension. Techniques of conscious relaxation allow the individual to control and cope with a variety of imposed stresses by being mentally alert to the task at hand while relaxing tense muscles that are superfluous to the activity (see Chapter 4). This is particularly important during labor and delivery when there are times that the woman should relax and allow the physiologic processes to occur without excessive tension in unrelated muscles.⁴⁸ Additional relaxation techniques for managing stress are described in Chapter 14. The following guidelines are most effective for the pregnant woman if consistently practiced in preparation for labor and delivery.

Visual Imagery

Use instrumental music and verbal guidance. Instruct the woman to concentrate on a relaxing image such as the beach, mountains, or a favorite vacation spot. Suggest that she focus on the same image throughout the pregnancy so that the image can be called up to the conscious level when recognizing the need to relax during labor.

Muscle Setting

- Have the woman lie in a comfortable position.
- Have her begin with the lower body. Instruct her to gently contract and then relax first the muscles in the feet, then legs, thighs, pelvic floor, and buttocks.
- Next progress to the upper extremities and trunk, then to the neck and facial muscles.
- Reinforce the importance of remaining awake and aware of the contrasting sensations of the muscles.

Emphasize “softening” of the muscles as the session continues.

- Add deep, slow, relaxed breathing to the routine.

Selective Tension

Progress the training by emphasizing awareness of muscles contracting in one part of the body while remaining relaxed in other parts. For example, while she is tensing the fist and upper extremity, the feet and legs should be limp. Reinforce the comparison between the two sensations and the ability to control both tension and relaxation.

Breathing

- General breathing techniques are described in Chapter 25. Slow, deep diaphragmatic breathing is the most efficient method for exchange of air to use with relaxation techniques and for controlled breathing during labor.
- Teach the woman to relax the abdomen during inspiration so that it feels as though the abdominal cavity is “filling up.” During exhalation, the abdominal cavity becomes smaller; active contraction of the abdominal muscles is not necessary with relaxed breathing.
- To prevent hyperventilation, emphasize a slow rate of breathing. Caution the woman to decrease the intensity of the breathing if she experiences dizziness or feels tingling in the lips and fingers.

Relaxation and Breathing During Labor

First Stage

As labor progresses, the contractions of the uterus become stronger, longer, and closer together. Relaxation during the contractions becomes more difficult. Provide the woman with suggested techniques to assist in relaxation.⁴⁹

- Ensure the woman has emotional support from the father, family member, or special friend to provide encouragement and assist with overall comfort.
- Seek comfortable positions including walking, hands and knees, lying on pillows, or sitting on a Swiss ball; include gentle repeated motions such as pelvic rocking.
- Breathe slowly with each contraction; use the visual imagery and relax with each contraction. Some women find it helpful to focus their attention on a specific visual object. Other suggestions include singing, talking, or moaning during each contraction to prevent breath-holding and encourage slow breathing.
- During transition (near the end of the first stage) there is often an urge to push. Teach the woman to use quick blowing techniques, using the cheeks, not the abdominal muscles, to overcome the desire to push until the appropriate time.
- Massage or apply pressure to any areas that hurt such as the low back. Using the hands may help distract the focus from the contractions.
- Apply heat or cold for local symptoms; wipe the face with a wet wash cloth.

Second Stage

Once dilation of the cervix has occurred, the woman may become active in the birth process by assisting the uterus during a contraction in pushing the baby down the birth canal.⁴⁸ Teach her the following techniques:

- While bearing down, take in a breath, contract the abdominal wall, and slowly breathe out. This will cause increased pressure within the abdomen along with relaxation of the pelvic floor.

PRECAUTION: Tell the woman that if she holds her breath, there will be increased tension and resistance in the pelvic floor. In addition, exertion with a closed glottis, known as the Valsalva maneuver, has adverse effects on the cardiovascular system.

- For maximum efficiency, maintain relaxation in the extremities, especially the legs and perineum. Keeping the face and jaw relaxed assists with this.
- Between contractions, perform total body relaxation.
- As the baby is delivered, just “let go” and breathe with light pants or groans to relax the pelvic floor as it stretches.

Unsafe Postures and Exercises During Pregnancy

Knee–chest position with buttocks elevated above heart level. An air embolism, although rare, can occur when the buttocks are elevated and the uterus moves superiorly. The pressure change causes air to be introduced into the vagina and uterus, where it can enter the circulatory system through the open placental site. A pregnant woman is at risk *only* if bleeding or other symptoms of early placental detachment are present. The pregnant woman should be instructed not to assume this position for 6 weeks postpartum.^{40,46}

Bilateral straight-leg raising. This exercise typically places more stress on the abdominal muscles and low back than they can tolerate. It can cause back injury or diastasis recti, and therefore should not be attempted.

“Fire hydrant” exercise. This exercise is performed on hands and knees, and one hip is abducted and externally rotated at a time (the “image” of a dog at a fire hydrant). If the leg is elevated too high, the sacroiliac joint and lumbar vertebrae can be stressed. The exercise can be performed safely if hip abduction remains within the physiologic range (Fig. 23.10). It should be avoided by any woman who has pre-existing sacroiliac joint symptoms or if these symptoms develop.

All-fours (quadruped) hip extension. This exercise can be performed safely only as explained earlier in this chapter (see Fig. 23.9). It becomes unsafe and can cause low back pain when the leg is elevated beyond the physiologic

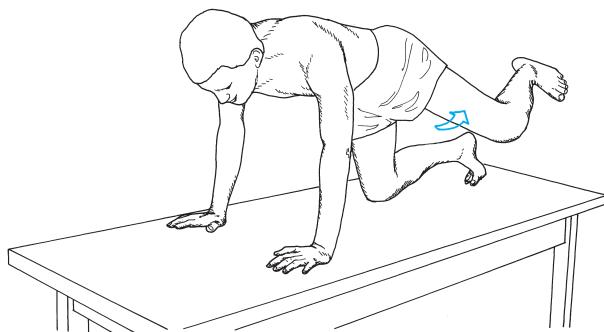

FIGURE 23.10 The fire hydrant is a potentially damaging exercise. To do this exercise correctly, the individual must stabilize the pelvis midrange, then stop the abduction external rotation motion when the hip has completed its range. The leg should not be “kicked as high as possible,” or stress to the hip, sacroiliac joint, and lumbar spine results.

range of hip extension, causing the pelvis to tilt anteriorly and the lumbar spine to hyperextend.

Unilateral weight-bearing activities. Weight bearing on one leg (which includes slouched standing with the majority of weight shifted to one leg and the pelvis tilted down on the opposite side) during pregnancy can cause sacroiliac joint irritation and should be avoided by women with pre-existing sacroiliac joint symptoms. Unilateral weight bearing also can cause balance problems because of the increasing body weight and shifting of the center of gravity. This posture becomes a significant problem postpartum when the woman carries her growing child on one hip. Any asymmetries become accentuated, and painful symptoms may develop.

Exercise Critical to the Postpartum Period

After an uncomplicated vaginal delivery, exercise can be started as soon as the woman feels able to exercise, and has been cleared by her physician or midwife.^{1,20,21,44,45,48,57}

Pelvic floor strengthening. Exercises should be resumed as soon after the birth as possible. These exercises may increase circulation and aid healing of lacerations or episiotomy. Combining pelvic floor contractions with feeding or changing the baby may help them become integrated into the daily routine.

Diastasis recti correction. The testing procedure for diastasis recti was described earlier in this chapter. The mother should be taught this test and encouraged to perform it on the third postpartum day. Corrective exercises (see Fig. 23.8) should continue until the separation is two finger-widths or less. At that time, more vigorous abdominal exercise can be resumed.

Aerobic and strengthening exercises. As soon as the woman feels able, cardiopulmonary exercise can be

resumed with gradual increasing intensity. A physical examination is suggested before the onset of vigorous exercise or sport-specific training.

PRECAUTIONS: Since the woman may not be seen for exercise instruction after the delivery, inform her of the following precautions:

- If bleeding increases or turns bright red, exercise should be postponed. Tell her to rest more and allow a longer recovery time.
- Joint laxity may be present for some time after delivery, especially if breastfeeding. Precautions should be taken to protect the joints as described previously.^{54,62,66} Adequate warm-up and cool-down time is important.
- Avoid the prone knee–chest position for at least 6 weeks postpartum because of the risk of air embolism.^{40,46}

CESAREAN CHILDBIRTH

A **cesarean section** is the delivery of a baby through an incision in the abdominal wall and uterus rather than through the pelvis and vagina.^{31,50} General, spinal, or epidural anesthesia may be used.

Significance to Physical Therapists

Cesarean section (C-section) delivery is now at an all-time high in the United States. In 2004, the rate was 29.1% of births, totaling 1.2 million deliveries.⁶⁹ The cesarean birth rate in the United States has fluctuated greatly over the last three to four decades, in part depending on the type of hospital and the population it serves. Since the early 1990s, the American College of Obstetricians and Gynecologists (ACOG) has discouraged repeat C-sections as routine practice; however, historically more than 33% of all Cesareans are repeat procedures. The Vaginal Birth After Cesarean (VBAC) movement has been quite visible, as historically more than one-third of all C-sections are repeat procedures. Recently, the perceived “convenience” of a C-section is becoming a factor, leading to increases in not only repeat but also elective C-sections. In addition to the appeal of scheduling a delivery date, there is some evidence that cesarean delivery may aid in prevention of future pelvic floor dysfunction.⁶¹ Although the overall number of women choosing Cesarean delivery remains small, from 2001 to 2003 the rate of elective C-sections in first-time mothers grew 36%.⁶⁸

Pregnant women need to be informed as to the risks and benefits of each choice in order to make informed decisions. These statistics are the focus of much discussion within obstetrics, and because of this high incidence and new trends, physical therapists must be prepared to address these issues with all pregnant patients.^{31,41,48–51,53,55,62}

Women who have had Cesarean delivery may still require pelvic floor rehabilitation. Many women experi-

ence a lengthy labor, including prolonged second stage (pushing), before a C-section is deemed necessary. Therefore, the pelvic floor musculature and the pudendal nerves are not always spared the stress of labor. Also, pregnancy itself creates significant strain on the pelvic floor musculature and tissues.

Postpartum intervention for the woman who has had cesarean delivery is similar to that of the woman who has had a vaginal delivery. However, a C-section is major abdominal surgery with all the risks and complications of such surgeries, and therefore the woman may also require general postsurgical rehabilitation.^{31,50,62} Impairments and management guidelines are summarized in Box 23.5.

All childbirth preparation classes do not adequately educate and prepare couples for the experience of a cesarean delivery. As a result, the woman with an unplanned C-section frequently feels as if her body has failed her, causing her to have more conflicting emotions than a woman who has experienced a vaginal delivery.

BOX 23.5 MANAGEMENT GUIDELINES—Postcesarean Section

Potential Impairments and Functional Limitations:

- Risk of pulmonary or vascular complications
- Postsurgical pain and discomfort
- Development of adhesions at incisional site
- Faulty posture
- Pelvic floor dysfunction
 - urinary or fecal incontinence
 - organ prolapse
 - hypertonus
 - poor proprioceptive awareness and disuse atrophy
- Abdominal weakness, diastasis recti
- General functional restrictions of post delivery

Plan of Care

1. Improve pulmonary function and decrease the risk of pneumonia.
2. Decrease incisional pain with coughing, movement, or breast feeding.
3. Prevent postsurgical vascular complications.
4. Enhance incisional circulation and healing; prevent adhesion formation.
5. Decrease postsurgical discomfort from flatulence, itching, or catheter.
6. Correct posture.
7. Prevent injury and reduce low back pain.
8. Prevent pelvic floor dysfunction.
9. Develop abdominal strength.

Suggested Activities for the Patient Following a Cesarean Section

Exercises

- Instruct the woman during her pregnancy in all appropriate exercises, if she is able.
- Instruct the woman to begin preventive exercises as soon as possible during the recovery period.^{31,48,49}
 - Initiate ankle pumping, active lower extremity ROM, and walking to promote circulation and prevent venous stasis.
 - Initiate pelvic floor exercises to regain tone and control of the muscles of the perineum.
 - Deep breathing and coughing or huffing is used to prevent pulmonary complications (see instructions below).
- Progress abdominal exercises slowly. Check for diastasis recti and protect the area of the incision to improve comfort. Initiate nonstressful muscle-setting techniques

Interventions

1. Breathing instruction, coughing and/or huffing.
2. Postoperative TENS; support incision with pillow when coughing or breastfeeding.
Incisional support with pillow or hands with movement
Education regarding incisional care and risk of injury.
3. Active leg exercises. Early ambulation.
4. Gentle abdominal exercise with incisional support. Scar mobilization and friction massage.
5. Positioning instruction, massage, and supportive exercises.
6. Posture instruction, particularly regarding child care.
7. Instruction in incisional splinting and positioning for ADLs. Body mechanics instruction.
8. Pelvic floor exercises. Education regarding risk factors and types of pelvic floor dysfunction.
9. Abdominal exercise progression, including corrective exercises for diastasis recti.

and progress as tolerated, based on the degree of separation.^{31,48,49}

- Teach posture correction as necessary. Retrain postural awareness and help realign posture with indicated therapeutic exercise. Develop control of the shoulder girdle muscles as they respond to the increased stress of caring for the new baby.
- Reinforce the value of deep diaphragmatic breathing techniques for pulmonary ventilation, especially when exercising, and relaxed breathing techniques to relieve stress and promote relaxation.
- The woman should wait at least 6 to 8 weeks before resuming vigorous exercise. Emphasize the importance of progressing at a safe and controlled pace and not expecting to begin at her prepregnancy level.

Coughing or Huffing

Coughing is difficult because of incisional pain. An alternative is huffing.⁴⁸ A huff is an outward breath caused by the upper abdominals contracting up and in against the diaphragm to push air out of the lungs. The abdominals are pulled up and in, rather than pushed out, causing decreased pressure in the abdominal cavity and less strain on the incision. Huffing must be done quickly to generate sufficient force to expel mucus. Instruct the patient to support the incision with a pillow or the hands and say “ha” forcefully and repetitively while contracting the abdominal muscles.

Interventions to Relieve Intestinal Gas Pains

- **Abdominal massage or kneading.** Have the patient lie supine or on the left side. This is very effective and typically done with either long or circular strokes. Begin on the right side at the ascending colon, stroking upward, then stroke across the transverse colon from right to left and down the descending colon, then finish with an “S” stroke along the sigmoid colon.
- **Pelvic tilting and/or bridging.** These can be done in conjunction with massage.
- **Bridge and twist.** Have the patient maintain a position of bridging while twisting her hips to the right and left. This position may also facilitate air embolism and therefore should be used with caution in the early postpartum period.
- **Partial abdominal curl-up.** Avoid strain to the linea alba.

Scar Mobilization

Cross-friction massage should be initiated around the incision site as soon as sufficient healing has occurred. This will minimize adhesions that may contribute to postural problems and back pain.

HIGH-RISK PREGNANCY

A **high-risk pregnancy** is one that is complicated by disease or problems that put the mother or fetus at risk for illness or death. Conditions may be pre-existing, induced by pregnancy, or caused by an abnormal physiologic reaction

during pregnancy.³² The goal of medical intervention is to prevent preterm delivery, usually through use of bed rest, restriction of activity, and medications, when appropriate. Various factors may lead to high-risk pregnancies; specialized care is required for successful outcomes.^{32,36,53–55,62}

High-Risk Conditions

Preterm rupture of membranes. The amniotic sac breaks, and amniotic fluid is lost before onset of labor. This can be dangerous to the fetus if it occurs before fetal development is complete. Labor may begin spontaneously after the membranes rupture. The chance for fetal infection also increases when the protection of the amniotic sac is lost. Leakage of amniotic fluid is an indication for immediate medical attention.

Premature onset of labor. Labor that begins before 37 weeks of gestation or before completion of fetal development is considered premature. Fetal life is endangered if delivery occurs too early.

Incompetent cervix. An incompetent cervix is the painless dilation of the cervix that occurs in the second trimester (after 16 weeks' gestation) or early in the third trimester of pregnancy. This may lead to premature membrane rupture and delivery of a fetus too small to survive.

Placenta previa. The placenta attaches too low on the uterus, near the cervix. As the cervix dilates, the placenta begins to separate from the uterus and may present before the fetus, thus endangering fetal life. The primary symptom is intermittent, recurrent, or painless bleeding that increases in intensity.

Pregnancy-related hypertension or pre-eclampsia. Characterized by hypertension, protein in the urine, and severe fluid retention, pre-eclampsia can progress to maternal convulsions, coma, and death if it becomes severe (eclampsia). It usually occurs in the third trimester and disappears after birth. The cause is not understood.

Multiple gestation. More than one fetus forms. Complications of multiple gestation include premature onset of labor and birth, increased incidence of perinatal mortality, lower birth weight infants, and increased incidence of maternal complications (e.g., hypertension).

Diabetes. Diabetes can be present before pregnancy or may occur as a result of the physiological stress of pregnancy. **Gestational diabetes**, which presents in pregnancy, affects 4% to 7% of pregnant women and usually disappears after pregnancy, but there remains a greater tendency for development of the disease at some future time.

Unlike many of the previously discussed high-risk conditions, women with gestational diabetes may be appropriate candidates for more traditional physical therapy treatment. Supervised, individualized exercise programs are excellent options for the woman with gestational diabetes. Exercise may actually prevent gestational diabetes in obese pregnant women.²⁰ In particular, recumbent bicy-

cling or arm ergometer exercises have been shown to stabilize and lower glucose levels.⁵³

Focus on Evidence

In a randomized study of overweight women with gestational diabetes ($N = 32$), the control group was treated with diet alone, while the remaining women also participated in circuit resistance training. The diet-plus-exercise group were able to postpone the use of insulin therapy until later in the pregnancy ($p < .05$) and were also prescribed less insulin overall ($p < .05$) than the diet-alone group.⁸

Management Guidelines and Precautions for High-Risk Pregnancies

All exercise programs for high-risk populations should be individually established based on diagnosis, limitations, physical therapy examination and evaluation, and consultation with the physician. Activities must address patient needs but should not further complicate the condition.^{54,62}

BOX 23.6

MANAGEMENT GUIDELINES—High-Risk Pregnancy

Potential Impairments and Functional Limitations:

Primary functional limitation is inability to be out of bed and prolonged static positioning which contributes to the following:

Joint stiffness and muscle aches

Muscle weakness and disuse atrophy

Vascular complications including risk of thrombosis and decreased uterine blood flow

Decreased proprioception in distal body parts

Constipation caused by lack of exercise

Postural changes

Boredom

Emotional stress; patient may be at risk of losing the baby

Guilt from the belief that some activity caused the problem or that the patient did not take good enough care of herself

Anxiety about her home situation, older children, finances or the impending birth

Plan of Care

1. Decrease stiffness.
2. Maintain muscle length and bulk.
3. Maximize circulation; prevent deep-vein thrombosis.
4. Improve proprioception.
5. Improve posture within available limits.
6. Relieve boredom.
7. Enhance relaxation.
8. Prepare for delivery.
9. Enhance postpartum recovery.

Interventions

1. Positioning instructions; assess for supports. Facilitation of joint motion in available range.
2. Stretching and strengthening exercises within limits imposed by the physician.
3. Ankle pumping; ROM.
4. Movement activities for as many body parts as possible.
5. Posture instruction, modified as necessary based on allowed activity level. Bed mobility and transfer techniques if able (avoid Valsalva).
6. Vary activities and positioning for exercises; encourage interaction with others on bed rest. (<http://www.sidelines.org>)
7. Relaxation techniques/stress management.
8. Childbirth education, breathing training, and exercises to assist and prepare for labor.
9. Exercise instruction and home program for postpartum period. Body mechanics instruction, particularly related to child care.

Management guidelines for the woman who is confined to bed because of her high-risk status are summarized in Box 23.6.

Develop good rapport with the patient and instill trust. Closely monitor the patient during all activities; re-evaluate her after each treatment and note any changes. It is also important to teach the patient self-monitoring techniques so that she will be alert to adverse reactions and respond appropriately.

- Prolonged static positioning is a primary concern. The position of choice for the high-risk patient is left side-lying, which is optimal for reducing pressure on the inferior vena cava and for maximizing cardiac output, thereby enhancing maternal and fetal circulation.
- Some exercises, especially abdominal exercises, may stimulate uterine contractions. If this occurs, modify or discontinue them.
- Monitor and report any uterine contractions, bleeding, or amniotic fluid loss.

- Do not allow the Valsalva maneuver to occur. Avoid any activities that increase intra-abdominal pressure. Body mechanics and postural instruction will stimulate abdominal contractions, so be sure the patient does not strain and closely monitor for adverse symptoms.
- Keep the exercises simple. Have the patient do them slowly, smoothly, and with minimal exertion.
- Many high-risk pregnancies result in cesarean deliveries, so educate the woman about cesarean delivery rehabilitation.
- Incorporate maximum muscle efficiency into each movement.
- Teach the patient self-monitoring techniques.

Suggestions for Exercise Programs with High-Risk Pregnancies

The following are adaptations of interventions that have already been described that should be considered for the bed-bound patient with a high-risk pregnancy.^{53,54,62}

Positioning

- Left side-lying to prevent vena cava compression, enhance cardiac output, and decrease lower extremity edema
- Pillows between the knees and under the abdomen
- Supine positioning for short periods, with a wedge placed under the right hip to decrease inferior vena cava compression (see Fig. 23.7)
- Modified prone positioning (side-lying, partially rolled toward prone, with pillow under abdomen) to decrease low back discomfort and pressure

Range of Motion (ROM)

- Active ROM of all joints.
- Motions should be slow, nonstressful, and through the full range if possible.
- Teach in a gravity-neutral position if antigravity ROM is too stressful.
- Individualize the number of repetitions and frequency to the woman's condition.
- Include the following exercises with the patient supine (with wedge under the right hip) or side-lying:

- Alternate knee to chest
- Ankle pumping and ankle circles
- Shoulder, elbow, and finger flexion and extension; reach to ceiling; arm circles
- Unilateral straight-leg raise in supine or side-lying position
- Unilateral active ROM in diagonal patterns for the upper and lower extremities
- Lower extremity abduction and adduction
- Pelvic tilt, bridging, gluteal setting
- Abdominal exercises (check for diastasis); these should be very low intensity and closely monitored.
- Pelvic floor exercises
- Neck motions: look up/down, turn head left/right.
- Backward shoulder circles

Ambulation/Standing

- Almost always contraindicated; when allowed, usually will be only to use the bathroom
- Good posture in ambulation
- Tip-toe or heel walking
- Gentle, partial-range squatting
- Lower extremity rotation

Relaxation Techniques, Bed Mobility and Transfer Activities

- Relaxation as in the uncomplicated pregnancy
- Moving up, down, side to side in bed
- Log rolling: incorporate neck, upper and lower extremities to aid movement
- Supine to sitting: use log roll technique assisted by arms

Preparation for Labor

- Relaxation techniques
- Modified squatting: supine, sitting, or side-lying with knees to chest
- Pelvic floor relaxation
- Breathing exercises: minimize forced abdominal exhalations

Postpartum Exercise Instruction

Instructions are the same as previously described in the uncomplicated pregnancy section.

INDEPENDENT LEARNING ACTIVITIES

● Critical Thinking and Discussion

1. Describe three normal changes of pregnancy that will affect exercise tolerance.
2. Explain the clinical significance of diastasis recti, the testing procedure, and the corrective exercise.
3. Differentiate between postural and sacroiliac back pain in the pregnant patient.
4. Name five risk factors for pelvic floor dysfunction.
5. What exercise guidelines are most helpful for a woman who has not exercised prior to becoming pregnant?

6. Discuss optimal positioning for an uncomplicated labor and delivery in terms of biomechanics, gravity, and energy conservation.
7. Vaginal delivery places great stretch and compression on which nerve?

● Laboratory Practice

1. Practice giving instructions to a lab partner on how to perform the following exercises. Observe that they are being done correctly. Reverse the experience and provide feedback.

- Diastasis recti exercises
- Pelvic clock exercises
- Breathing and relaxation for the different stages of labor and delivery
- 2.** Practice giving instructions and get verbal feedback as to the success of instructions for the pelvic floor awareness training and strengthening exercises
- 3.** Observe an exercise class for pregnant women. Critique the effectiveness and inclusiveness of the instruction.

Case Studies

- 1.** Ms. V. is a 32-year-old pregnant woman referred with a diagnosis of “low back pain,” that became severe at 24 weeks’ gestation. She reports (L) lumbar/thoracic, (R) anterior rib/pectoral, and cervical symptoms, which are worsening as the pregnancy progresses. Before her pregnancy, she wore a custom-made bra (32-MM), which is now much too small and provides inadequate support. Wearing this bra greatly increases her cervical and upper trapezius symptoms. Wearing a sports bra or standing more than 10 to 15 minutes causes increased low back symptoms. Pain is severely limiting her daily activities both at home and in the community. She has difficulty climbing stairs, grocery shopping, doing laundry, and other household chores. She is wakened at night by pain and also reports LE numbness at night. She is a single mother of a 6-year-old son. Pertinent medical history includes: weight gain of 100 lbs. with her previous pregnancy; C-section delivery; removal of fibrocystic breast tissue three times. No systemic medical conditions or medications other than prenatal vitamins. Current weight: 238 lb, height: 5'4.

CLINICAL FINDINGS

- Postural assessment reveals marked forward-head/shoulders with internal rotation at both shoulder joints, significant lordosis (cervical and lumbar), recurvatum bilaterally, decreased longitudinal arches, increased base of support with excessive ER at both hips. All dynamic movements are pain inhibited: frequent weight shift and asymmetrical transitions, antalgic gait pattern with increased ER of hips. Lumbar extension and (L) cervical rotation most limited by pain and spasm.

Diastasis recti of 9 cm noted above umbilicus; abdominal strength 3–5. Pelvic landmarks difficult to assess due to adipose tissue; leg lengths appear equal. Slight tenderness over pubic symphysis with palpation.

- Identify the impairments and functional limitations.
- Identify goals that deal with impairments and functional limitations.

- Develop a treatment plan to meet the goals; identify specific interventions and parameters, number of times she will be seen, and any follow-up or referrals that you believe will be necessary.

- 2.** Mrs. W. is a 71-year-old woman with an 11-year history of urinary incontinence and urgency. She experiences frequent, large-volume accidents, using 8 to 10 large incontinence pads and 8 panty liners/day for garment protection. Voiding frequency is 13 to 16 times every 24 hours. She also reports constipation and straining for evacuation, which improves with increased fiber intake. Caffeine intake is two servings per day. Mrs. W is a nonsmoker. She is much less active with social and community activities as a result of this problem. Urodynamic testing revealed diminished bladder capacity at 150 cc and confirmed the diagnosis of detrusor instability.

Pertinent medical history includes nine pregnancies and seven live births (G9, P7) with one breech presentation. LBP and “sciatic nerve problems” of long standing were reported with lumbar fusion done when she was 44 and 48 years of age. Other surgical history includes rectocele/cystocele repair when she was 36 and partial hysterectomy when she was 37. Hypertension and asthma are both well controlled with medication.

CLINICAL FINDINGS

Pelvic floor muscle assessment reveals poor sensory awareness, decreased resting tone, and a MMT of 2/5. Patient able to hold a contraction 4 seconds and repeat 10 “quick flicks” in 10 seconds. Accessory recruitment of the abdominals noted. Pressure perineometry confirms muscle weakness with 6.35 cm of water pressure generated. Levator ani contraction is enhanced with stretch facilitation to the pelvic floor (R > L).

Abdominal strength is 3/5. Diastasis recti noted above the umbilicus of 4.5 cm. Diaphragmatic breathing pattern present, no Valsalva with exertion. All dynamic movements of the trunk are mildly restricted because of lumbar fusion.

The patient underwent physical therapy treatments approximately 18 months ago and is independent with her LB program. (Because of insurance limitations of 10 visits, the patient requested primary attention to pelvic floor dysfunction and incontinence.)

- Identify the impairments and functional limitations
- Identify goals that deal with the impairments and functional limitations
- Design a treatment plan to meet the goals; identify specific interventions and parameters, number of times she will be seen, and any follow-up or referrals that you believe will be necessary.

INDEPENDENT LEARNING ACTIVITIES 847

Vascular disorders causing insufficient circulation to the extremities, can result in significant physical impairments and subsequent loss of function of either the upper or lower extremities. Disturbances of structure or function of the circulatory systems are broadly classified as acute or chronic *peripheral vascular disease* (PVD) and can be caused by a number of underlying pathologies of the arterial, venous, or lymphatic systems, including occlusion, inflammation, vasomotor dysfunction, or neoplasms.^{33,38,46} In addition, surgical procedures or radiation therapy necessary for the treatment of some forms of cancer can impair lymphatic circulation.^{5,39,63,68}

To contribute to the effective management of patients with vascular disorders, a therapist must possess a sound understanding of the underlying pathologies and the clinical manifestations of many types of arterial, venous, and

lymphatic disorders. A therapist must also be aware of the use, effectiveness, and limitations of therapeutic exercise in the comprehensive management and rehabilitation of patients with vascular disorders.

DISORDERS OF THE ARTERIAL SYSTEM

Types of Arterial Disorders

Acute Arterial Occlusion

A thrombus (blood clot), embolism, or trauma can cause acute loss of blood flow to peripheral arteries. The most common location of an arterial embolus is at the femoral-popliteal bifurcation, although an embolus can occur at

other arterial bifurcations in the extremities.^{33,38} Crush injuries to the vessels of the extremities also can disrupt arterial blood flow and must be repaired quickly to restore circulation and prevent tissue necrosis. If a patient develops an acute arterial occlusion, immediate medical or surgical measures must be taken to maintain the viability of the limb. These measures could include complete bed rest, systemic anti-coagulation therapy, thromboembolectomy, or reconstructive arterial bypass surgery.^{27,33,54}

PRECAUTION: With an acute occlusion therapeutic exercise is contraindicated. Use of support hose or application of direct heat over painful areas also is contraindicated.⁵⁴

Arteriosclerosis Obliterans

Arteriosclerosis obliterans (ASO), also called *chronic occlusive arterial disease*, *peripheral arterial occlusive disease*, or *atherosclerotic occlusive disease*, accounts for 95% of all the arterial disorders affecting the lower extremities.³³ It is a chronic disorder, most often seen in elderly patients. ASO is more common in men than women and is associated with risk factors that include elevated serum cholesterol ($> 200 \text{ mg/dL}$), smoking, high systolic blood pressure, obesity, and diabetes.^{13,33,35,66}

ASO is characterized by chronic, progressive occlusion of the peripheral circulation, most often in the large and medium arteries of the lower extremities. It is caused by atherosclerotic plaque formation.^{33,66}

Thromboangiitis Obliterans (Buerger's Disease)

Thromboangiitis obliterans is a chronic disease seen predominantly in young male patients who smoke; it involves an inflammatory reaction of the arteries to nicotine. Initially, it becomes evident in the small arteries of the feet and hands and progresses proximally. It results in vasoconstriction, decreased arterial circulation to the extremities, ischemia, and eventual ulceration and necrosis of soft tissues.^{27,38,46} The inflammatory reaction and resulting signs and symptoms can be controlled if the patient stops smoking.

Raynaud's Disease

Raynaud's disease, also known as *primary Raynaud's syndrome*, is a chronic, functional arterial disorder that occurs more often in women than men. Thought to be caused by an abnormality of the sympathetic nervous system, it is characterized by digital vasospasm, most often affecting the small arteries and arterioles of the fingers and sometimes the toes. Vasospasm is brought on by exposure to cold, vibration, or stress. The response is characterized by temporary pallor (blanching), then cyanosis and pain, followed by numbness and a cold sensation of the digits. Symptoms are relieved slowly by warmth.^{27,33,38,46,54}

When the disorder is primary, it is called *idiopathic Raynaud's disease* or *Raynaud's syndrome*. When it is a secondary complication and associated with another dis-

ease (such as scleroderma, systemic lupus erythematosus, systemic sclerosis, or vasculitis), it is called *Raynaud's phenomenon*.^{46,78}

Clinical Manifestations of Peripheral Arterial Disorders

The following signs and symptoms are associated with peripheral arterial disorders.

Diminished or Absent Peripheral Pulses

The more occluded or restricted the arterial blood flow and the more diminished the peripheral pulses, the more severe or advanced is the arterial disease.^{27,33,46,50,54} If the collateral circulation is extensive, the patient may not experience pain despite diminished pulses.

Integumentary Changes

A number of integumentary changes are associated with peripheral arterial disease.^{27,33,34,38,46,53,54}

- Skin discoloration, including *pallor* at rest or with exercise, or *reactive hyperemia* can develop. Pallor is more evident when the extremity is elevated above the level of the heart for several minutes. Reactive hyperemia occurs when the extremity is moved from an elevated to a dependent position. The skin takes on a bright red appearance rather than a normal pink flush. (Refer to the test for rubor of dependency in the following section.) Pallor of the distal extremity may also occur with exercise. After exercise, cutaneous ischemia causes blanching of the skin as arterial blood flow is diverted to the exercising muscles and away from the surface tissues of the distal extremity.
- *Trophic changes* include a shiny, waxy appearance and dryness of the skin and loss of hair distal to the occlusion.
- Skin temperature is decreased.
- *Ulcerations* may develop, particularly at weight-bearing areas or over bony prominences.

Sensory Disturbances

Intolerance to heat or cold and paresthesia (initially tingling, then numbness) can develop.^{27,46,54}

Exercise Pain and Rest Pain

Pain during exercise and at rest is associated with progressive peripheral arterial disease and leads to significant disability.^{27,34,35,46,54}

Exercise pain. Pain that occurs and gradually increases with exercise is referred to as *intermittent claudication*.^{13,27,30,32,46,54} It is experienced most common in the lower extremities and occurs more frequently and with greater intensity as the severity of chronic arterial insufficiency progresses. During the early stages of arterial disease, intermittent claudication is characterized by a feeling of fatigue or weakness and, later, as cramping or aching in the muscles used during exercise.

TABLE 24.1 Common Sites of Exercise Pain and Associated Arterial Occlusion

Site of Pain	Occluded Artery
Chronic arterial insufficiency	
Calf	Femoral
Foot	Popliteal
Thigh	Iliac
Buttocks or low back	Aortic
Thromboangiitis obliterans	
Arch of the foot	Plantar and tibial
Palm of the hand	Palmar and ulnar

Pain is located distal to the occluded vessels and is caused by insufficient blood supply and activity-induced ischemia in the exercising muscles. Leg pain typically is brought on by walking and gradually subsides when the patient stops walking. Intermittent claudication does not occur with extended periods of standing (as seen with spinal stenosis)³⁴ or with prolonged sitting (as seen with sciatica).^{9,35}

Although exercise pain is most common in the calf, it also can occur more proximally. Table 24.1 identifies common sites of intermittent claudication.^{9,27,33,34,46,54}

If peripheral vessels such as the popliteal, femoral, or iliac arteries are occluded, symptoms usually occur in one extremity; whereas if the occlusion is in the lower aorta, symptoms are present not only in both extremities but in the buttocks and low back regions as well. As the disease progresses and arterial insufficiency increases, exercise tolerance deteriorates as ischemic pain occurs more readily with activity.

Rest pain. When a burning, tingling sensation gradually becomes evident in the distal extremities at rest or with elevation, it may be indicative of severe ischemia. With ischemia, pain frequently occurs at night because the heart rate and volume of blood flow to the extremities decreases with rest. Sometimes partial or complete relief of pain is possible if the leg is placed in a dependent position, such as over the edge of a bed. In contrast, elevation of the limb increases the pain.

Muscle Weakness

Loss of strength, muscle atrophy, and eventual loss of motor function, particularly in the hands and feet, occur with progressive arterial vascular disease. Loss of motor function is compounded by pain, which further compromises functional strength.^{27,54}

Examination and Evaluation of Arterial Sufficiency

A comprehensive examination of a patient with known or suspected peripheral arterial disease is necessary to

determine or verify the etiology of a patient's impairments and functional limitations. For example, the origin of a patient's buttock and leg pain or lower extremity weakness could be caused by vascular or neuromuscular pathologies.^{34,35} The initial and subsequent examinations also provide a basis to determine a patient's status before treatment and the effectiveness of the interventions at the conclusion of treatment.

Various procedures for testing arterial sufficiency and identifying stenosis or occlusion are listed in Box 24.1 and described briefly in this section.^{42,46,50,54} Some procedures are used by therapists to indirectly assess arterial blood flow, whereas others, such as angiography or arteriography, are administered by practitioners with specialized training and are interpreted by a physician.

Palpation of Pulses

The basis of any evaluation of the integrity of the arterial system is the detection of pulses in the distal portion of the extremities. Pulses are described as *normal*, *diminished*, or *absent*. The strength of pulses also can be rated quantitatively from 0 to +3. Even if pulses appear normal, blood flow to the extremity may, in fact, be substantially restricted.¹² Pulselessness is a sign of severe arterial insufficiency.

The femoral, popliteal, dorsalis pedis, and posterior tibial pulses should be palpated in the lower extremities. The radial, ulnar, and brachial pulses are palpated in the upper extremities.

NOTE: Pulses are difficult to assess quantitatively by palpation alone. Other, more accurate and reliable noninvasive tests (such as Doppler ultrasonography) supplement the information gained from palpating the pulses.

Skin Temperature

The temperature of the skin can be assessed grossly by palpation. A limb with diminished arterial blood flow is cool to the touch. If a discrepancy exists between an involved and an unininvolved extremity, skin temperature should be quantitatively measured with an electronic thermometer.

BOX 24.1 Tests and Measurements of Arterial Sufficiency

- Palpation and comparison of pulses in the involved and unininvolved upper or lower extremities
- Skin temperature
- Skin integrity and pigmentation
- Tests for reactive hyperemia (rubor of dependence)
- Claudication time
- Ultrasonography, Doppler measurement of blood flow, transcutaneous oximetry
- Magnetic resonance angiography
- Arteriography

Skin Integrity and Pigmentation

Diminished or absent arterial blood flow to an extremity causes trophic changes in the skin peripherally. The patient's skin is dry, and its color is diminished (pallor). Hair loss and a shiny appearance to the skin also occur. Skin ulcerations may be present.

Rubor Dependency Test—Reactive Hyperemia

Changes in skin color that occur with elevation and dependency of the limb as the result of altered blood flow are determined. Rubor/reactive hyperemia can be assessed in two ways.^{42,46}

Procedure. The legs are elevated for several minutes above the level of the heart while the patient is lying supine. Pallor (blanching) of the skin occurs in the feet within 1 minute or less if arterial circulation is poor. The time necessary for blanching to develop is noted. Then the legs are placed in a dependent position, and the color of the feet is noted.

Normally, a pinkish flush appears in the feet within several seconds after the legs are placed in a dependent position. With occlusive arterial disease, a bright bluish-red color, or rubor, of the distal legs and feet is evident that is caused by reduced blood flow in the capillaries. The rubor may take as long as 30 seconds to appear.

Alternate procedure. Reactive hyperemia also can be evaluated by temporarily restricting blood flow to the distal portion of the lower extremity with a blood pressure cuff. This restriction causes an accumulation of CO₂ and lactic acid in the distal extremity. These metabolites are vasodilators and affect the vascular bed of the blood flow-deprived area.¹²

When the cuff is released and blood flow resumes to the distal extremity, a normal hyperemia (flushing) of the extremity should occur within 10 seconds. With arteriosclerotic vascular disease it may take as long as 1 to 2 minutes for a flush to appear, whereas with vasospastic arterial disease (Raynaud's disease) flushing occurs within the normal time frame.¹²

NOTE: This method of assessing reactive hyperemia is quite painful and is not tolerated well by either normal individuals or patients with occlusive arterial disease.

Claudication Time

An objective assessment of exercise pain (intermittent claudication) is performed to determine the amount of time a patient can exercise before experiencing cramping and pain in the distal musculature.^{30,46,66}

A commonly used test is to have the patient walk at a slow, predetermined speed on a level treadmill (1 to 2 mph). The time that the patient is able to walk before the onset of pain or before pain prohibits further walking is noted.^{30,46} This measurement should be undertaken to determine a baseline for exercise tolerance before initiating a program to improve exercise tolerance.

Doppler Ultrasonography

Doppler measurement of blood flow with ultrasound imaging is a noninvasive assessment that uses the Doppler principle to determine the relative velocity of blood flow in the major arteries and veins.^{27,42,46,54} A soundhead, covered with coupling gel, is placed on the skin directly over the artery to be evaluated. An ultrasonic beam is directed transcutaneously to the artery. Blood cells moving in the path of the beam cause a shift in the frequency of the reflected sound.

The frequency of the reflected sound emitted varies with the velocity of blood flow. This information is transmitted visually onto an oscilloscope or printed tape or audibly via a loudspeaker or stethoscope.

Transcutaneous Oximetry

Transcutaneous oximetry provides information about the oxygen saturation of blood by means of a photoelectric device (a pulse oximeter).³³ A beam of red and infrared light passes through a pulsating capillary bed (e.g., in the fingertip). The ratio of red to infrared transmission varies with the oxygen saturation of the blood. Because it responds only to pulsating objects, it does not detect nonpulsating objects, such as venous blood or skin.

Arteriography

Arteriography is an invasive procedure that involves injecting a radiopaque dye (contrast medium) directly into an artery.^{33,38,46} The arteries are then radiographically visualized to detect any restriction of movement of the dye in arterial vessels indicating a partial or complete occlusion. Collateral circulation can also be visualized. Because arteriography gives a highly accurate picture of the location and extent of an arterial obstruction, it is used most often prior to reconstructive arterial bypass surgery.

Magnetic Resonance Angiography

Magnetic resonance angiography, a noninvasive procedure, provides radiographic visualization of arteries without the use of a contrast medium.³³

Management of Acute Arterial Occlusion

Acute arterial occlusion often is a medical or surgical emergency. The resulting ischemia causes severe pain, the risk of tissue necrosis and local or systemic infection, and the possible need for amputation. The viability of the limb depends on the location and extent of the occlusion and the availability of collateral circulation.

Medical or surgical measures must be taken to reduce ischemia and to restore circulation. Medical management includes bed rest and complete systemic anticoagulation therapy. Complementary physical interventions to improve peripheral blood flow while the patient is on bed rest may include warming the limb by reflex heating of the torso or opposite extremity or elevating the head of the bed slightly.^{27,46} Several contraindications also are warranted (Box 24.2).

BOX 24.2 Contraindications with Acute Arterial Occlusion

- Exercise—passive or active
- Prolonged positioning during bed rest, which could cause pressure on and potential breakdown of skin
- Local, direct heat on the involved extremity because of the potential for a burn to the ischemic tissue
- Use of support hose, which may increase peripheral resistance to blood flow
- Restrictive clothing that could compromise blood flow

Surgical interventions for an acute occlusion are *thromboembolectomy* or an arterial bypass graft. If circulation cannot be significantly improved or restored, gangrene develops within a very short time, and amputation of the extremity is necessary.³³

BOX 24.3
MANAGEMENT GUIDELINES—Chronic Arterial Insufficiency
Impairments

Decreased endurance and increased frequency of muscular fatigue with functional activities such as walking

Pain with exercise or at rest

Skin breakdown and ulcerations

Limitation of passive and active motion

Weakness and disuse atrophy

Plan of Care

1. Teach the patient how to minimize or prevent potential impairments and correct impairments or functional limitations currently affecting functional capabilities.
2. Communicate with health professionals from other disciplines appropriate for consultation with the patient.
3. Improve exercise tolerance for ADL and decrease the incidence of intermittent claudication.
4. Relieve pain at rest.
5. Prevent skin ulcerations.
6. Improve vasodilation in affected arteries.
7. Prevent or minimize joint contractures and muscle atrophy, particularly if the patient is confined to bed.
8. Promote healing of any skin ulcerations that develop.

Interventions

1. Self-management of current or potential impairments through patient education.
2. Medical or surgical management including medications; nutritional counseling for weight control and to decrease salt, sucrose, cholesterol, and caffeine intake; smoking cessation.
3. Regular, graded aerobic conditioning program of walking or bicycling^{30,46,54,65,66,79} (see Chapter 7).
4. Sleep with the legs in a dependent but supported position over the edge of the bed or with the head of the bed slightly elevated.
5. Proper care and protection of the skin, particularly the feet¹⁴ or hands.
 - Proper nail care.¹²
 - Proper shoe selection and fit.¹²
 - Avoid use of support hose and restrictive clothing.
 - Avoid exposure to extremes of temperature, both hot and cold.
6. Vasodilation by iontophoresis.²
 - Vasodilation by reflex heating.²
- NOTE:** Although these physical measures have been advocated, their effectiveness is questionable.
7. Repetitive, active ROM against low loads and/or gentle stretching exercises; proper positioning in bed to maintain joint and muscle extensibility.
8. Wound management procedures for treating ischemic ulcers, including electrical stimulation and oxygen therapy.^{27,55}

Management of Chronic Arterial Insufficiency

Except with advanced disease, chronic arterial insufficiency caused, for example, by ASO or Raynaud's disease is managed conservatively by medical and physical means and does not constitute a medical or surgical emergency.^{27,46,54,66} Box 24.3 summarizes management guidelines for chronic arterial insufficiency.

Medical/Surgical Management

Medical management of chronic arterial insufficiency must be ongoing. Related medical disorders must be identified and treated. Diabetes and hypertension are commonly associated with chronic arteriosclerotic vascular disease and must be controlled with medication, diet, and exercise.⁶⁶

Lifestyle changes are an important aspect of management. In all cases, patients are advised to stop smoking and alter their diet, such as limiting or avoiding salt, sucrose, and alcohol to lower blood pressure and triglyceride and

cholesterol levels. These measures do not cure chronic arterial disorders but do minimize risk factors and promote wellness.

For patients with leg pain at rest due to advanced disease, reconstructive vascular surgery, such as a bypass graft, may be required. Patients with vasospastic disease may benefit from sympathetic blocks or sympathectomies to increase blood flow.⁴⁶ If a patient develops ulcerations or gangrene that cannot be treated medically or with conservative surgical procedures, amputation of the limb is necessary.^{46,55}

Role of Exercise

For patients with mild to moderate arterial disease, a graded exercise program should be initiated to improve exercise tolerance and functional capacity in activities of daily living. A regular program of mild- to moderate-level aerobic exercise, such as walking or bicycling, is known to have benefits for patients with chronic arterial insufficiency.^{13,30,32,65,66,79}

Demonstrated benefits include an increase in the time before the onset of exercise pain during walking, improvement in the efficiency of oxygen utilization in exercising muscles (enabling patients to tolerate exercise over longer periods of time), and quantitative improvement of quality of life.^{30,65,79} However, the characteristics of an optimal exercise program or whether exercise programs improve collateral circulation in the extremities is less clear.

Focus on Evidence

Brandsma and co-investigators¹³ conducted a systematic review of the literature to identify the indications, characteristics, and effectiveness of walking programs for patients with intermittent claudication. A review of 10 articles that met the inclusion criteria revealed no consensus with regard to indications for participation in a walking program for patients with intermittent claudication or optimal characteristics of such a program. However, the reviewers did confirm that all walking programs significantly improved walking distance in patients who participated in programs compared with those who did not.

In addition to increased walking distance, Gardner et al.³² demonstrated by means of a randomized study of elderly individuals with chronic arterial insufficiency that after a 6-month walking program improvement in the distance walked before the onset of claudication was dependent on an increase in peripheral blood flow.

Buerger or Buerger-Allen exercises, another approach to exercise developed a number of decades ago, were designed to promote collateral circulation through a series of positional changes of the affected limb (from an elevated to a dependent position) combined with active ankle pumping exercises.⁸² Although used frequently in the past and occasionally today, there is little to no evidence to support the efficacy of these exercises for improving blood

flow to an extremity.^{27,54} Consequently, there is little reason to include them in a patient's exercise program.

Special Considerations in a Graded Exercise Program for Patients with Chronic Arterial Insufficiency

Rationale for Graded Exercise

The following factors related to the body's normal response to exercise are the basis for using a graded exercise program to improve the functional status of patients with chronic arterial insufficiency.^{27,66,79}

- Blood flow temporarily decreases during active contraction of a muscle, but the blood flow rapidly increases immediately after the contraction.
- After cessation of exercise, there is a rapid decrease in blood flow during the first 3 to 4 minutes. This is followed by a slow decline to resting levels within 15 minutes.
- With repeated moderate-level exercise, blood flow in muscles can be increased beyond the resting values for blood flow.

Exercise Guidelines

- The patient should be encouraged to walk or bicycle as far as possible to a predetermined maximum target heart rate but without causing intermittent claudication.
- The graded endurance exercise should be carried out 3 to 5 days per week.
- The patient should perform mild warm-up and stretching activities prior to initiating walking or bicycling. Warm-up activities could include active pumping exercises of the ankle and toes.
- Refer to Chapter 7 for additional guidelines for establishing an aerobic exercise program.

Precautions and contraindications for participation in a walking program for patients with chronic arterial insufficiency are noted in Box 24.4.^{27,46,54,55}

BOX 24.4 Precautions and Contraindications for a Walking Program for Patients with Chronic Arterial Insufficiency

Precautions

- Avoid exercising outside during very cold weather.
- Wear shoes that fit properly, have sufficient padding, and do not cause skin irritation.
- Inspect the feet carefully for evidence of skin irritation after each exercise session.
- Discontinue a walking program if leg pain increases rather than decreases over time.

Contraindications

- Presence of skin irritation, an ulceration, a wound, or a fungal infection of the feet
- Leg pain at rest due to advanced vascular disease

DISORDERS OF THE VENOUS SYSTEM

Just as arterial disorders of the extremities can be acute or chronic, so can venous disorders.^{34,40} Therapeutic exercise is one aspect of management of patients with an acute disease, such as thrombophlebitis, or a chronic disorder, such as varicose veins or chronic venous insufficiency.^{27,33,46,54}

Types of Venous Disorders

Thrombophlebitis and Deep Vein Thrombosis

Thrombophlebitis is a disorder typically affecting the lower extremities and caused by thrombosis (the development/formation of a blood clot—i.e., a thrombus). It is characterized by acute inflammation with partial or complete occlusion of a superficial or deep vein.^{27,33,38,42}

Lower extremity venous thrombosis can occur in the superficial vein system (greater or small saphenous veins) or the deep vein system (popliteal, femoral, or iliac veins) (Fig. 24.1).³³ A thrombus in one of the superficial veins in

the calf usually is small and resolves without serious consequences.^{33,67} In contrast, thrombus formation in a deep vein in the calf or more proximally in the thigh or pelvic region, known as a *deep vein thrombosis* (DVT), tends to be larger and can cause serious complications. When a clot breaks away from the wall of a vein and travels proximally, it is called an *embolus*. When an embolus affects pulmonary circulation, it is called a *pulmonary embolism*, which is a potentially life-threatening disorder.^{33,67}

A lower extremity DVT is a common complication after musculoskeletal injury or surgery, prolonged immobilization, or bed rest and is attributed to venous stasis, injury to and inflammation of the walls of a vein, or a hypercoagulable state of the blood.^{33,38,75} Risk factors for DVT are listed in Box 24.5.^{33,38,67}

Chronic Venous Insufficiency

Chronic venous insufficiency is defined as inadequate venous return over a prolonged period of time. It may begin after a severe episode of DVT, may be associated with varicose veins, or may be the result of trauma to the lower extremities or blockage of the venous system by a neoplasm.^{33,38,46} In all of these disorders damaged or incompetent valves in the veins prevent or compromise venous return, leading to venous hypertension and venous stasis in the lower extremities. Chronic pooling of blood in the veins causes inadequate oxygenation of cells and removal of waste products. This, in turn, leads to necrosis of tissues and the development of *venous stasis ulcers*.^{33,38,55}

Clinical Manifestations of Venous Disorders

Deep Vein Thrombosis and Thrombophlebitis: Signs and Symptoms

During the early stages of a DVT, only 25% to 50% of cases can be identified by clinical manifestations, such as dull aching or severe pain, swelling, or changes in skin temperature and color, specifically heat and redness.^{4,33,38,67}

Although edema in the vicinity of the clot may be present, it may be too deep to palpate. If the clot is in the

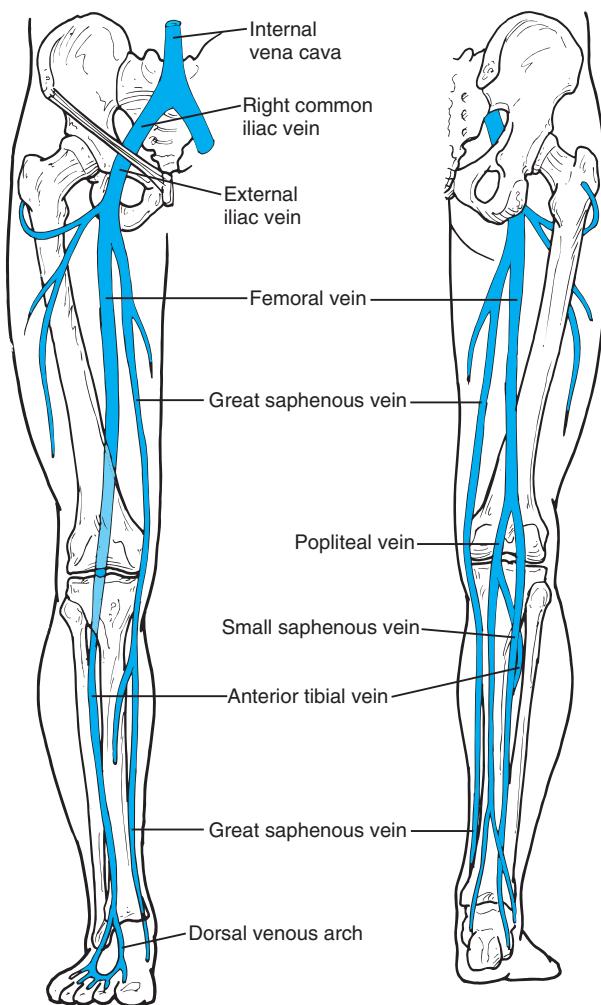

FIGURE 24.1 Veins of the lower extremity

BOX 24.5 Risk Factors for Deep Vein Thrombosis and Thrombophlebitis

- Postoperative or postfracture immobilization
- Prolonged bed rest
- Trauma to venous vessels
- Limb paralysis
- Active malignancy (within past 6 months)
- History of deep vein thrombosis or pulmonary embolism
- Advanced age
- Obesity
- Sedentary lifestyle or extended episode of sitting during long-distance travel
- Congestive heart failure
- Use of oral contraceptives
- Pregnancy

calf (distal DVT), pain or tenderness of the calf may be felt with passive dorsiflexion of the affected foot (*Homans' sign*). However, the sensitivity of this test is poor and often reflects a false-negative or false-positive finding.^{4,75} Only measurement by ultrasonography, venous duplex screening, or venography can confirm a DVT.^{4,75}

Pulmonary Embolism: Signs and Symptoms

As described previously, pulmonary embolism is a possible consequence of DVT. Risk factors for pulmonary embolism are similar to those already identified for DVT (see Box 24.5).

The signs and symptoms of pulmonary embolism vary considerably depending on the size of the embolus, the extent of lung involvement, and the presence of coexisting cardiopulmonary conditions.⁸⁴ The hallmark signs and symptoms are a sudden onset of shortness of breath (dyspnea), rapid and shallow breathing (tachypnea), and chest pain located at the lateral aspect of the chest that intensifies with deep breathing and coughing. Other signs and symptoms include swelling in the lower extremities, anxiety, fever, excessive sweating (diaphoresis), a cough, and blood in the sputum (hemoptysis).⁸⁴

When a patient presents with signs or symptoms of possible pulmonary embolism, immediate medical referral is warranted for a definitive diagnosis.

Chronic Venous Insufficiency: Signs and Symptoms

Dependent, peripheral edema occurring with long periods of standing or sitting is a common manifestation of chronic venous dysfunction. Edema decreases if the limb is elevated. Patients often report dull aching or tiredness in the affected extremity.^{27,33,38,46,62,86} If the insufficiency is associated with varicose veins, venous distention (bulging) also is notable. When edema persists, the skin becomes less supple over time and takes on a brownish pigmentation.

Examination and Evaluation of Venous Sufficiency

As with arterial disorders, a complete history and systems review help determine the presence of a venous disorder. Some specific tests to determine venous sufficiency are listed in Box 24.6 and are briefly described in this section.^{27,34,42,53,62} These tests complement a comprehensive

integumentary and neuromuscular examination that includes skin integrity, mobility, color, texture, temperature, vital signs including peripheral pulses, sensation, pain, functional mobility, ROM, strength, and cardiopulmonary endurance.

Girth Measurements

Circumferential measurements of the involved and uninvolving limbs are taken to determine the presence and extent of edema.^{27,46,53} Measurements are taken at anatomical landmarks or at predetermined and consistent distances apart (e.g., 8 or 10 cm apart).

Competence of the Greater Saphenous Vein (Percussion Test)

Evaluating the valves of the saphenous vein is a common test used if a patient has symptomatic varicose veins.

Procedure. Ask the patient to stand until the veins in the legs appear to fill. While palpating a portion of the saphenous vein below the knee, sharply percuss a portion of the vein above the knee. If valves are not functioning adequately, the examiner feels a backflow of fluid distally under the palpating fingertips.^{38,46,53}

Tests for Deep Vein Thrombosis

The following tests determine the possible presence of a DVT in a lower extremity.

Homans' Sign

Procedure. With the patient supine and the knee extended, passively dorsiflex the ankle and gently squeeze the calf muscles. If pain occurs in the calf, Homans' sign is positive, indicating the possible presence of a DVT.^{4,46,53} However, this is not a definitive test. Homans' sign has been found to be positive in more than 50% of subjects who did not have a DVT. In addition, it has been shown to be positive in fewer than one-third of patients with a confirmed DVT in the calf.^{4,75}

Application of a Blood Pressure Cuff Around the Calf

Procedure. Inflate the cuff gradually until the patient experiences calf pain. A patient with acute thromboembolitis usually cannot tolerate pressures above 40 mm Hg.⁵³

Additional Special Tests

Tests designed to confirm the presence of a venous disorder are performed and analyzed by the patient's physician or a practitioner with specialized training. Tests include ultrasonographic imaging, Doppler measurement of blood flow, and venous duplex scanning (all of which are noninvasive) and venography (phlebography), an invasive procedure.^{4,33,46,50,53} Venography involves injecting radiopaque dye and radiographic visualization of the venous system.

BOX 24.6 Tests and Measures of Venous Sufficiency

- Girth measurements of the upper or lower extremities
- Percussion test: compliance of the greater saphenous vein
- Homans' sign
- Response to compression of the limb with a blood pressure cuff
- Doppler ultrasonography
- Venous duplex screening/scanning
- Venography

BOX 24.7**MANAGEMENT GUIDELINES—Deep Vein Thrombosis and Thrombophlebitis****Impairments**

Dull ache or pain usually in the calf

Tenderness, warmth, and swelling with palpation

Plan of Care

1. Relieve pain during the acute inflammatory period.
2. As acute symptoms subside, regain functional mobility.
3. Prevent recurrence of the acute disorder.

Interventions

1. Bed rest, pharmacological management (systemic anticoagulant therapy); elevation of the affected lower extremity, keeping the knee slightly flexed.
2. Graded ambulation with legs wrapped in elastic or nonelastic bandages or when pressure-gradient support stockings are worn.
3. Continuation of appropriate medical and pharmacological management. Use of strategies to prevent DVTs.

Contraindications: Passive or active motion or application of moist heat; use of a sequential pneumatic compression pump.

Prevention of Deep Vein Thrombosis and Thrombophlebitis

Every effort should be made to prevent the occurrence of a DVT and subsequent thrombophlebitis, particularly in patients at risk. The following interventions are implemented to reduce the risk of a DVT.^{45,75,77}

- Prophylactic use of anticoagulant therapy (high-molecular-weight heparin) for the high-risk patient (e.g., the patient who has undergone lower extremity surgery or who is on bed rest)
- Initiation of ambulation as soon as possible after surgery, preferably no more than a day or two postoperatively
- Elevating the legs while lying supine and on a footstool or ottoman when sitting
- No prolonged periods of sitting, especially for the patient with a long-leg cast
- Active “pumping” exercises (active dorsiflexion, plantarflexion, and circumduction of the ankle) regularly throughout the day while lying supine in bed
- Use of compression stockings to support the walls of the veins and minimize venous pooling
- For patients on bed rest, use of a sequential pneumatic compression unit

Management of Deep Vein Thrombosis and Thrombophlebitis

If the presence of DVT and resulting thrombophlebitis is confirmed, immediate medical intervention is essential to reduce the risk of pulmonary embolism. Initial management includes administering anticoagulant medication, placing the patient on complete bed rest, elevating the involved extremity, and using graduated compression stockings. The reported time frame for bed rest varies from 2 days to more than a week.³ Box 24.7 summarizes the guidelines for management of acute DVT and thrombophlebitis.^{27,46,54}

During the period of bed rest, exercises usually are contraindicated because movement of the involved extremity may cause pain and is thought to increase congestion in the venous channels when tissues are inflamed. However, the optimal timing of when it is prudent to discontinue bed rest and resume ambulation after initiating anticoagulant therapy is in question.

**Focus on Evidence**

Aldrich and colleagues³ conducted a systematic review of the literature to determine when a patient with DVT should be allowed to begin walking. The review revealed a limited number of studies (a total of five, three of which were randomized, controlled trials) that addressed this issue. Results of these studies suggest that early ambulation, begun within the first 24 hours after initiating anticoagulant therapy, does not increase the incidence of pulmonary embolism in patients without an existing pulmonary embolism and who have adequate cardiopulmonary reserve. However, if a patient has a known pulmonary embolism, an ambulation program must be initiated more cautiously. It is important to note that in the studies reviewed all patients who participated in an early ambulation program wore compression garments.

The results also revealed that early ambulation is associated with more rapid resolution of pain and swelling. The authors of the review were unable to identify studies that investigated the initiation and progression of other forms of exercise for patients with DVT.

Management of Chronic Venous Insufficiency and Varicose Veins

Patient education is fundamental in the management of chronic venous insufficiency and varicose veins. A patient must be advised on how to prevent dependent edema, skin ulceration, and infections. The therapist may be involved

BOX 24.8**MANAGEMENT GUIDELINES—Chronic Venous Insufficiency and Varicose Veins****Impairments**

Edema

Increased risk of skin ulcerations and infections

Aching of involved limb

Decreased functional mobility, strength, and endurance

Plan of Care	Interventions
<ol style="list-style-type: none"> Teach the patient how to prevent or minimize impairments. Prevent lymphedema; minimize venous stasis. Increase venous return and reduce lymphedema if already present. Prevent skin abrasions, ulcerations, and wound infections. 	<ol style="list-style-type: none"> Patient education and self-management skills for skin care, self-massage for lymphedema, and a home exercise program. Use of individually tailored pressure-gradient support stockings donned before getting out of bed in the morning and worn every day. Support garment worn during exercise and ambulation. Light active exercise, such as walking, on a regular basis. Elevate the lower extremities after graded ambulation until the heart rate returns to normal. Avoid prolonged periods of standing still and sitting with legs dependent. Elevate involved limb(s) above the level of the heart (about 30° to 45°) when resting or sleeping (see Box 24.10 for additional methods to prevent lymphedema). Use intermittent mechanical compression pump and sleeve with involved limb elevated for several hours a day. Manual massage to drain edema. Stroke in a distal-to-proximal direction clearing the proximal nodes and areas of lymphedema first, then the middle, and finally the distal areas. Relaxation and active ROM (pumping exercises) of the distal muscles while involved limb is elevated. Proper skin care (see Box 24.10).

in (1) measuring and fitting a patient for a pressure-gradient support garment; (2) teaching the patient how to put on the garment before getting out of bed; (3) setting up a program of regular exercise; and (4) teaching the patient proper skin care.

Box 24.8 summarizes the guidelines for management of chronic venous insufficiency and varicose veins.^{27,46,54,56,62,86} Exercises and related interventions for chronic lymphedema described in the final section of this chapter are indicated for management of lymphedema arising from chronic venous insufficiency.

DISORDERS OF THE LYMPHATIC SYSTEM

One of the primary functions of the lymphatic system, which consists of lymph vessels and nodes, is to collect

and clear excess tissue fluid from interstitial spaces and return it to the venous system (Fig. 24.2).^{33,86} Edema is a natural consequence of trauma to and healing of soft tissues. If the lymphatic system is compromised and does not function efficiently, lymphedema develops and impedes wound healing.

Lymphedema is an excessive and persistent accumulation of extravascular and extracellular fluid and proteins in tissue spaces.^{16,20,26,49,86} It occurs when lymph volume exceeds the capacity of the lymph transport system, and it is associated with a disturbance of the water and protein balance across the capillary membrane. An increased concentration of proteins draws larger amounts of water into interstitial spaces, leading to lymphedema.^{26,39,86} Furthermore, many disorders of the cardiopulmonary system can cause the load on lymphatic vessels to exceed their transport capacity and subsequently cause lymphedema.^{39,49}

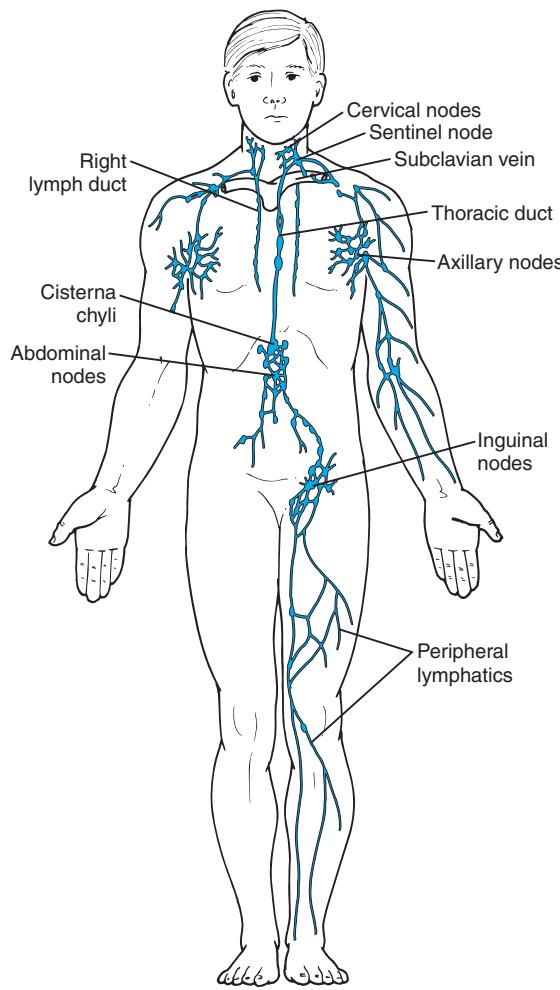

FIGURE 24.2 Major vessels of the lymphatic system.

Conditions Leading to Insufficiency of the Lymphatic System

Disorders of the lymphatic transport system can cause primary or secondary lymphedema.³³ Remember, lymphedema is not a disease but, rather, a symptom of a malfunctioning lymphatic system. Most of the patients seen by health care practitioners for management of lymphedema have secondary lymphedema.⁶⁸ By far, the most common causes of secondary lymphedema are related to the comprehensive management of cancers of the breast, pelvis, and abdomen.^{5,14,16,33,38,39,68,69}

Congenital Malformation of the Lymphatic System

Primary lymphedema, although uncommon, is the result of insufficient development (dysplasia) and congenital malformation of the lymphatic system.^{33,38}

Infection and Inflammation

Inflammation of the lymph vessels (*lymphangitis*) or lymph nodes (*lymphadenitis*) and enlargement of lymph nodes (*lymphadenopathy*) can occur as the result of a systemic infection or local trauma. Any of these conditions can cause disruption of lymph circulation.^{33,38,39,86}

Obstruction or Fibrosis

Trauma, surgery, and neoplasms can block or impair the lymphatic circulation.^{33,39,76} Radiation therapy associated with treatment of malignant tumors also can cause fibrosis of vessels.^{5,15}

Surgical Dissection of Lymph Nodes

Lymph nodes and vessels often are surgically removed (*lymphadenectomy*) as an aspect of treatment of a primary malignancy or metastatic disease. For example, axillary lymph node dissection is performed in most types of breast cancer surgeries to determine the extent and progression of breast cancer.^{15,18,33,43} Likewise, pelvic or inguinal lymph node excision often is necessary for the treatment of pelvic or abdominal cancers.^{5,68,69}

Chronic Venous Insufficiency

Although not a primary disorder of the lymphatic system, chronic venous insufficiency and varicose veins are associated with venous stasis and accumulation of edema in the extremities.^{33,38,46,86}

Clinical Manifestations of Lymphatic Disorders

Lymphedema

Location. When lymphedema develops, it is most often apparent in the distal extremities, particularly over the dorsum of the foot or hand.^{26,39} The term *dependent edema* describes the accumulation of fluids in the peripheral aspects of the limbs, particularly when the distal segments are lower than the heart. In contrast, lymphedema also can manifest more centrally, for example in the axilla, groin, or even the trunk.^{26,33,38,86}

Severity. The severity of lymphedema may be described quantitatively or qualitatively. Lymphedema is described by the severity of changes that occur in skin and subcutaneous tissues. The three categories—*pitting*, *brawny*, and *weeping* edema—are described in Box 24.9. Although all three types reflect a significant degree of lymphedema,

BOX 24.9 Types of Lymphedema

Pitting edema: Pressure on the edematous tissues with the fingertips causes an indentation of the skin that persists for several seconds after the pressure is removed. This reflects significant but short-duration edema with little or no fibrotic changes in skin or subcutaneous tissues.

Brawny edema: Pressure on the edematous areas feels hard with palpation. This reflects a more severe form of interstitial swelling with progressive, fibrotic changes in subcutaneous tissues.

Weeping edema: This represents the most severe and long-duration form of lymphedema. Fluids leak from cuts or sores; wound healing is significantly impaired. Lymphedema of this severity occurs almost exclusively in the lower extremities.

they are listed in order of severity, from least severe to most severe.^{18,20,33,38,71}

Descriptors such as mild, moderate, and severe sometimes are based on how much larger the size of the edematous limb is compared with the noninvolved limb.⁶¹ However, there are no standard definitions associated with size and severity.

Increased Size of the Limb

As the volume of interstitial fluid in the limb increases, so does the size of the limb (weight and girth).^{17,39,46,86} Increased volume, in turn, causes tautness of the skin and susceptibility to skin breakdown.^{18,33}

Sensory Disturbances

Paresthesia (tingling, itching, or numbness) or occasionally a mild aching pain may be felt particularly in the fingers or toes. In many instances the condition is painless, and the patient perceives only a sense of heaviness of the limb. Fine finger coordination also may be impaired as the result of the sensory disturbances.^{18,39,61,71}

Stiffness and Limited Range of Motion

Range of motion (ROM) decreases in the fingers and wrist or toes and ankle or even in the more proximal joints, leading to decreased functional mobility of the involved segments.^{18,58}

Decreased Resistance to Infection

Wound healing is delayed; and frequent infections (e.g., cellulitis) may occur.^{39,46,86}

Examination and Evaluation of Lymphatic Function

A patient's history, a systems review, and specific tests and measures provide information to determine impairments and functional limitations that can arise from lymphatic disorders and the presence of lymphedema. Key components in the examination process that are particularly relevant when lymphatic dysfunction is suspected or lymphedema is present are summarized in this section.^{19,27,46,54,58,74,86} Other tests and measurements, such as vital signs, ROM, strength, posture, and sensory, functional, and cardiopulmonary testing, also are appropriate.

History and Systems Review

Note any history of infection, trauma, surgery, or radiation therapy. The onset and duration of lymphedema, delayed wound healing, or previous treatment of lymphedema are pertinent pieces of information. Identify the occupation or daily activities of the patient and determine if long periods of standing or sitting are required.

Examination of Skin Integrity

Visual inspection and palpation of the skin provide information about the integrity of the skin. The location of the edema should be noted. When the limb is in a dependent position, palpate the skin to determine the type and severity of lymphedema and changes in skin and subcutaneous tissues. Areas of pitting, brawny, or weeping edema should be noted.

NOTE: When palpating the skin over lymph nodes, note any tenderness of the nodes (cervical, supraclavicular, inguinal). Tenderness may or may not indicate ongoing infection or serious disease.³⁴ Evidence of warm, enlarged, tender, painless, or adherent nodes should be reported to the physician.

The presence of wounds or scars and the color and appearance of the skin, which often is shiny and red in an edematous limb, should be noted. Photographic documentation is convenient in the clinical or home setting and provides visual evidence of changes in skin integrity.⁸⁶ If a wound or scar is identified, its size should be noted, as should scar mobility or the presence of inflammation or infection in a wound.

Girth Measurements

Circumferential measurements of the involved limb should be taken and compared with the noninvolved limb if the problem is unilateral.^{17,54,61} Identify specific intervals or landmarks at which measurements are taken so measurements during subsequent examinations are reliable. Use of circumferential measurements at anatomical landmarks has been shown to be a valid and reliable method of calculating limb volume.⁷⁴

Volumetric Measurements

An alternative method of measuring limb size is to immerse the limb in a tank of water to a predetermined anatomical landmark and measure the volume of water displaced.^{17,54,74} Although this method also has been shown to be valid and reliable, for routine clinical use it is more cumbersome and less practical than girth measurements.⁷⁴

Prevention of Lymphedema

If a patient is at risk of developing lymphedema secondary to infection, inflammation, obstruction, surgical removal of lymphatic structures, or chronic venous insufficiency, prevention of lymphedema should be the priority of patient management. In some situations, such as after removal of lymph nodes or vessels, preventive measures may be needed for a lifetime. Even when a patient takes every measure to prevent edema, it still may develop at some time, particularly after trauma to or surgical removal of lymph vessels. Box 24.10 summarizes precautions and measures to prevent or reduce the risk of lymphedema.^{16,18,20,41,58,64,71,76,86}

Management of Lymphedema

Background and Rationale

Comprehensive management of lymphedema involves a combination of appropriate medical management and direct therapeutic intervention by a therapist combined with self-management by the patient. Treatment also includes appropriate pharmacological management for infection control and prevention or removal of excessive fluid and proteins.^{16,33,38}

The overall goal of management when lymphedema has developed is to improve drainage of obstructed areas

BOX 24.10 Precautions, Prevention, and Self-Management of Lymphedema
Prevention of Lymphedema

- Avoid static, dependent positioning of the lower extremities, such as prolonged sitting or standing. Avoid sitting with legs crossed.
- When traveling long distances by car, stop periodically and walk around or support an involved upper extremity on the car's window ledge or seat back.
- Elevate involved limb(s) and perform repetitive pumping exercises frequently during the day.
- Avoid *vigorous*, repetitive activities with the involved limb. Avoid carrying heavy loads, such as a suitcase, a heavy backpack, or shoulder bag. Avoid use of heavy weights when exercising.
- Wear compressive garments while exercising.
- Avoid wearing clothing that restricts circulation, such as sleeves or socks with tight elastic bands. Do not wear tight jewelry such as rings or watches.
- Monitor diet to maintain an ideal weight and minimize sodium intake.
- Avoid hot environments or use of local heat.
- If possible, avoid having blood pressure taken on an involved upper extremity or injections in either an involved upper or lower extremity.

Skin Care

- Keep the skin clean and supple; use moisturizers but avoid perfumed lotions.
- Avoid infections; pay immediate attention to a skin abrasion or cut, an insect bite, a blister, or a burn.
- Protect hands and feet; wear socks or hose, properly fitting shoes, rubber gloves, oven mitts, etc.
- Avoid contact with harsh detergents and chemicals.
- Use caution when cutting nails. Women need to use an electric razor when shaving legs or underarm area.
- Avoid hot baths, whirlpools, and saunas that elevate the body's core temperature.

and theoretically to channel fluids into unobstructed, collateral vessels. The following must be accomplished to increase lymphatic drainage.

- The hydrostatic pressures on edematous tissues must be increased.²⁶ This is accomplished by *external compression of tissues* with manual lymphatic drainage, sequential pneumatic compression machines, or compressive garments.^{16-19,48,58,76,86}

NOTE: It appears that compression facilitates the evacuation and reabsorption of fluids but does not increase the reabsorption of proteins in the edema fluid.³³

- Lymphatic and venous return also is enhanced by *elevating* the involved limb. Lymphedema caused by infection or inflammation of the lymphatic system (e.g., lymphangitis or cellulitis) does not diminish as readily with elevation as does edema secondary to chronic venous insufficiency.^{26,33,76}

Comprehensive Regimens and Components

A comprehensive approach to the management of lymphedema is referred to in the literature by a variety of terms, including *complex lymphedema therapy*, *complete* or *complex decongestive physical therapy*, or *decongestive lymphatic therapy*.^{10,11,21,22,25,44,51,52,70,72,85,86} Box 24.11 summarizes the components of these programs.

All of these regimens combine manual lymphatic drainage through light, superficial massage and compressive bandaging with active ROM, low-intensity resistance exercises, cardiopulmonary conditioning exercises, and good skin hygiene.

Manual lymphatic drainage. Manual lymphatic drainage involves slow, very light repetitive stroking and circular massage movements done in a specific sequence with the involved extremity elevated whenever possible.^{10,11,21,22,25,47,73,85,86} Proximal congestion in the trunk, groin, buttock, or axilla is cleared first to make room for fluid from the more distal areas. The direction of the massage is toward specific lymph nodes and usually involves *distal to proximal* stroking. Fluid in the involved extremity then is cleared, first in the proximal portion and then in the distal portion of the limb. Because manual lymphatic drainage is extremely labor- and time-intensive, methods of self-massage are taught to the patient as soon as possible in a treatment program.

Exercise. Active ROM, stretching, and low-intensity resistance exercises are integrated with manual drainage techniques.^{7,16,18,21,23,24,57,59,60,86} Exercises are performed while wearing a compressive garment or bandages and in a specific sequence, often with the edematous limb(s) elevated. A low-intensity cardiovascular/pulmonary endurance activity, such as bicycling, often follows ROM and strengthening exercises. Specific exercises and a suggested sequence for the upper and lower extremities, compiled from several sources, are described and illustrated in the last section of this chapter.

BOX 24.11 Components of a Decongestive Lymphatic Therapy Program

- Elevation
- Manual lymphatic drainage (massage)
 - Direct intervention by a therapist
 - Self-massage by the patient
- Compression
 - Nonelastic or low-stretch bandages or custom-fitted garments
 - Intermittent, sequential pneumatic compression pump
- Individualized exercise program
 - Active ROM (pumping exercises)
 - Flexibility exercises
 - Low-intensity resistance exercises
 - Cardiovascular conditioning
- Skin care and daily living precautions

Elevation. The involved limb is elevated during use of a sequential compression pump, while sleeping or resting, or even during sedentary activities. The compressive bandages or garment are worn during periods of elevation.^{11,16,18,58,76}

Compressive bandages, garments, or pumps. No-stretch, nonelastic bandages or low-stretch elastic bandages or garments are recommended because they provide relatively low compressive forces on the edematous extremity at rest. In addition, they provide a higher working pressure with active muscular contractions because of their less yielding nature than high-stretch bandages.^{16,18,21,25,76,86} High-stretch sports bandages, such as Ace wraps, are not recommended for treating lymphedema.^{11,16,76} Daily use of a sequential, pneumatic compression pump also may be advisable during the early stages of treatment of substantial lymphedema.^{16,19,25,58}

Skin care and hygiene. Lymphedema predisposes the patient to skin breakdown, infection, and delayed wound healing. Meticulous attention to skin care and protection of the edematous limb are essential elements of self-management of lymphedema.^{16,18,58,76}

Management Guidelines

Guidelines for the management of lymphatic disorders are essentially the same as those already described for the management of chronic venous insufficiency and associated lymphedema (see Box 24.8). As with chronic venous insufficiency, management of lymphatic disorders initially involves direct interventions by a therapist and an emphasis on patient education, followed by lifelong prevention and self-management by the patient.

Precautions and Self-Management of Lymphedema

Precautions that patients should take to prevent lymphedema and skin breakdown or infection are an important aspect of self-management (see Box 24.10).

Use of Community Resources

A valuable resource for patients and health care professions is the National Lymphedema Network (www.lymphnet.org). This nonprofit organization provides education and guidance about lymphedema. Another resource is the Lymphedema Internet Network (<http://www.lymphedema.org>).

BREAST CANCER-RELATED LYMPHATIC DYSFUNCTION

Background

Breast cancer-related dysfunction of the lymphatic system and subsequent lymphedema of the upper extremity is a somewhat common and potentially serious complication of the treatment for breast cancer. It is estimated that 15% to 20%⁶³ or as many as one in four patients²⁹ with invasive breast cancer develop upper extremity lymphedema during or sometime after the course of treatment.

Current treatment usually involves removing a portion or all of the breast accompanied by excision or irradiation of adjacent axillary lymph nodes, the principal site of regional metastases. Axillary dissection places a patient at risk not only for upper extremity lymphedema but also for loss of shoulder mobility and limited function of the arm and hand.^{7,8,14,15,17,18,31,61,63,69} In addition, chemotherapy or hormonal therapy may also be employed.

Axillary dissection and removal of lymph nodes interrupt and slow the circulation of lymph, which in turn can lead to lymphedema.^{7,15,18,29} Radiation therapy can cause fibrosis of tissues in the area of the axilla, which obstructs the lymphatic vessels and contributes to pooling of lymph in the arm and hand.^{7,15,18,29} The extent of the axillary dissection and exposure to radiation is associated with the degree of risk for lymphedema to develop. In addition, shoulder motion can become impaired as the result of incisional pain, delayed wound healing, and skin ulcerations (associated with radiation therapy), and postoperative weakness of the muscles of the shoulder girdle.^{18,58}

A comprehensive approach to postoperative management that emphasizes patient education and includes therapeutic exercise and other direct interventions to prevent or treat lymphedema and other impairments or functional limitations are key to successful outcomes.^{5,8,16,18,58,64}

As with most cancers, the diagnosis of breast cancer and the ensuing treatments have an enormous emotional impact on patients and their families.^{18,71} The advent of breast cancer-related lymphedema not only has an impact on a breast cancer survivor's physical function but is known to have a significantly adverse effect on health-related quality of life, making prevention of lymphedema and, if it develops, aggressive treatment high priorities for management.⁶⁹

Surgical Procedures

Surgical treatment of breast cancer falls into two broad categories—mastectomy and breast-conserving surgeries—both of which are coupled routinely with partial or complete axillary node dissection. Differences in surgical procedures are related to the extent of removal of breast tissue and surrounding or underlying soft tissues.^{1,10,40} A course of radiation therapy routinely follows surgery to decrease the risk of regional recurrence of the disease. Chemotherapy also may be initiated postoperatively to prevent the systemic spread of the disease.

Mastectomy

Mastectomy involves removing the entire breast. In addition, a mastectomy may involve removing the fascia over the chest muscle. With late-stage, invasive disease, a radical mastectomy in which the pectoralis muscles also are excised may be required, leading to significant muscle weakness and impaired shoulder function.

Breast-Conserving Surgery

Options for resecting the tumor and preserving a portion of the breast include *lumpectomy*, which involves excision of

the mass and a margin of healthy surrounding breast tissue, or *segmental mastectomy* (also known as *quadrectomy*), which is excision of the affected quadrant of the breast. These procedures are being used increasingly, rather than mastectomy, in combination with adjuvant therapy for patients with stage I or II tumors.^{1,40}

There are now multiple randomized clinical trials that show that the 10- to 20-year survival rate for patients with stage I or II disease who underwent breast-conserving surgery combined with radiation therapy is equivalent to that achieved by patients who underwent mastectomy alone or mastectomy with adjuvant therapy.¹

Patients who undergo breast-conserving procedures without removal of lymph nodes are still at risk for developing postoperative lymphedema and impaired shoulder mobility because of potential complications from radiation therapy and biopsy of at least one lymph node.^{18,58}

Dissection of Axillary Lymph Nodes (Lymphadenectomy)

As mentioned, at this time axillary lymph node dissection is a standard part of mastectomy and breast-conserving surgery, although the extent of node removal is controversial.^{1,40} A minimum of a level I axillary node dissection and removal of the sentinel node in the axilla at the lateral borders of the breast is required for biopsy to assess regional lymph node involvement and for staging the disease. More extensive dissection for metastatic disease removes the nodes under the pectoralis minor muscle or around the clavicle.

Impairments and Complications Related to Breast Cancer Treatment

The following impairments and complications may occur in association with treatment of breast cancer. Many of these problems are interrelated and must be considered jointly when a comprehensive postoperative rehabilitation program is developed for the patient.*

Postoperative Pain

Incisional pain. A transverse incision across the chest wall is made to remove the breast tissue and underlying fascia on the chest musculature. The incision extends into the axilla for lymph node dissection. Postoperatively, the sutured skin over the breast area may feel tight along the incision. Movement of the arm pulls on the incision and is uncomfortable for the patient. Healing of the incision may be delayed as the result of radiation therapy. Delayed wound healing, in turn, prolongs pain in the area of the incision.

Posterior cervical and shoulder girdle pain. Pain and muscle spasm may occur in the neck and shoulder region as a result of muscle guarding. The levator scapulae, teres major and minor, and infraspinatus often are tender to palpation and can restrict active shoulder motion. Decreased

use of the involved upper extremity after surgery due to pain sets the stage for the patient to develop a chronic frozen shoulder and increases the likelihood of lymphedema in the hand and arm.

Postoperative Vascular and Pulmonary Complications

Decreased activity and extended time in bed increase venous stasis and the risk of DVT. Risk of pulmonary complications, such as pneumonia, also is higher because of the patient's reduced activity level. Incisional pain may make the patient reluctant to cough or breathe deeply, both of which are necessary postoperatively to keep the airways clear of fluid accumulation.

Lymphedema

As noted previously, patients who undergo any level of lymph node dissection or whose treatment regimen includes radiation therapy remain at risk throughout life for developing ipsilateral upper extremity lymphedema.^{7,18,58,86} Lymphedema can occur almost immediately after lymph node dissection, during the course of radiation therapy, or many months or even years after treatment has been completed. It is typically evident in the hand and arm but occasionally develops in the upper chest or back area.^{15,18,58,61,86} In turn, lymphedema leads to impaired upper extremity function, poor cosmesis, and emotional distress.^{18,31,61,71}

Chest Wall Adhesions

Restrictive scarring of underlying tissues on the chest wall can develop as the result of surgery, radiation fibrosis, or wound infection. Chest wall adhesions can lead to increased risk of postoperative pulmonary complications, restricted mobility of the shoulder, postural asymmetry and dysfunction, and discomfort in the neck, shoulder girdle, and upper back.

Decreased Shoulder Mobility

It is well documented that patients may experience temporary and sometimes long-term loss of shoulder mobility after surgery or radiation therapy for treatment of breast cancer.^{7,37,43,58,64,80,81,83} Factors contributing to impaired shoulder mobility after surgery are listed in Box 24.12.

Weakness of the Involved Upper Extremity

Shoulder weakness. If the long thoracic nerve is traumatized during axillary dissection and removal of lymph nodes, this results in weakness of the serratus anterior and compromised stability of the scapula, limiting active flexion and abduction of the arm. Faulty shoulder mechanics and use of substitute motions with the upper trapezius and levator scapulae during overhead reaching can cause subacromial impingement and shoulder pain. Shoulder impingement, in turn, can be a precursor to a frozen shoulder. If the pectoralis muscles were disturbed, which occurs with a radical mastectomy for advanced disease, weakness is evident in horizontal adduction.

Decreased grip strength. Grip strength is often diminished as the result of lymphedema and secondary stiffness of the fingers.

*See refs. 6, 8, 14, 15, 18, 31, 36, 37, 43, 58, 61, 81, 83, 86.

BOX 24.12 Factors Contributing to Impaired Shoulder Mobility After Breast Cancer Surgery

- Incisional pain immediately after surgery or associated with delayed wound healing
- Muscle guarding and tenderness of the shoulder and posterior cervical musculature
- Need for protected shoulder ROM until the surgical drain is removed
- Fibrosis of soft tissues in the axillary region due to adjuvant radiation therapy
- Adherence of scar tissue to the chest wall, causing adhesions
- Temporary or permanent weakness of the muscles of the shoulder girdle
- Rounded shoulders and kyphotic or scoliotic trunk posture associated with age or incisional pain
- A feeling of heaviness of the upper extremity due to lymphedema
- Decreased use of the hand and arm for functional activities

Postural Malalignment

The patient may sit or stand with rounded shoulders and kyphosis because of pain, skin tightness, or psychological reasons. An increase in thoracic kyphosis associated with aging is commonly seen in the older patient.³⁶ This contributes to faulty shoulder mechanics and eventually restricts active use of the involved upper extremity. Asymmetry of the trunk and abnormal scapular alignment may occur as the result of a subtle lateral weight shift, particularly in a large-breasted woman.

Fatigue and Decreased Endurance

Patients undergoing radiation therapy or chemotherapy often experience debilitating fatigue.^{1,33} Anemia may develop as a result of chemotherapy. Nutritional intake and subsequent energy stores may be diminished, particularly if a patient is experiencing nausea for several days after a cycle of chemotherapy. Fatigue also is associated with depression. As a result, exercise tolerance and endurance during functional activities are markedly reduced.

Psychological Considerations

A patient undergoing treatment for breast cancer experiences a wide range of emotional and social issues.⁷¹ The needs and concerns of both the patient and the family must be considered. The patient and family members must cope with the potentially life-threatening nature of the disease and a difficult treatment regimen. It is common for a patient to feel anxiety, agitation, anger, depression, a sense of loss, and significant mood swings during treatment and recovery from breast cancer.

In addition to the obvious physical disfigurement and altered body image associated with mastectomy, medications such as immunosuppressants and corticosteroids can

affect the emotional state of a patient. Psychological manifestations affect physical well-being and can contribute to general fatigue, the patient's perception of functional disability, and motivation during treatment.

Guidelines for Management After Breast Cancer Surgery

Guidelines for postoperative management for the patient who has undergone a mastectomy or breast-conserving surgery and who may currently be receiving adjuvant therapy are outlined in Box 24.13. The guidelines identify therapeutic interventions for common impairments during the early postoperative period and those that could develop at a later time.

NOTE: The guidelines outlined in Box 24.13 also can be modified to prevent or manage problems that can develop in the trunk and lower extremities after surgery for abdominal or pelvic cancers and accompanying inguinal lymph node dissection.

Special Considerations

Patient education. The length of stay for patients after surgery for breast cancer is short. Therefore, direct intervention by a therapist starts on the first postoperative day with an emphasis on patient education for *prevention* of postoperative complications and impairments, including pulmonary complications, thromboemboli, lymphedema, and loss of shoulder mobility. Recommendations for preventing lymphedema or for self-management if it develops are reviewed with the patient (see Box 24.10).

Exercise. The postoperative exercise program focuses on three main areas: improving shoulder function, regaining an overall level of fitness, and preventing or managing lymphedema. Early, but protected, assisted or active ROM of the shoulder is the key to restoring shoulder mobility. Postoperative risks that contribute to restricted shoulder mobility were summarized previously (see Box 24.12).^{1,18,40,58,60} These risks are highest during the early postoperative period until drains have been removed and the incision has healed.

NOTE: Radiation therapy to the axillary and breast areas can delay wound healing beyond the typical 3- to 4-week period.^{1,40} Even after initial healing of the incision, the scar has a tendency to contract and can become adherent to underlying tissues, which, in turn, can restrict shoulder motion.

Although strengthening exercises and aerobic conditioning are important for upper extremity function and total body fitness, *moderation* in an exercise program is imperative. Exercises must be progressed gradually, excessive fatigue must be avoided, and energy conservation must be emphasized, especially if the patient is undergoing chemotherapy or radiation therapy. Exercise precautions for the patient undergoing treatment are noted in Box 24.14.^{7,18,60,64}

BOX 24.13**MANAGEMENT GUIDELINES—After Surgery for Breast Cancer****Potential Postoperative Impairments**

- Pulmonary and circulatory complications
- Lymphedema
- Restricted mobility of the upper extremity
- Postural malalignment
- Weakness and decreased functional use of the upper extremity
- Fatigue and decreased endurance for functional activities
- Emotional and social adjustments

Plan of Care	Interventions
<ol style="list-style-type: none"> 1. Prepare the patient for post-operative self-management. 2. Prevent postoperative pulmonary complications and thromboemboli. 3. Prevent or minimize postoperative lymphedema. 4. Decrease lymphedema if or when it develops. 5. Prevent postural deformities. 6. Prevent muscle tension and guarding in cervical musculature. 7. Prevent restricted mobility of the upper extremity. 8. Regain strength and functional use of the involved extremity. 9. Improve exercise tolerance and sense of well-being; reduce fatigue. 10. Provide information about resources for patient and family support and ongoing patient education. 	<ol style="list-style-type: none"> 1. Interdisciplinary patient education involving all aspects of potential impairments and functional limitations. Self-management activities and preparation for participation in a home program on the first postoperative day. 2. Pre- or postoperative instruction in deep breathing, emphasizing maximal inspirations and effective coughing (see Chapter 25). Active ankle exercises (calf pumping exercises). 3. Elevation of the involved upper extremity on pillows (about 30°) while the patient is in bed or sitting in a chair. Wrapping the involved upper extremity with bandages or wearing an elastic pressure gradient sleeve. Pumping exercises of the arm on the side of the surgery. Early ROM exercises. <p>PRECAUTION: Avoid static, dependent positioning of the arm.</p> <ol style="list-style-type: none"> 4. Manual lymphatic drainage massage. Daily regimen of exercises to reduce lymphedema. Use of custom-fit elastic compression garment when lymphedema is stabilized. Adherence to precautions for skin care (see Box 24.10). 5. Posture awareness training; encourage the patient to assume an erect posture when sitting or standing to minimize a rounded shoulder posture. Posture exercises with an emphasis on scapular retraction exercises. 6. Active ROM of the cervical spine to promote relaxation. Shoulder shrugging and shoulder circle exercises. Gentle massage to cervical musculature. 7. Active-assistive and active ROM exercises of the shoulder, elbow, and hand initiated as soon as possible but cautiously usually on the first postoperative day. <p>NOTE: Exercise may be initiated even when the drainage tubes and sutures are still in place.</p> <p>After the incision has healed, self-stretching to the shoulder.</p> <ol style="list-style-type: none"> 8. Upper extremity ergometry initially against minimal and, later, moderate resistance. Use of the involved extremity for light functional activities. 9. Graded, low-intensity aerobic exercise such as walking or cycling. <ol style="list-style-type: none"> 10. Resources: American Cancer Society for family support and ongoing patient education (www.cancer.org); National Breast Cancer Coalition; National Lymphedema Network.

Precautions: Shoulder exercise should be performed within *protected* ROM, usually no more than 90° of elevation of the arm until after removal of drains. Observe the incision and sutures carefully during exercises. Avoid any undue tension on the incision or blanching of the scar during shoulder exercises. Avoid exercises with the involved arm in a dependent position. Progress graded exercise program very slowly, particularly if the patient is receiving adjuvant therapy.

BOX 24.14 Exercise Precautions and Treatment of Breast Cancer

- Exercise only at a moderate level and never to the point that the affected arm aches during or after exercise, even if there is no evidence of lymphedema.
- Monitor upper extremity girth measurements closely.
- Adjust the *timing* of exercise during cycles of radiation therapy or chemotherapy. With some chemotherapy medications, a patient can develop cardiac arrhythmia and therefore should not perform aerobic exercises, such as stationary cycling, for 24 to 48 hours after a chemotherapy session.
- Return to more physically demanding work and recreational activities gradually after completion of chemotherapy or radiation therapy.

Although early intervention for the prevention of lymphedema and upper extremity mobility impairments is often advocated by therapists and suggested in descriptive articles in the literature, patients often are not referred for postoperative rehabilitation until after impairments and functional limitations have developed. This may be due to concerns raised in the literature²⁹ that early postoperative ROM could disturb drains or delay wound healing or that exercises, if performed too vigorously, could initiate or exacerbate lymphedema. In addition, few studies have rigorously investigated the efficacy of specific interventions or rehabilitation protocols.^{58,80} However, a recent review of the literature of exercise and cancer-related lymphedema revealed that exercise neither worsened preexisting lymphedema nor was associated with a significant increase in the occurrence of lymphedema.⁷

From the information available in the literature, the following recommendations for exercise are made.*

- Integrate several interventions including exercise, massage, and use of compression devices into a patient's comprehensive plan of care.
- Implement shoulder ROM exercises early in a postoperative program to prevent mobility impairments.
- Include moderate-intensity aerobic conditioning exercises to improve fitness and quality of life.
- Progress all forms of exercise gradually and avoid any form of high-intensity training.

Community resources Reach to Recovery is a one-to-one patient education program sponsored by the American Cancer Society (www.cancer.org). Representatives of this program, most of whom are breast cancer survivors, provide emotional support to the patient and family as well as current information on breast prostheses and reconstructive surgery. The National Lymphedema Network (www.lymphnet.org) is another valuable source of information for patients at risk for or who have developed lymphedema.

*See refs. 6, 14, 15, 17, 18, 31, 37, 44, 52, 57, 59, 60, 72, 80, 81, 85, 86.

EXERCISES FOR THE MANAGEMENT OF LYMPHEDEMA

Background and Rationale

As noted previously in this chapter, exercise is just one aspect of a decongestive lymphatic therapy program. The rationale for including exercise in the comprehensive treatment of patients with upper or lower extremity lymphedema is to move and drain lymph fluid to reduce the edema and to improve the functional use of the involved limb or limbs. Principles on which exercises for lymphatic drainage are based are summarized in Box 24.15.^{7,59,86}

The exercises employed in lymph drainage regimens cover a wide spectrum of therapeutic exercise interventions, specifically deep breathing, relaxation, flexibility, strengthening, cardiovascular conditioning exercises, and a sequence of lymphatic drainage exercises as well. Exercise regimens have been described in an extensive number of publications.* No particular combination or sequence of exercises has been shown to be superior to another. Although a critical review of the literature a decade ago⁶² indicated that the effectiveness of exercise regimens for lymph drainage was based primarily on clinical observations and opinions of experienced practitioners or case reports, there is now an emerging body of evidence documenting the efficacy of specific components of these programs.^{7,44,57,58,72}

Components of Exercise Regimens for Management of Lymphedema

Deep Breathing and Relaxation Exercises

- Deep breathing is interwoven throughout exercise regimens for the management of lymphedema. It has been

BOX 24.15 Exercises for Lymphatic Drainage: Principles and Rationale

- Contraction of muscles pumps fluids by direct compression of the collecting lymphatic vessels.
- Exercise reduces soft tissue and joint hypomobility that can contribute to static positioning and lead to lymphostasis.
- Exercise strengthens and prevents atrophy of muscles of the limbs, which improves the efficiency of the lymphatic pump.
- Exercise increases heart rate and arterial pulsations, which in turn contribute to lymph flow.
- Exercise should be sequenced to clear the central lymphatic reservoirs before the peripheral areas.
- Wearing compression bandages during exercises enhances lymph flow and protein reabsorption more efficiently than exercising without bandages.

*See refs. 10, 11, 18, 21-24, 41, 44, 48, 51, 52, 59, 60, 64, 69, 72, 85, 86.

suggested that the use of abdominal-diaphragmatic breathing assists in the movement of lymphatic fluid as the diaphragm descends during a deep inspiration and the abdominals contract during a controlled, maximum expiration.¹⁸ Changes in intra-abdominal and intrathoracic pressures create a gentle, continual pumping action that moves fluids in the central lymphatic vessels, which run superiorly in the chest cavity and drain into the venous system in the neck (see Fig. 24.2).

- Progressive, total body relaxation exercises²⁸ (described in Chapter 4 of this text) are performed at the beginning of each exercise session to decrease muscle tension, which may be contributing to restricted mobility and lymph congestion.^{18,21,24,86} Deep breathing is an integral component of the sequence of relaxation exercises.

Flexibility Exercises

Gentle, self-stretching exercises are used to minimize soft tissue and joint hypomobility, particularly in proximal areas of the body that may contribute to static postures and lymph congestion.

Strengthening and Muscular Endurance Exercises

Both isometric and dynamic exercises using self-resistance, elastic resistance, and weights or weight machines are appropriate if done against light resistance (initially, 1 to 2 lb) and by progressing resistance and repetitions gradually. Regardless of whether lymphedema has developed, it is important to monitor the circumferential size and the skin texture of the involved limb closely to determine whether an appropriate intensity of exercise has been established. Emphasis is placed on improving endurance and strength of central and peripheral muscle groups that enhance an erect posture and minimize fatigue in muscles that contribute to the efficiency of the lymphatic pump mechanism.

Cardiovascular Conditioning Exercises

Activities such as upper extremity ergometry, swimming, cycling, and walking increase circulation and stimulate lymphatic flow.¹⁸ Thirty minutes of aerobic endurance exercises complement lymph drainage exercises. Conditioning exercises are done at low intensity (at 40% to 50% of the target heart rate) when lymphedema is present and at higher intensities (up to an 80% level) when the lymphedema has been reduced and exercise is otherwise safe.^{18,59}

Lymphatic Drainage Exercises

Lymphatic drainage exercises, often referred to as *pumping exercises*, move fluids through lymphatic channels. Active, repetitive ROM exercises are performed throughout each session. *The exercises follow a specific sequence to move lymph away from congested areas.*^{18,21,23,24,86} It is similar to the sequence of massage applied during manual lymph drainage.^{47,73} In general, the exercises first focus on proximal areas of the body to clear central collecting vessels and then involve distal muscle groups to begin to move peripheral edema in a centripetal direction to the central lymph vessels. The affected upper or lower extremity or

extremities are held in an elevated position during many of the exercises. Static, dependent postures are avoided. Self-massage also is interspersed throughout the exercise sequence to further enhance drainage. These exercises also maintain mobility of the involved limbs.

Guidelines for Lymphatic Drainage Exercises

The patient should follow these guidelines when performing a sequence of lymphatic drainage exercises. These guidelines apply to management of upper or lower extremity lymphedema and reflect the combined opinions of several authors and experts in the field.^{18,21-23,59,86}

Preparation for Lymphatic Drainage Exercises

- Set aside approximately 20 to 30 minutes for each exercise session.
- Perform exercises twice daily every day.
- Have needed equipment at hand, such as a foam roll, wedge, or exercise wand.

During Lymphatic Drainage Exercises

- Wear compression bandages or a customized compression garment.
- Precede lymphatic drainage exercises with total body relaxation activities.
- Follow a specified order of exercises.
- Perform active, repetitive movements slowly, about 1 to 2 seconds per repetition.
- Elevate the involved limb above the heart during distal pumping exercises.
- Combine deep breathing exercises with active movements of the head, neck, trunk, and limbs.
- Initially, perform a low number of repetitions. Increase repetitions gradually to avoid excessive fatigue.
- Do not exercise to the point where the edematous limb aches.
- Incorporate self-massage into the exercise sequence to further enhance lymph drainage.
- Maintain good posture during exercises.
- When strengthening exercises are added to the lymph drainage sequence, use light resistance and avoid excessive muscle fatigue.

After Lymphatic Drainage Exercises

- If possible, rest with the involved extremity elevated for 30 minutes.
- Set aside time several times per week for low-intensity aerobic exercise activities, such as walking or bicycling for 30 minutes.
- Carefully check for signs of redness or increased swelling in the edematous limb, either of which could indicate that the level of exercise was excessive.

Selected Exercises for Lymphatic Drainage: Upper and Lower Extremity Sequences

The selection and sequences of exercises described in this section and summarized in Box 24.16 are designed to assist

BOX 24.16 Sequence of Selected Exercises for Management of Upper or Lower Extremity Lymphedema**Exercises Common to Upper and Lower Extremity Regimens**

NOTE: Start an upper or lower extremity regimen with these exercises

- Deep breathing and total body relaxation exercises
- Posterior pelvic tilts and partial curl-ups
- Cervical ROM
- Bilateral scapular movements

Upper Extremity Exercises

- Active circumduction with the involved arm elevated while lying supine
- Bilateral active movements of the arms while lying supine or on a foam roll
- Bilateral hand press while lying supine or sitting
- Shoulder stretches (with wand, doorway, or towel) while standing
- Active elbow, forearm, wrist, and finger exercises of the involved arm
- Bilateral horizontal abduction and adduction of the shoulders
- Overhead wall press while standing
- Finger exercises
- Partial curl-ups
- Rest with involved upper extremity elevated

Lower Extremity Exercises

- Alternate knee to chest exercises
- Bilateral knees to chest
- Gluteal setting and posterior pelvic tilts
- Single knee to chest with the involved lower extremity
- External rotation of the hips while lying supine with both legs elevated and resting on a wedge or wall
- Active knee flexion of the involved lower extremity while lying supine
- Active plantarflexion and dorsiflexion and circumduction of the ankles while lying supine with lower extremities elevated
- Active hip and knee flexion with legs externally rotated and elevated against a wall
- Active cycling and scissoring movements with legs elevated
- Bilateral knee to chest exercises, followed by partial curl-ups
- Rest with lower extremities elevated

in the drainage of upper or lower extremity lymphedema. Many of the individual exercises suggested in lymphedema protocols, such as ROM of the cervical spine and some of the shoulder girdle or upper extremity exercises, are not exclusively used for lymph drainage. They also are used to improve mobility and strength. Several of the exercises highlighted in this section already have been described in previous chapters in this text. Only those exercises or variations of exercises that are somewhat unique or not previously addressed are described or illustrated in this section.

Sequence of Exercises

- Total body relaxation exercises are implemented prior to lymphatic drainage exercises.
- Exercises for lymphatic drainage should follow a particular sequence to assist lymph flow. The central and proximal lymphatic vessels, such as the abdominal, inguinal, and cervical nodes (see Fig. 24.2), are cleared first with trunk, pelvic, hip, and cervical exercises. Then, for the most part, exercises proceed distally from shoulders to fingers or from hips to toes. If lymph nodes have been surgically removed (e.g., with a unilateral axillary node dissection for breast cancer or a bilateral inguinal node dissection for cancers of the abdominal or pelvic organs), lymph must be channeled to the remaining nodes in the body.

NOTE: Because no single sequence of exercises has been shown to be more effective than another, the upper and lower extremity sequences of exercises outlined in this sec-

tion do not reflect the exercises included in any one specific protocol. Rather, the exercise sequences are based on the recommendations of several authors.^{18,21-23,44,57-59,72,86} Sequences of exercises for upper or lower extremity lymphedema are summarized in the remaining portion of this chapter. Therapists are encouraged to modify or add other exercises to the sequences in this chapter as they see fit to meet the individual needs of their patients.

Exercises Common to Upper and Lower Extremity Sequences

These initial exercises should be included in programs for unilateral or bilateral upper or lower extremity lymphedema. They are designed to help the patient relax and then to clear the central channels and nodes.

● Total body relaxation

- Have the patient assume a comfortable supine position and begin deep breathing. Then, isometrically contract and relax the muscles of the lower trunk (abdominals and erector spinae) followed by the hips, lower legs, feet, and toes.
- Then contract and relax the muscles of the upper back, shoulders, upper arms, forearms, wrist, and fingers.
- Finally, contract and relax the muscles of the neck and face.
- Relax the whole body for at least a minute.
- Perform diaphragmatic breathing throughout the entire sequence. Avoid breath-holding and the Valsalva maneuver.

● **Posterior pelvic tilts and partial curl-ups**

- Perform these exercises with hips and knees flexed, in the supine position.
- **Unilateral knee-to-chest movements.** These exercises are designed to target the inguinal nodes. This is important even for upper extremity lymphedema.
 - In the supine position flex one hip and knee, and grasp the lower leg. Pull the knee to the chest. Gently press or bounce the thigh against the abdomen and chest about 15 times.
 - Repeat the procedure with the opposite lower extremity.

NOTE: If lymphedema is present in only one lower extremity, initiate the knee-to-chest exercises with the *uninvolved* lower extremity.

● **Cervical ROM.** Perform each motion for a count of 5 for five repetitions.

- Rotation
- Lateral flexion

● **Scapular exercises.** Perform exercise for a count of 5 for five repetitions.

- Active elevation and depression (shoulder shrugs)
- Active shoulder rolls
- Active scapular retraction and protraction. With arms at sides and elbows flexed, bilaterally retract the scapulae, pointing elbows posteriorly and medially. Then protract the scapulae.

NOTE: Be sure to shrug the shoulders as high as possible and then *actively* pull down the shoulders (depress the scapulae) as far as possible

Exercises Specifically for Upper Extremity Lymphedema Clearance

The following sequence of exercises is performed after the general, total body exercises just described. The exercises, which are performed in a proximal to distal sequence, are done specifically for upper extremity lymph clearance.

NOTE: Periodically during the exercise sequence have the patient perform self-massage to the axillary node area of the *uninvolved* side proceeding from the axilla to the chest.

● **Active circumduction of the arm (Fig. 24.3).** While lying supine, flex the involved arm to 90° (reach toward the ceiling) and perform active circular movements of the arm about 6 to 12 inches in diameter. Do this clockwise and counterclockwise, five repetitions in each direction.

PRECAUTION: Avoid pendular motions or circumduction of the edematous upper extremity with the arm in a dependent position.

● **Exercises on a foam roll (Fig. 24.4).** While lying supine on a firm foam roll (approximately 6 inches in diameter), perform horizontal abduction and adduction as well as flexion and extension of the shoulder. These movements target congested axillary nodes and are done unilaterally. For home exercises, if special equipment such as an Ethyfoam® roller is not available, have the patient perform these exercises on a foam pool “noodle.” Although

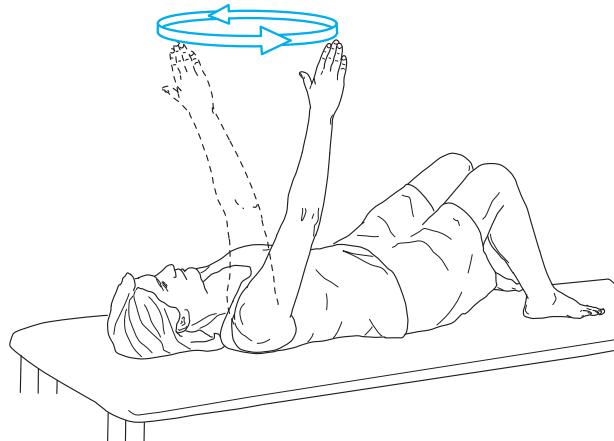

FIGURE 24.3 Active circumduction of the edematous extremity.

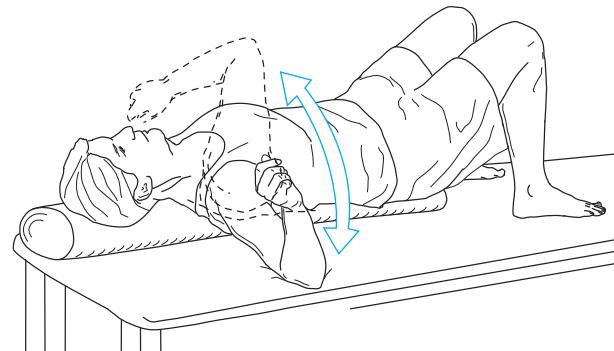

FIGURE 24.4 Active shoulder exercises on a firm, foam roll.

the diameter is smaller, a towel or folded sheet can be wrapped around the foam “noodle” to increase the diameter of the roll.

● **Bilateral hand press.** With arms elevated to shoulder level or higher and the elbows flexed, place the palms of the hands together in front of the chest or head. Press the palms together (for an isometric contraction of the pectoralis major muscles) while breathing in for a count of 5. Relax and then repeat up to five times.

● **Wand exercise, doorway or corner stretch, and towel stretch.** Incorporate several exercises to increase shoulder mobility and to decrease congestion and assist lymph flow in the upper extremity. Hold the position of stretch for several seconds with each repetition. These exercises have been described and are illustrated in Chapter 17.

● **Unilateral arm exercises with the arm elevated.** The following exercises are done with the patient seated and the arm supported at shoulder level on a tabletop or countertop or with the patient supine and the arm supported on a wedge or elevated overhead.

- Shoulder rotation with the elbow extended. Turn the palm up, then down, by rotating the shoulder, not simply pronating and supinating the forearm.
- Elbow flexion and extension.
- Circumduction of the wrist.
- Hand opening and closing.

- **Bilateral, horizontal abduction and adduction.** While standing or sitting, place both hands behind the head. Horizontally adduct and abduct the shoulders by bringing the elbows together and then pointing them laterally.
- **Overhead wall press.** Face a wall; place one or both palms on the wall with the hands above shoulder level. Gently press the palms into the wall for several seconds without moving the body. Relax and repeat approximately five times.
- **Wrist and finger exercises.** If swelling is present in the wrist and hand, repetitive active finger movements are indicated with the arm elevated.
 - After performing the overhead wall press as just described, keep the heel of the hand on the wall and alternatively move all of the fingers away from and back to the wall (Fig. 24.5).
 - In the same position as just described, alternately press individual fingers into the wall, as if playing a piano, while keeping the heel of the hand in contact with the wall.
 - Place the palms of both hands together with the hands overhead or at least above shoulder level. One finger at a time, press matching fingers together and then pull them away from each other.
- **Partial curl-ups.** To complete the exercise sequence, perform additional curl-ups (about five repetitions) with hands sliding on the thighs.
- **Rest.** Rest in a supine position with the involved arm elevated on pillows for about 30 minutes after completing the exercise sequence.

Exercises Specifically for Lower Extremity Lymphedema Clearance

NOTE: After completing the general lower body, neck, and shoulder exercises previously described, have the patient perform self-massage first to the axillary lymph nodes on the *involved* side of the body. Then massage the lower abdominal area superiorly to the waist and then laterally

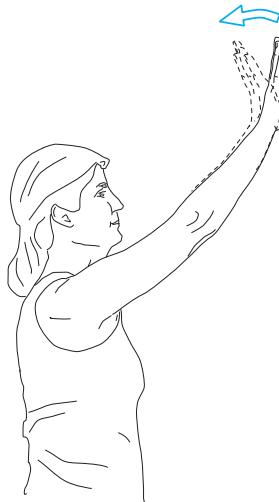

FIGURE 24.5 Overhead wall press.

and superiorly to the axillary area of the involved side. This sequence is repeated periodically throughout the lower extremity exercise sequence.

- **Unilateral knee-to-chest movements.** In the supine position, repeat this exercise for another 15 repetitions. If lymphedema is present in only one lower extremity, perform repeated knee to chest movements with the *uninvolved leg first* and then the involved leg.
- **Bilateral knees to chest.** In the supine position, flex both hips and knees, grasp both thighs, and gently pull them to the abdomen and chest. Repeat 10 to 15 times.
- **Gluteal setting and posterior pelvic tilts.** Repeat five times, holding each contraction for several seconds and then slowly releasing.
- **External rotation of the hips (Fig. 24.6).** Lie in the supine position with the legs elevated and resting against a wall or on a wedge. Externally rotate the hips, pressing the buttocks together, and holding the outwardly rotated position. Repeat several times.
- **Knee flexion to clear the popliteal area.** While lying in the supine position and keeping the uninvolved lower extremity extended, flex the involved hip and knee enough to clear the foot from the mat table. Actively flex the knee as far as possible by quickly moving the heel to the buttocks. Repeat approximately 15 times.
- **Active ankle movements.** With both legs elevated and propped against a wall, or just the involved leg propped against a door frame and the uninvolved leg resting on the floor, actively plantarflex the ankle and curl the toes; then dorsiflex the ankle and extend the toes as far as possible for multiple repetitions. Finally, actively circumduct the foot clockwise and counterclockwise for several repetitions.
- **Wall slides in external rotation (Fig. 24.7).** With the feet propped up against the wall, legs externally rotated, and

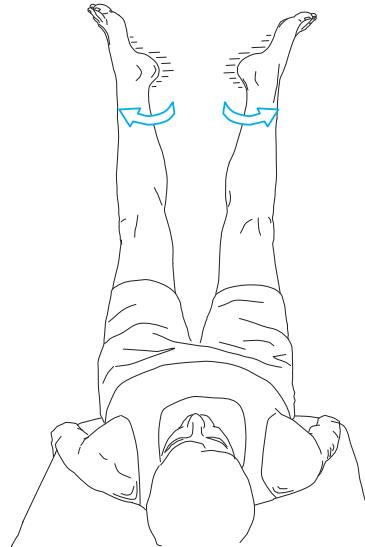

FIGURE 24.6 Repeated outward rotation of the hips with legs elevated.

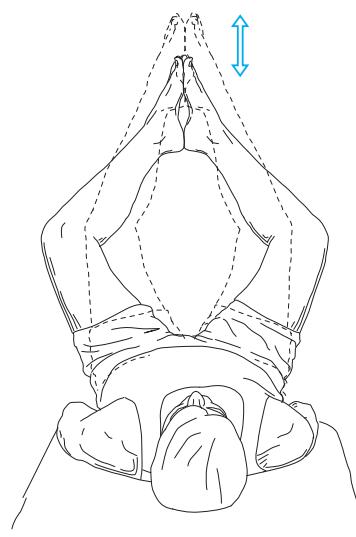

FIGURE 24.7 Wall slides with hips externally rotated.

- heels touching, slide both feet down the wall as far as possible and then back up the wall for several repetitions.
- **Leg movements in the air (Fig. 24.8).** With both hips flexed and the back flat on the floor and both feet pointed to the ceiling, alternately move the legs, simulating cycling, walking, and scissoring motions.
 - **Hip adduction across the midline (Fig. 24.9).** Lie in the supine position with the uninvolved leg extended. Flex the hip and knee of the involved leg. Grasp the lateral aspect of the knee with the contralateral hand; pull the involved knee repeatedly across the midline in a rocking motion.

NOTE: If lymphedema is bilateral, repeat this exercise with the other lower extremity.

- **Bilateral knee to chest.** Repeat bilateral gentle, bouncing movements of the legs previously described.
- **Partial curl-ups.** To complete the exercise sequence, perform additional partial curl-ups, about five repetitions.

- **Rest.** With feet elevated and legs propped up against the wall, rest in this position for several minutes after completing exercises. Then rest the legs partially elevated on a wedge, and remain in this position for another 30 minutes.

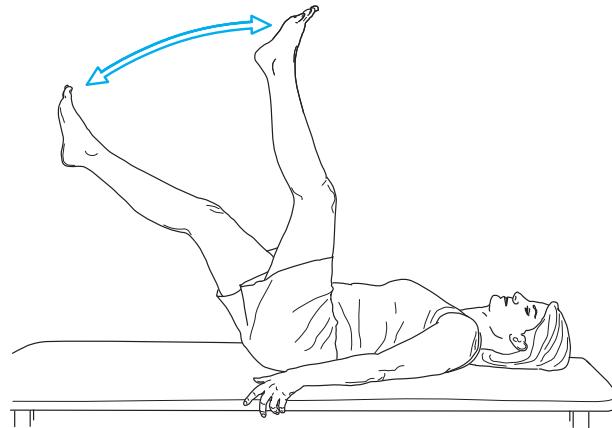

FIGURE 24.8 Repeated walking movements.

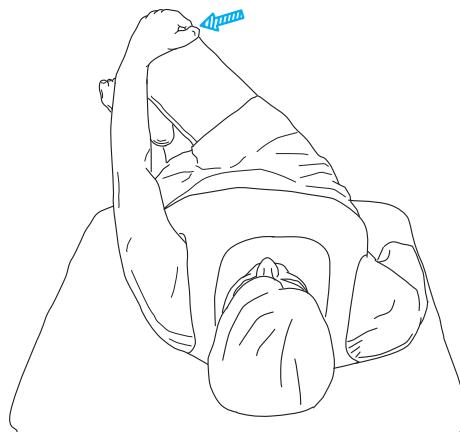

FIGURE 24.9 Hip adduction across the midline to clear inguinal nodes.

INDEPENDENT LEARNING ACTIVITIES

Critical Thinking and Discussion

1. Differentiate between the signs and symptoms associated with chronic arterial insufficiency and chronic venous insufficiency.
2. You have been asked to participate in a patient education program at your community's cancer society for patients who have undergone surgery for breast cancer. Your responsibility in this program is to help these breast cancer survivors prevent physical impairments and functional limitations associated with their surgery and any related adjuvant therapies. Outline the compo-

nents of such a program, and explain the rationale for the activities you have chosen to include.

3. What part does a program of exercise and physical activity play in the overall prevention or management of deep vein thrombophlebitis? What are the signs and symptoms of DVT that a patient at risk for this problem must learn to recognize? If you suspect that a patient you are seeing after some type of orthopedic surgery of the lower extremity has developed a DVT, what questions should you ask the patient? What should you do before contacting the patient's physician?

4. A patient presents with leg pain that occurs intermittently during the day but not at night. Describe how you would evaluate the patient's signs and symptoms and determine whether the cause of the pain is vascular or neurological.

Laboratory Practice

Perform the sequence of exercises and suggested repetitions for the exercise plan you have designed for case 2 (Ms. L).

Case Studies

CASE 1

Mr. A, a 65-year-old man with a 5-year history of type II diabetes and peripheral vascular disease, has been referred to you in your home health practice to establish a program to help him improve his overall level of physical activity. He enjoys golf but recently has had difficulty completing a round because of calf pain that occurs when he walks for even short distances along the course. His pain goes away when he stands or sits.

What additional information do you need to secure during the examination and evaluation process? What tests and measurements would be of particular importance? From your evaluation, design a plan of care that includes a program of exercise to help Mr. A improve his level of physical activity and prevent vascular-related complications.

CASE 2

Ms. L underwent surgery for metastatic pelvic cancer and lymphadenectomy (lymph node dissection) 3 months ago. She also received a series of radiation therapy treatments as part of her comprehensive oncologic management. About 2 weeks ago, she began to notice bilateral swelling in her legs, most notably in her feet and ankles.

She has been referred by her oncologist to the outpatient facility where you work to “evaluate and treat” her for her lymphedema. Describe the examination procedures you would use in your evaluation and then develop a plan of care, including a program of exercise, to help her manage and reduce her lymphedema and prevent potential complications related to the lymphedema.

● INDEPENDENT LEARNING ACTIVITIES 880

Cardiovascular and pulmonary physical therapy is a multifaceted area of professional practice that deals with the management of patients of all ages with acute or chronic, primary or secondary cardiovascular and pulmonary disorders. Although the cardiovascular and pulmonary systems are inherently linked as they interface with all other body systems, the focus of this chapter is on examination procedures and therapeutic interventions used for the management of patients with pulmonary dysfunction. In particular, exercise interventions and manual techniques that enhance ventilation and airway clearance are presented.

The goals of cardiovascular and pulmonary physical therapy for patients with respiratory dysfunction are to:

- Prevent airway obstruction and accumulation of secretions that interfere with normal respiration/oxygen transport.
- Improve airway clearance, cough effectiveness, and ventilation through mobilization and drainage of secretions.
- Improve endurance, general exercise tolerance, and overall well-being.
- Reduce energy costs during respiration through breathing retraining.
- Prevent or correct postural deformities associated with pulmonary or extrapulmonary disorders.
- Maintain or improve chest mobility.

All of these goals are aimed at improving a patient's overall ability to meet necessary and desired functional demands.

Treatment settings vary widely, from intensive care or postsurgical care units and extended care/subacute rehabilitation facilities to outpatient pulmonary centers and the home setting.

REVIEW OF RESPIRATORY STRUCTURE AND FUNCTION

Respiration is a general term used to describe gas exchange within the body and can be categorized as either external respiration or internal respiration. Basic terms are described here but an in-depth discussion of respiratory physiology, including diffusion and perfusion, goes well beyond the scope or purpose of this chapter. The reader is referred to several references for further study.^{11,22,34,59,61}

External respiration describes the exchange of gas at the alveolar-capillary membrane and the pulmonary capillaries. When a person inhales and oxygen is delivered to the alveoli via the tracheobronchial tree, oxygen diffuses through the alveolar wall and interstitial space and into the bloodstream through the pulmonary capillary walls. The opposite occurs with carbon dioxide transport. *Internal respiration* describes the exchange of gas between the pulmonary capillaries and the cells of the surrounding tissues. Internal respiration occurs when oxygen in arterial blood diffuses from red blood cells into tissues requiring oxygen for function. The reverse occurs with carbon dioxide transport.

Ventilation, as it refers to the respiratory system, is the mass exchange of air to and from the body during inspiration and expiration. This cyclic process requires coordinated ventilatory muscle activity, rib cage movements, and appropriate structure and function of the upper and lower respiratory tracts.^{8,22,34,59,61}

Thorax and Chest Wall: Structure and Function

The main functions of the thoracic cage, also referred to as the chest wall, are to protect the internal organs of respiration, circulation, and digestion and to participate in ventilation of the lungs.⁵⁸ The thoracic cage provides the site of attachment for the muscles of ventilation to mechanically enlarge the thorax for inspiration or to compress the thorax for expiration.⁶⁸ It is also the site of attachment of upper extremity muscles, which function during lifting, pulling, or pushing activities. These activities usually are carried out in conjunction with inspiratory effort.

Along the posterior aspect of the thorax, the dorsal portions of the ribs articulate with the 12 thoracic vertebrae at the costotransverse and costovertebral joints. Along the anterior aspect of the thoracic cage, the first to seventh ribs

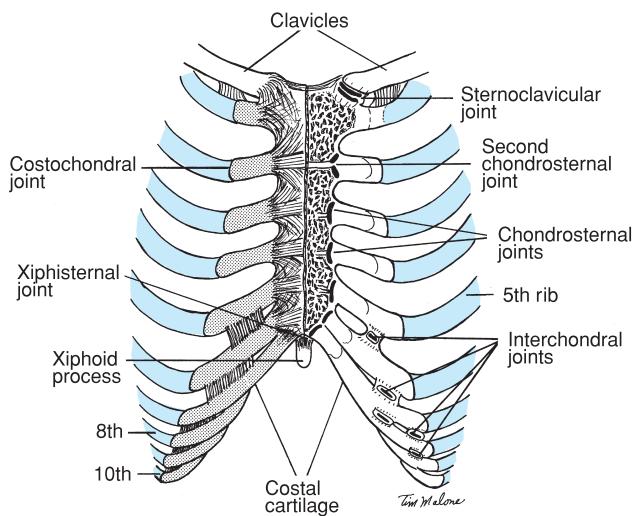

FIGURE 25.1 Anterior view of the rib cage. (From Starr, J, Dalton, D: The thorax and chest wall. In Levangie, PK, Norkin, CC [eds] Joint Structure and Function: A Comprehensive Analysis, ed 4. FA Davis, Philadelphia, 2005, p 197, with permission.)

articulate directly with the sternum via the costal cartilage. The eighth to tenth ribs have cartilaginous attachments to the rib above, whereas the eleventh and twelfth are floating ribs (Fig. 25.1).⁶⁸

Muscles of Ventilation

Multiple muscles attaching to the thoracic cage have an impact on the movement of air in and out of the lungs during either the inspiratory or expiratory phases of breathing.^{8,11,68} Box 25.1 lists the muscles of ventilation.⁹

Ventilatory muscles, also referred to as respiratory muscles, are classified as primary or accessory.^{56,68} The *primary muscles of ventilation* are recruited during quiet (tidal) breathing, whereas the *accessory muscles of ventilation* are only recruited during deep, forced, or labored breathing. During quiet inspiration the *diaphragm*, *scalenae*, and *parasternals* are activated.^{56,68} In contrast, no primary ventilatory muscles contract during resting expiration. During deep or forced breathing different accessory muscles of ventilation are recruited, depending on whether inspiration or expiration is occurring, as noted in Box 25.1.

Inspiration

Diaphragm. The diaphragm, the major muscle of inspiration, is innervated by the phrenic nerve (C3, C4, C5). During relaxed inspiration it is the primary muscle responsible for movement of air, and under these quiet conditions it performs about 70% to 80% of the work of breathing.⁵⁶ As the diaphragm contracts, it moves caudally from its dome-shaped position at rest to increase the capacity of the thoracic cage.

Scalenae. The scalenes, which insert proximally on the transverse processes of the lower five cervical vertebrae and distally on the upper surface of the first two ribs, also

BOX 25.1 Primary and Accessory Ventilatory Muscles
Inpiration

- Primary muscles: diaphragm, scalenes, parasternals
- Accessory muscles: sternocleidomastoids, upper trapezius, pectoralis major and minor, subclavius, and possibly the external intercostals

Expiration

- Primary muscles: none active during tidal (resting) expiration
- Accessory muscles: abdominals including the rectus abdominis, transversus abdominis, and internal and external obliques; pectoralis major; and possibly the internal intercostals

are active during quiet inspiration.^{56,68} They begin to contract at the onset of inspiration and generate an even greater amount of tension late into the inspiratory cycle as the tension-producing capacity of the diaphragm is decreasing. The scalenes lift the sternum and the first two ribs in a “pump handle” action, which causes an upward and outward action of the upper portion of the rib cage.

Parasternal intercostals. The parasternals, a portion of the internal intercostals, are active during resting inspiration. They function to stabilize the rib cage and prevent inward movement of the superior aspect of the chest wall.^{56,68}

Accessory muscles of inspiration. The sternocleidomastoid (SCM), upper trapezius, pectoralis major and minor, and subclavius muscles are all active during deep or labored inspiration.^{9,56,68} These muscles become increasingly active with greater inspiratory effort, which occurs frequently during strenuous physical activity.

The accessory muscles of inspiration may become the primary muscles of inspiration and may become active during resting inspiration when the diaphragm is ineffective or weak as the result of pathology. For example, paralysis of the abdominals as the result of a spinal cord injury reduces the support to the viscera (when the patient is in an upright position) which, in turn, allows the diaphragm to assume a flattened rather than a normal dome-shaped position. Thus, diaphragmatic excursion is reduced, and breathing is less efficient, which necessitates recruitment of the accessory muscles of inspiration.

The *SCM muscles* elevate the sternum to increase the anteroposterior (AP) diameter of the thorax. In patients with weakness of the diaphragm, the SCM muscles are required to act as primary muscles of inspiration. The *upper trapezius* muscles elevate the shoulders and, indirectly, the rib cage during labored inspiration. They also fixate the neck so the scalenes have a stable attachment. The *pectoralis major* muscles can act to elevate the rib cage and contribute to inspiration when the arms are overhead.

Expiration

Expiration is a passive process when a person is at rest. When the diaphragm relaxes after a contraction, the diaphragm rises and the ribs drop. The elastic recoil of tissues decreases the intrathoracic area and increases intrathoracic pressure, which causes exhalation. During active expiration, which can be controlled, forced, or prolonged, several accessory muscles groups are active.^{9,56,68}

Abdominals. The rectus abdominis, the internal and external obliques, and the transversus abdominis contract to force down the thoracic cage and force the abdominal contents superiorly into the diaphragm. When the abdominals contract, the intrathoracic pressure increases and air is forced out of the lungs. A strong contraction of the abdominals also is necessary for a strong cough. The abdominals are innervated by spinal cord levels T10 to T12.

Other accessory muscles of expiration include the pectoralis major muscles (when the distal insertion is inferior to the clavicle and the arm is fixed in position), the *quadratus lumborum*, because of its attachment to the twelfth rib, which enables it to act to stabilize the diaphragm during phonation, and possibly the *internal intercostals*, which may act to depress the rib cage.^{56,68}

Mechanics of Ventilation
Movements of the Thorax During Ventilation

Each rib has its own pattern of movement, but generalizations can be made. The ribs attach anteriorly to the sternum (except ribs 11 and 12) and posteriorly to the vertebral bodies, disks, and transverse processes, making a closed kinematic chain. The thorax enlarges in all three planes of movement during inspiration.^{8,11,56,68}

Increase in the AP dimension. There is a forward and upward movement of the sternum and upper ribs, described as a *pump-handle* motion. The thoracic spine extends (straightens), enabling greater excursion of the sternum.

Increase in the transverse (lateral) dimension. There is an elevation and outward turning of the lateral (midshaft) portions of the ribs, described as a *bucket handle* motion. The lower ribs (8–10), which are not attached directly to the sternum, also flare or open outward, increasing the subcostal angle. This is described as *caliper* motion. The angle at the costochondral junction also increases, making the rib segments longer during inspiration.

Increase in vertical dimension. The central tendon of the diaphragm descends as the muscle contracts. This is described as a *piston action*. Elevation of the ribs increases the vertical dimension of the thorax and improves the effectiveness of the diaphragm. At the end of inspiration, the muscles relax and elastic recoil causes the diaphragm to move superiorly. The ribs return to their resting position.

Movement of Air

As noted previously, *ventilation* is the mass exchange of gases to and from the body. During inspiration, as the thorax enlarges, the pressure inside the lungs (alveolar pressure) becomes lower than the atmospheric pressure, and air rushes into the lungs. At the end of inspiration, the muscles relax, and the elastic recoil of the lungs pushes the air out, resulting in expiration.

NOTE: Breathing exercises, a common intervention for the management of patients with cardiopulmonary, neuromuscular, and musculoskeletal conditions, are designed to affect the movement of air to and from the lungs.^{11,28,48,56}

Compliance

Compliance refers to the distensibility of tissue or how easily the lungs inflate during inspiration. With regard to ventilation, it relates to how easily the lungs inflate or the chest wall expands during inspiration.^{22,59,61} Normal lungs are highly distensible (compliant), but compliance changes with age and the presence of disease. During the normal aging process lung tissue becomes more compliant. Diseases of the pulmonary system that, for example, cause fibrosis of tissues (alveolar or pleural) make the lungs rigid (i.e., less compliant), whereas emphysema, one of the chronic obstructive diseases, makes lung tissue more compliant to pressures.^{22,59,61}

Airway Resistance

The amount of resistance to the flow of air through the airways depends on a number of factors.^{22,59,61} The bifurcation and branching of airways is a source of airway resistance. The size (diameter) of the lumen of each airway also influences resistance. The diameter of the lumen can be decreased by mucus or edema in the airways, contraction of smooth muscles, and the degree of elasticity or distensibility of the lung parenchyma.

Normally, the airways widen during inspiration and narrow during expiration. As the diameter of the airway decreases, the resistance to airflow increases. With diseases that cause bronchospasm (asthma) or increased mucus production (chronic bronchitis), airway resistance is even greater than normal, particularly during expiration.

Flow Rates

Flow rates indicate measurements of the amount of air moved in or out of the airways over a period of time. Flow rates, which are related to airflow resistance, reflect the ease with which ventilation occurs.^{22,59,61} *Expiratory flow rate* is determined by the volume of air exhaled divided by the amount of time it takes for the volume of gas to be exhaled.²⁷

Flow rates are altered as the result of diseases that affect the respiratory tree and chest wall. For example, with chronic obstructive pulmonary disease, the expiratory flow rate is decreased in comparison to normal. That is, it takes a longer than the normal amount of time to exhale a specific volume of air.

Anatomy and Function of the Respiratory Tracts

Upper Respiratory Tract

The structures of the upper respiratory tract are the *nasal cavity*, *pharynx*, and *larynx*.^{11,58,66,69} As air is brought into the body, the nasal cavity and pharynx filter and remove particles in the air and begin to humidify and warm it to body temperature. The mucosal lining of these structures has cells that secrete mucus and cells that are ciliated. Cilia and mucus trap particles; a sneeze removes large particles.

With illness and elevated body temperature, the mucous membrane tends to dry out, so the body secretes more mucus. This mucus dries out, and a cycle begins. The action of the cilia is inhibited by drying of mucus. The patient tends to breathe by mouth, which decreases the humidification of mucus and increases its viscosity.

The larynx, which extends from C3 to C6, controls airflow; and when it contracts rapidly, the epiglottis prevents food, liquids, or foreign objects from entering the airway.⁴⁷

Lower Respiratory Tract

The lower respiratory tract is composed of conducting airways of the tracheobronchial tree and the terminal respiratory units. There are approximately 23 generations (branchings) of the structures within the tracheobronchial tree, which extends from the trachea to the terminal respiratory units of the lungs. The structures and branchings of the lower respiratory tract are summarized in Box 25.2.^{11,58,66,69}

The initial branchings of the tracheobronchial tree are depicted in Figure 25.2. The first 16 airway branchings of the lower respiratory tract primarily conduct air, whereas the last 6 are respiratory airways that end (in the mature lung) in approximately 300 million alveoli.⁶⁹ The diameter of the airways becomes increasingly smaller with each successive generation of the tracheobronchial tree.

Trachea. The trachea is an oval, flexible tube supported by semicircular rings of cartilage. It extends from C6 in an oblique, downward direction to the sternal angle level of rib 2 and T6, at which point it bifurcates. The posterior wall is smooth muscle, and it contains an equal number of ciliated epithelial cells and mucus-containing goblet cells.

BOX 25.2 Structures and Branchings of the Lower Respiratory Tract

- Trachea
- Mainstem bronchi: 2
- Lobar bronchi: 5
- Segmental bronchi: 18
- Bronchioles: subsegmental, terminal, and respiratory
- Alveolar ducts and sacs

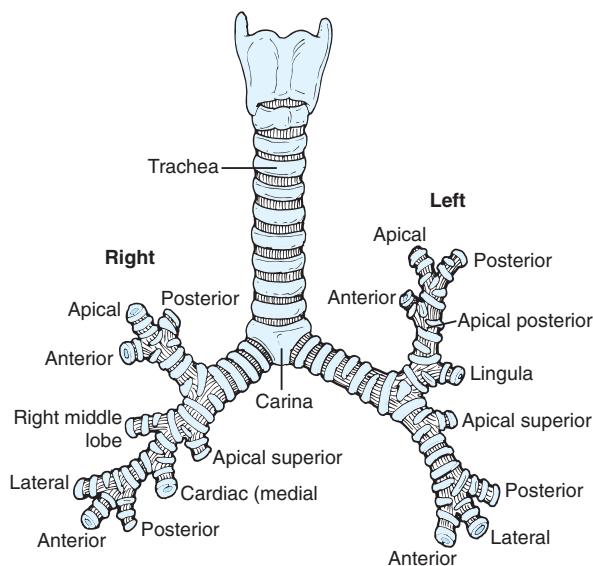

FIGURE 25.2 Lower respiratory tract—tracheobronchial tree. (From Frownfelter, DL: *Chest Physical Therapy and Pulmonary Rehabilitation*. Year-Book Medical Publishers, Chicago, 1987, p 26, with permission.)

Mainstem bronchi. The trachea branches into two mainstem bronchi: the right, which is directed almost vertically, and the left, which is directed more obliquely.

Lobar bronchi. The two mainstem bronchi then divide into five lobar bronchi: three on the right and two on the left. Mainstem and lobar bronchi have a great amount of cartilage, which helps maintain airway patency.

Segmental bronchi. Each of the lobar bronchi divide into two or more segmental bronchi: 10 on the right and 8 on the left. Segmental bronchi have scattered cartilage, smooth muscle, elastic fibers, and a capillary network. The mainstem, lobar, and segmental bronchi have a mucous membrane essentially the same as the trachea.

Bronchioles. Segmental bronchi divide into subsegmental bronchi and bronchioles, which have less and less cartilage and ciliated epithelial cells. These bronchioles divide into the *terminal bronchioles*, which are distal to the last cartilage of the tracheobronchial tree. Terminal bronchioles contain no ciliated cells. Terminal bronchioles divide into *respiratory bronchioles* and provide a transitional zone between the bronchioles and alveoli.

Alveoli. The respiratory bronchioles divide into alveolar ducts and alveolar sacs (Fig. 25.3). One duct may supply several sacs. The ducts contain smooth muscle, which narrows the lumen of the duct with contraction. The alveoli are located in the periphery of the alveolar ducts and sacs and are in contact with capillaries (alveolar-arterial membrane). Gas exchange occurs here.

Summary of Function of the Upper and Lower Respiratory Tracts

The upper and lower respiratory tracts, as a unit, serve the following functions. They:

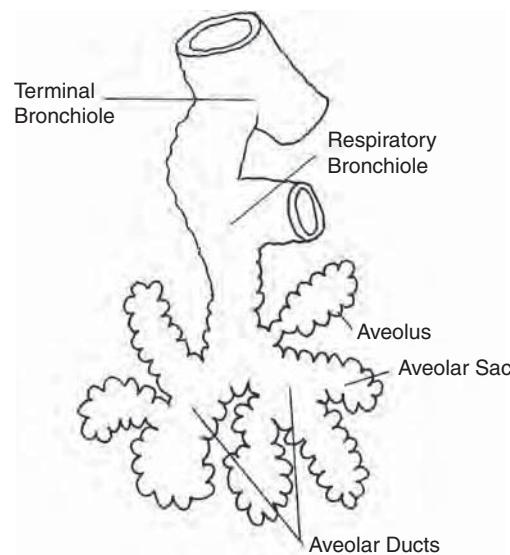

FIGURE 25.3 Bronchopulmonary segment.

- Conduct air to and from the alveolar system for gas exchange
- Assist with humidification and trap small particles to clean the air with the mucosal lining
- Warm the air by the vascular supply
- Move mucus upward with the cilia
- Elicit the cough reflex to clear the larger airways

The Lungs and Pleurae

The lungs and pleurae are made up of the following components. The *right lung* has three lobes—the upper, middle, and lower—and 10 bronchopulmonary segments. The *left lung* has two true lobes—the upper and lower—and a slip of lung called the lingula, which is not considered a “true” lobe of the lungs. The left lung has eight bronchopulmonary segments. The lobes of the lungs are depicted in Figure 25.4.

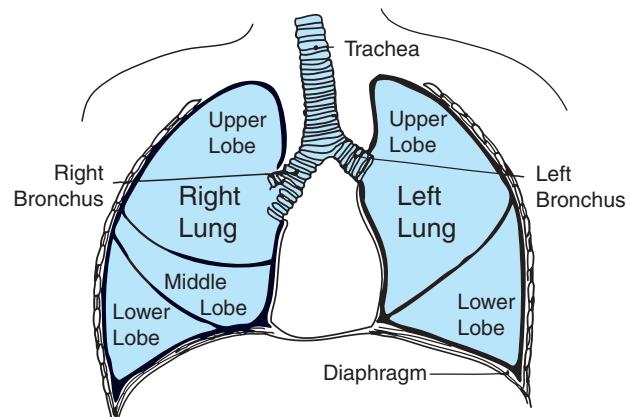

FIGURE 25.4 Structure of the right and left lungs.

Each lung is covered in *pleura*, a serous membrane known as the *visceral pleura*. This membrane adheres to all surfaces of each lung. The *parietal pleura* lines the inside of the thoracic wall. The parietal pleura is sensitive to pain, but the visceral pleura appears to be insensitive.^{30,31} A negative pressure in the minute space between the pleurae serves to keep the lungs inflated. Pleural fluid is found between the pleurae and lubricates the pleurae as they slide on each other during ventilation.

Lung Volumes and Capacities

Pulmonary function tests that measure lung volumes and capacities are performed to evaluate the mechanical function of the lungs (Fig. 25.5). Lung volumes and capacities are related to a person's age, weight, sex, and body position and are altered by disease.^{27,59,61} Two or more lung volumes, when combined, are described as a capacity. A basic understanding of these measurements and what the values reflect is useful for a therapist treating patients with pulmonary dysfunction.

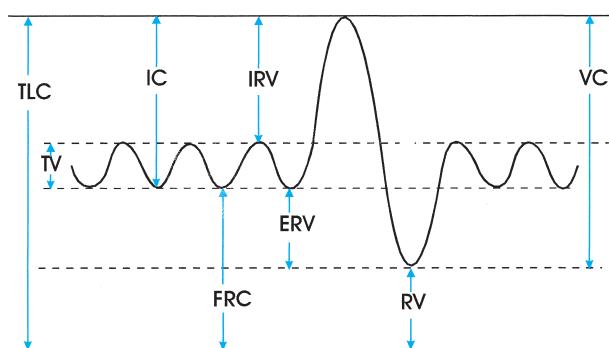

FIGURE 25.5 Normal lung values and capacities.

Total Lung Capacity

Total lung capacity (TLC) is the total amount of air contained in the lungs after a maximum inspiration. TLC can be subdivided into four volumes: tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume. The vital capacity plus the residual volume equal the TLC, which is approximately 6000 mL in a healthy, young adult.

Tidal Volume

The amount of air exchanged during a relaxed inspiration followed by a relaxed expiration is called the tidal volume (TV). In a healthy, young adult, TV is approximately 500 mL per inspiration. Approximately 350 mL of the tidal volume reaches the alveoli and participates in gas exchange (respiration).

Inspiratory Reserve Volume

Inspiratory reserve volume (IRV) is the amount of air a person can breathe in after a resting inspiration (approximately 3000 mL).

Expiratory Reserve Volume

Expiratory reserve volume (ERV) is the amount of air a person can exhale after a normal resting expiration (approximately 1000 mL).

Residual Volume

Residual volume (RV) is the amount of air left in the lungs after a maximum expiration (approximately 1500 mL). RV increases with age and with restrictive and obstructive pulmonary diseases.

Inspiratory Capacity

Inspiratory capacity (IC) is the maximum amount of air a person can breathe in after a resting expiration (approximately 3500 mL).

Functional Residual Capacity

Functional residual capacity (FRC) is the amount of air remaining in the lungs after a resting (tidal) expiration (approximately 2500 mL). It is the sum of the ERV and RV. FRC represents the point during ventilation at which the forces that expand the thoracic wall are in balance with the forces that tend to collapse the lungs.⁵⁹

Vital Capacity

Vital capacity (VC) is the sum of the TV, IRV, and ERV. It is measured by a maximum inspiration followed by a maximum expiration (approximately 4500 mL). Vital capacity decreases with age and is less in the supine position than in an erect posture (sitting or standing). VC decreases in the presence of restrictive and obstructive diseases.

EXAMINATION

Evaluation of the patient with pulmonary dysfunction and determination of a diagnosis, prognosis, and intervention plan are based on the findings derived from a comprehensive examination, including a history, systems review, and specific tests and measures.³¹ The multiple purposes of this examination are summarized in Box 25.3.

BOX 25.3 Purpose of the Examination

- Determine a patient's primary and secondary respiratory and ventilatory impairments and how they limit physical function.
- Determine the adequacy of the ventilatory pump and the oxygen uptake/carbon dioxide elimination mechanisms to meet the oxygen demands at rest and during functional activities.
- Ascertain a patient's suitability for participation in a pulmonary rehabilitation program.
- Develop an appropriate level intervention plan for the patient.
- Establish a baseline to measure a patient's progress and the effectiveness of the treatment.
- Determine when to discontinue specific interventions and implement a home program as a basis for self-management.

Components of the Examination

A comprehensive examination of a patient with known or suspected dysfunction related to primary and secondary pulmonary or chest disorders has many elements. The examination procedures described in this section are those often used by a therapist during an initial evaluation to establish a therapy-related diagnosis or during subsequent assessments for modification of therapeutic interventions.^{11,31,35,38,52,67} Additional examination procedures not described in this section but integral to the management of a patient with pulmonary dysfunction are radiography, evaluation of blood gases, tomography, bronchoscopy, and hematological tests.

History and Systems Review

The examination process begins with a patient's history including an interview with the patient and sometimes family members if they are available. During the interview a therapist can identify a patient's and/or family members' perception of any functional limitations or disabilities and determine a patient's chief complaints and why he or she is seeking treatment. In preparation for the interview, the medical history and any medical diagnoses are obtained from the patient's medical record, if available, or more generally, from the patient or family. Relevant occupational and social history are obtained; particularly important are on-the-job physical demands, the environment of the workplace, and social habits that affect a person's well-being, such as tobacco or alcohol use. Assessment of the home or family environment might include a patient's family responsibili-

ties, the housing situation, and available family support systems. A brief systems review should follow the history.

General Appearance of the Patient

Table 25.1 describes the type of information that can be obtained by visual inspection of a patient and the possible implications of these observations. Many of these findings can be noted during the course of the history or during the systems review.

Analysis of Chest Shape and Dimensions

Symmetry of the chest and trunk. Observe anteriorly, posteriorly, and laterally; the thoracic cage should be symmetrical.

Mobility of the trunk. Check active movements in all directions and identify any restricted spinal motions, particularly in the thoracic spine.

Shape and dimensions of the chest. The anteroposterior (AP) and lateral dimensions are usually 1:2. Common chest deformities include:

- **Barrel chest.** The circumference of the upper chest appears larger than that of the lower chest. The sternum appears prominent, and the AP diameter of the chest is greater than normal. Many patients with chronic obstructive pulmonary disorders, who are usually upper chest breathers, develop a barrel chest.
- **Pectus excavatum (funnel breast).** The lower part of the sternum is depressed and the lower ribs flare out. Patients with this deformity are diaphragmatic breathers;

TABLE 25.1 General Appearance of the Patient and Implications

General Appearance	Implications
<ul style="list-style-type: none"> • <i>Level of awareness</i> (level of consciousness): alert, responsive, or cooperative versus lethargic, disoriented, or inattentive • <i>Body type</i>: normal, obese, or cachectic • <i>Color</i>: cyanosis (bluish appearance) peripherally (nailbeds) or centrally (lips) • <i>Facial signs or expressions</i>: focused or dilated pupils, nasal flaring, sweating, or distressed appearance • <i>Jugular vein engorgement</i>: visualization of the jugular venous pulse with the patient supine and the head and neck on pillows at a 45° angle • <i>Hypertrophy of or use at rest of accessory muscles of ventilation</i>: SCM, upper trapezius • <i>Supraclavicular or intercostal retractions</i> occurring with inspiration • <i>Use of pursed lip breathing</i> (usually with expiration) • <i>Clubbing of digits</i>: loss of angle between the nail bed and DIP joint • <i>Peripheral edema</i> 	<ul style="list-style-type: none"> • Respiratory acidosis, hypercarbia (increased PCO_2 level), or hypoxia (decreased PO_2 level) can alter level of consciousness • May reflect intolerance to exercise • Peripheral cyanosis may indicate low cardiac output; central cyanosis may indicate inadequate gas exchange in the lungs • Signs of respiratory distress, fatigue, or pulmonary or musculoskeletal pain • Bilateral distention associated with congestive heart failure/right-sided heart failure • Seen in patients with early chronic lung disease or weakness of the diaphragm • Seen in patients with labored breathing • Indicates difficulty with expiration; often seen in patients with COPD • May be linked to perfusion • Sign of right ventricular failure or lymphatic dysfunction

excessive abdominal protrusion and little upper chest movement occur during breathing.

- **Pectus carinatum (pigeon breast).** The sternum is prominent and protrudes anteriorly.

Posture or Preferred Positioning

Identify a patient's preferred sitting or standing posture. A patient who has difficulty breathing as the result of chronic lung disease often leans forward on hands or forearms to stabilize and elevate the shoulder girdle to assist with inspiration (Fig. 25.6). This position increases the effectiveness of the pectoralis and serratus anterior muscles to act as accessory muscles of inspiration by reverse action. It is also important to identify a patient's preferred sleeping position. A patient with cardiopulmonary dysfunction often prefers to sleep in a head-up rather than a fully recumbent position. Assuming a horizontal position may result in shortness of breath.

FIGURE 25.6 A patient who is short of breath at rest or after activity often assumes a forward-bent position with hands or elbows resting on the thighs to reduce or relieve symptoms.

In addition, note any postural deformities such as kyphosis and scoliosis and postural asymmetry from thoracic surgery, which could restrict chest movements and ventilation.

Breathing Pattern

Assess the *rate*, *regularity*, and *location* of ventilation at rest and with activity. A normal respiratory rate for a healthy adult is 12 to 20 breaths per minute. This is most accurately determined when a patient is unaware that his or her respiratory rate is being measured, as when taking the pulse rate. The normal ratio of inspiration to expiration at rest is 1:2 and with activity 1:1. A patient with chronic obstructive pulmonary disease (COPD) may have a ratio of 1:4 at rest, which reflects difficulty with the expiratory phase of breathing.

The normal sequence of inspiration at rest is (1) the diaphragm contracts and descends and the abdomen (epigastric area) rises; (2) this is followed by lateral costal expansion as the ribs move up and out; and finally (3) the upper chest rises. The neck muscles that act as accessory muscles of inspiration should be inactive during relaxed inspiration.

To assess the breathing sequence, have the patient assume a comfortable position (semireclining or supine). Place your hands on the patient's epigastric region and sternum to observe movements in these two areas.

A number of terms are used to describe abnormal breathing patterns and are defined in Box 25.4.^{11,35,38,52}

Chest Mobility

Symmetry of chest movement. Analysis of the symmetry of the moving chest during breathing gives the therapist information about the mobility of the thorax and indicates indirectly what areas of the lungs may or may not be responding.

Procedure. Place your hands on the patient's chest and assess the excursion of each side of the thorax during inspiration and expiration. Each of the three lobar areas can be checked.^{11,35,38,52}

- To check *upper lobe expansion*, face the patient; place the tips of your thumbs at the midsternal line at the sternal notch. Extend your fingers above the clavicles. Have the patient fully exhale and then inhale deeply.
- To check *middle lobe expansion*, continue to face the patient; place the tips of your thumbs at the xiphoid process and extend your fingers laterally around the ribs. Again, ask the patient to breathe in deeply (Fig. 25.7A).
- To check *lower lobe expansion*, place the tips of your thumbs along the patient's back at the spinous processes (lower thoracic level) and extend your fingers around the ribs. Ask the patient to breathe in deeply (Fig. 25.7B).

BOX 25.4 Abnormal Breathing Patterns

- **Dyspnea.** Distressed, labored breathing as the result of shortness of breath.
- **Tachypnea.** Rapid, shallow breathing; decreased tidal volume but increased rate; associated with restrictive or obstructive lung disease and use of accessory muscles of inspiration.
- **Bradypnea.** Slow rate with shallow or normal depth and regular rhythm; may be associated with drug overdose.
- **Hyperventilation.** Deep, rapid respiration; increased tidal volume and increased rate of respiration; regular rhythm.
- **Orthopnea.** Difficulty breathing in the supine position.
- **Apnea.** Cessation of breathing in the expiratory phase.
- **Apneusis.** Cessation of breathing in the inspiratory phase.
- **Cheyne-Stokes.** Cycles of gradually increasing tidal volumes followed by a series of gradually decreasing tidal volumes and then a period of apnea. This is sometimes seen in the patient with a severe head injury.

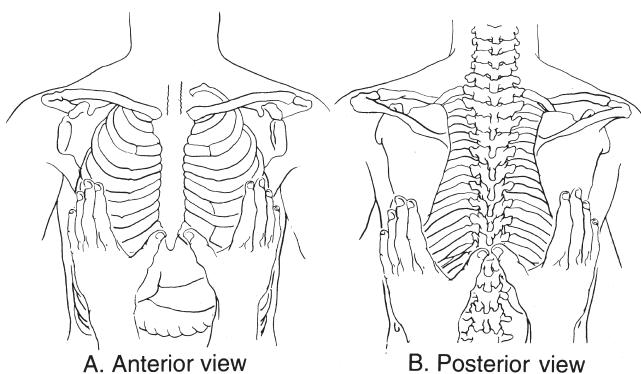

FIGURE 25.7 (A) Anterior and (B) posterior placement of a therapist's hands on a patient's thorax to assess the symmetry of movement during breathing. (From Brannon, FJ, et al: *Cardiopulmonary Rehabilitation—Basic Theory and Application*, ed 3, FA Davis, Philadelphia, 1998, p. 288. Adapted from Rothstein, JH, Roy, SH, Wolf, SL: *The Rehabilitation Specialist's Handbook*, FA Davis, Philadelphia, 2005, p 416–417, with permission.)

Extent of excursion. The extent of chest mobility can be measured by two methods.^{35,38}

- Measure the girth of the chest with a tape measure at three levels (axilla, xiphoid, lower costal). Document change in girth after a maximum inspiration and a maximum expiration.
- Place both hands on the patient's chest or back as previously described. Note the distance between your thumbs after a maximum inspiration.

Palpation

Palpation of the thorax provides evidence of dysfunction of the underlying tissues including the lungs, chest wall, and mediastinum.^{11,35,38,52}

Tactile (vocal) fremitus. Tactile fremitus is the vibration felt while palpating over the chest wall as a patient speaks.

Procedure: Place the palms of your hands lightly on the chest wall and ask the patient to speak a few words or repeat “99” several times. Normally, fremitus is felt uniformly on the chest wall. Fremitus is increased in the presence of secretions in the airways and decreased or absent when air is trapped as the result of obstructed airways.

Chest wall pain. Specific areas or points of pain over anterior, posterior, or lateral aspects of the chest wall can be identified with palpation.

Procedure: Firmly press against the chest wall with your hands to identify any specific areas of pain potentially of musculoskeletal origin. Ask the patient to take a deep breath and identify any painful areas of the chest wall. Chest wall pain of musculoskeletal origin often increases with direct point pressure during palpation and during a deep inspiration.^{35,38}

NOTE: Pain in the anterior, posterior, or lateral region of the chest can be of musculoskeletal, pulmonary, or cardiac origin.³¹ Pain of pulmonary origin is usually localized to a region of the chest but also may be felt in the neck or shoulder region. Several pulmonary or cardiac conditions

can mimic musculoskeletal pain, such as pulmonary embolism, pleurisy, pneumonia, pneumothorax, and pulmonary artery hypertension.³¹

Mediastinal shift. The position of the trachea normally is oriented centrally in relation to the suprasternal notch indicating symmetry of the mediastinum. The position of the trachea shifts as the result of asymmetrical intrathoracic pressures or lung volumes. For example, if the patient has had a pneumonectomy (removal of a lung), the lung volume on the operated side decreases, and the trachea shifts toward that side. Conversely, if the patient has a hemothorax (blood in the thorax), intrathoracic pressure on the side of the hemothorax increases, and the mediastinum shifts away from the affected side of the chest.^{11,35,38,52}

Procedure: To identify a *mediastinal shift*, have the patient sit facing you with the head in midline and the neck slightly flexed to relax the sternocleidomastoid muscles. With your index finger, gently palpate the soft tissue space on either side of the trachea at the suprasternal notch. Determine whether the trachea is palpable at the midline or has shifted to the left or right.

Mediate Percussion

Mediate percussion is an examination technique designed to assess lung density, specifically, the air-to-solid ratio in the lungs.^{11,35,38,52}

Procedure: Place the middle finger of the nondominant hand flat against the chest wall along an intercostal space. With the tip of the middle finger of the opposite hand, firmly tap on the finger positioned on the chest wall. Repeat the procedure at several points on the right and left and anterior and posterior aspects of the chest wall. This maneuver produces a resonance; the pitch varies with the density of the underlying tissue. The subjective determination of pitch indicates the following.

- The sound is dull and flat if there is a greater than normal amount of solid matter (tumor, consolidation) in the lungs in comparison with the amount of air.
- The sound is hyperresonant (tympanic) if there is a greater than normal amount of air in the area (as in patients with emphysema).
- If asymmetrical or abnormal findings are noted, the patient should be referred to the physician for additional objective tests such as a chest radiograph.

Auscultation of Breath Sounds

Auscultation is a general term that refers to the process of listening to sounds within the body, specifically to breath sounds during an examination of the lungs.^{11,35,38,52} Breath sounds occur because of movement of air in the airways during inspiration and expiration. A stethoscope is used to magnify these sounds. Breath sounds should be assessed to:

- Identify the areas of the lungs in which congestion exists and in which airway clearance techniques should be performed.
- Determine the effectiveness of any airway clearance intervention.

- Determine whether the lungs are clear and whether interventions should be discontinued.

Procedure: When assessing breath sounds, be sure the setting is quiet. Have the patient assume a comfortable, relaxed, sitting position to allow access to the chest wall. Place the diaphragm of the stethoscope directly against the patient's skin along the anterior or posterior chest wall. Be sure that the tubing does not rub together or come in contact with clothing during auscultation, as this contact produces extraneous sounds.

Follow a systematic pattern (Fig. 25.8A&B) and place the stethoscope against specific thoracic landmarks (T2, T6, T10) along the right and left sides of the chest wall. Ask the patient to breathe in deeply and out quickly through the mouth as you move the stethoscope from point to point. Note the quality, intensity, and pitch of the breath sounds.

PRECAUTION: Auscultate slowly from one area to another. Allow the patient to breathe in a relaxed manner

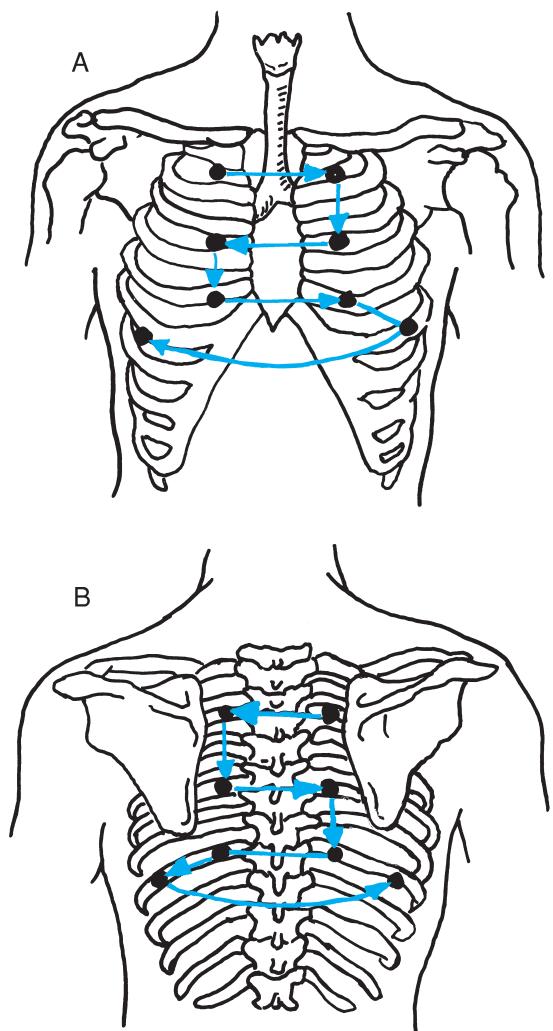

FIGURE 25.8 Pattern of specific thoracic landmarks for auscultation. The diaphragm of the stethoscope is placed along the right and left (A) anterior chest wall and the (B) posterior chest wall at T2, T6, and T10. (From Frownfelter, DL: *Chest Physical Therapy and Pulmonary Rehabilitation*. Year-Book Medical Publishers, Chicago, 1987, p 135, with permission.)

after several deep breaths to prevent dizziness from hyperventilation. Guard the patient closely to prevent loss of balance if lightheadedness occurs.

Classification of Breath Sounds

Breath sounds are classified by location, pitch, and intensity as well as the ratio of sounds heard on inspiration versus those heard on expiration. Breath sounds also are identified as normal or adventitious (extra).^{5,50,52,77}

Normal breath sounds occur in the absence of pathology and are heard predominantly during inspiration. Normal breath sounds are categorized as *vesicular*, *bronchial*, or *bronchovesicular* based on the location and quality of the sound. They are described in Box 25.5.^{5,77} Adventitious breath sounds are abnormal sounds in the lungs that are heard with a stethoscope. Although terminology in the literature is inconsistent, the nomenclature used most often was proposed by a joint committee of the American College of Chest Physicians and the American Thoracic Society.^{5,77} Adventitious breath sounds are categorized as *crackles* or *wheezes*. Box 25.5 describes the location and quality of these breath sounds.

BOX 25.5 Normal and Adventitious Breath Sounds

Normal Breath Sounds

- Vesicular.** Soft, low-pitched, breezy but faint sounds heard over most of the chest except near the trachea and mainstem bronchi and between the scapulae. Vesicular sounds are audible considerably longer on inspiration than expiration (about a 3:1 ratio).
- Bronchial.** Loud, hollow, or tubular high-pitched sounds heard over the mainstem bronchi and trachea. Bronchial sounds are heard equally during inspiration and expiration; a slight pause in the sound occurs between inspiration and expiration.
- Bronchovesicular.** Softer than bronchial breath sounds; also heard equally during inspiration and expiration but without a pause in the sound between the cycles. The sounds are heard in the supraclavicular, suprascapular, and parasternal regions anteriorly and between the scapulae posteriorly.

Adventitious Breath Sounds

- Crackles.** Fine, discontinuous sounds (similar to the sound of bubbles popping or the sound of hairs being rubbed between your fingers next to your ear). Crackles, which can be fine or coarse, are heard primarily during inspiration as the result of secretions moving in the airways or in closed airways that are rapidly reopening. The former term for crackles was *rales*.
- Wheezes.** Continuous high- or low-pitched sounds or sometimes musical tones heard during exhalation but occasionally audible during inspiration. Bronchospasm or secretions that narrow the lumen of the airways cause wheezes. The term previously used for wheezes was *rhonchi*.

Breath sounds may be totally absent or substantially diminished over a portion of the lungs. This indicates total or partial obstruction and lack of aeration of lung tissue. The absence of air and collapse of an area of lung tissue is known as *atelectasis*. Obstruction of airways may be caused by fluids, mucus, bronchospasm, or compression by tumor.

Cough and Cough Production

The *strength, depth, length, and frequency* of a patient's cough must be assessed. An effective cough is sharp and deep. In the patient with current or potential pulmonary dysfunction a cough can be described as weak, shallow, soft, or throaty. A patient may have a weak, shallow cough as the result of pain or paralysis. A sudden onset of a cough or a sustained cough often is described as paroxysmal or spasmodic. If a cough is substantially weak or ineffective, suctioning may be required to clear the airways.^{11,35,52}

A cough may be productive or nonproductive in the presence of pathology. The productivity of the cough and secretions produced by the cough should be assessed. Secretions are checked for:

- Color (clear, yellow, green, blood-stained)
- Consistency (viscous, thin, frothy)
- Amount (minimal to copious)
- Odor (no odor to foul-smelling)

Production of a small amount of clear or white secretions on a daily basis is normal. Copious but clear secretions are common with chronic bronchitis. Yellow, green, and purulent secretions with a strong odor are indicative of some type of infection. Blood-streaked secretions, known as *hemoptysis*, is indicative of some degree of hemorrhage in the lungs. Frothy, white secretions are associated with pulmonary edema and heart failure.

When secretions are produced during the course of interventions, such as exercise or airway clearance, it is the responsibility of the therapist to document the characteristics of the secretions.

Additional Areas of Examination

The examination procedures described in this section are complemented with other areas of examination, which may include a patient's use of assistive respiratory equipment, ROM particularly of the shoulders, neck, and trunk, muscle strength, general endurance and graded exercise testing, and a patient's identification of functional abilities or limitations and perceived disability and quality of life.

BREATHING EXERCISES AND VENTILATORY TRAINING

Breathing exercises and ventilatory training are fundamental interventions for the prevention or comprehensive management of impairments related to acute or chronic pulmonary disorders. For example, these interventions are frequently advocated in the literature for patients with

BOX 25.6 Goals of Breathing Exercises and Ventilatory Muscle Training

- Improve or redistribute ventilation.
- Increase the effectiveness of the cough mechanism and promote airway clearance.
- Prevent postoperative pulmonary complications.
- Improve the strength, endurance, and coordination of the muscles of ventilation.
- Maintain or improve chest and thoracic spine mobility.
- Correct inefficient or abnormal breathing patterns and decrease the work of breathing.
- Promote relaxation and relieve stress.
- Teach the patient how to deal with episodes of dyspnea.
- Improve a patient's overall functional capacity for daily living, occupational, and recreational activities.

COPD (chronic bronchitis, emphysema, asthma) or cystic fibrosis, for patients with a high spinal cord lesion, for patients who have undergone thoracic or abdominal surgery and are at high risk for acute pulmonary complications, or for patients who must remain in bed for an extended period of time.*

Breathing exercises and ventilatory training can take on many forms including diaphragmatic breathing, segmental breathing, inspiratory resistance training, incentive spirometry, and breathing techniques for the relief of dyspnea during exertion. The goals of these interventions are listed in Box 25.6.

Research studies indicate that although breathing exercises or ventilatory muscle training may affect and possibly alter a patient's rate and depth of ventilation these interventions may not necessarily have any impact on gas exchange at the alveolar level or on oxygenation.^{11,28,48,60} Therefore, breathing exercises or ventilatory training should be only one aspect of management to improve pulmonary status and to increase a patient's overall endurance and function during daily living activities. Depending on a patient's underlying pathology and impairments, exercises to improve ventilation often are combined with medication, airway clearance, the use of respiratory therapy devices, and a graded exercise (aerobic conditioning) program.

Guidelines for Teaching Breathing Exercises

- If possible, choose a quiet area for instruction in which you can interact with the patient with minimal distractions.
- Explain to the patient the aims and rationale of breathing exercises or ventilatory training specific to his or her particular impairments and functional limitations.
- Have the patient assume a comfortable, relaxed position and loosen restrictive clothing. Initially, a semi-Fowler's position with the head and trunk elevated approximately

* See references 3, 7, 11, 14, 15, 28, 36, 40, 44, 45, 48, 57, 60, 63, 66, 76.

45°, is desirable. By supporting the head and trunk, flexing the hips and knees, and supporting the legs with a pillow, the abdominal muscles remain relaxed. Other positions, such as supine, sitting, or standing, may be used initially or as the patient progresses during treatment.

- Observe and assess the patient's spontaneous breathing pattern while at rest and later with activity.
- Determine whether ventilatory training is indicated.
- Establish a baseline for assessing changes, progress, and outcomes of intervention.
- If necessary, teach the patient relaxation techniques. This relaxes the muscles of the upper thorax, neck, and shoulders to minimize the use of the accessory muscles of ventilation. Pay particular attention to relaxation of the sternocleidomastoids, upper trapezius, and levator scapulae muscles.
- Depending on the patient's underlying pathology and impairments, determine whether to emphasize the inspiratory or expiratory phase of ventilation.
- Demonstrate the desired breathing pattern to the patient.
- Have the patient practice the correct breathing pattern in a variety of positions at rest and with activity.

PRECAUTIONS: When teaching breathing exercises, be aware of the following precautions^{11,28,48,60}:

- Never allow a patient to force expiration. Expiration should be relaxed or lightly controlled. Forced expiration only increases turbulence in the airways, leading to bronchospasm and increased airway restriction.
- Do not allow a patient to take a highly *prolonged* expiration. This causes the patient to gasp with the next inspiration. The patient's breathing pattern then becomes irregular and inefficient.
- Do not allow the patient to initiate inspiration with the accessory muscles and the upper chest. Advise the patient that the upper chest should be relatively quiet during breathing.
- Allow the patient to perform deep breathing for only three or four inspirations and expirations at a time to avoid hyperventilation.

Diaphragmatic Breathing

When the diaphragm is functioning effectively in its role as the primary muscle of inspiration, ventilation is efficient and the oxygen consumption of the muscles of ventilation is low during relaxed (tidal) breathing.^{7,28} When a patient relies substantially on the accessory muscles of inspiration, the mechanical work of breathing (oxygen consumption) increases and the efficiency of ventilation decreases.

Although the diaphragm controls breathing at an involuntary level, a patient with primary or secondary pulmonary dysfunction can be taught how to control breathing by optimal use of the diaphragm and decreased use of accessory muscles.

Controlled breathing techniques, which emphasize diaphragmatic breathing, are designed to improve the efficiency of ventilation, decrease the work of breathing, increase the excursion (descent or ascent) of the diaphragm, and improve gas exchange and oxygenation.^{11,28,44,48,60} Diaphragmatic breathing exercises also are used during postural drainage to mobilize lung secretions.^{25,51}

Procedure

- Prepare the patient in a relaxed and comfortable position in which gravity *assists* the diaphragm, such as a semi-Fowler's position.
- If your examination revealed that the patient initiates the breathing pattern with the accessory muscles of inspiration (shoulder and neck musculature), start instruction by teaching the patient how to relax those muscles (shoulder rolls or shoulder shrugs coupled with relaxation).
- Place your hand(s) on the rectus abdominis just below the anterior costal margin (Fig. 25.9). Ask the patient to breathe in slowly and deeply through the nose. Have the patient keep the shoulders relaxed and upper chest quiet, allowing the abdomen to rise slightly. Then tell the patient to relax and exhale slowly through the mouth.

FIGURE 25.9 The semireclining (as shown) and semi-Fowler's positions are comfortable, relaxed positions in which to teach diaphragmatic breathing.

- Have the patient practice this three or four times and then rest. Do not allow the patient to hyperventilate.
- If the patient is having difficulty using the diaphragm during inspiration, have the patient inhale several times in succession through the nose by using a *sniffing* action.^{28,60} This action usually facilitates the diaphragm.
- To learn how to self-monitor this sequence, have the patient place his or her own hand below the anterior costal margin and feel the movement (Fig. 25.10). The patient's hand should rise slightly during inspiration and fall during expiration.

FIGURE 25.10 The patient places his or her own hands on the abdomen to feel the movement of proper diaphragmatic breathing. By placing the hands on the abdomen, the patient can also feel the contraction of the abdominals, which occurs with controlled expiration or coughing.

- After the patient understands and is able to control breathing using a diaphragmatic pattern, keeping the shoulders relaxed, practice diaphragmatic breathing in a variety of positions (sitting, standing) and during activity (walking, climbing stairs).

NOTE: Evidence concerning the effect of diaphragmatic breathing exercises on the rate of ventilation, the work of breathing and oxygen consumption, excursion of the diaphragm, and exercise capacity in normal subjects and in patients with pulmonary disorders is inconclusive, with some studies supporting and others refuting the benefits of diaphragmatic breathing.^{13,28,44,62}

Segmental Breathing

It is questionable whether a patient can be taught to expand localized areas of the lungs while keeping other areas quiet. It is known, however, that hypoventilation does occur in certain areas of the lungs because of chest wall fibrosis, pain, and muscle guarding after surgery, atelectasis, and pneumonia. Therefore, there are certain instances such as during postural drainage or following thoracic surgery when it is important to emphasize expansion of problem areas of the lungs and chest wall.

Two examples of segmental breathing that target the lateral and posterior segments of the lower lobes are described in this section. However, segmental breathing techniques also may need to be directed to the middle and upper lobes if there is accumulation of secretions or insufficient lung expansion in these areas.

Lateral Costal Expansion

Lateral costal expansion, sometimes called *lateral basal expansion*, can be carried out unilaterally or bilaterally.

Deep breathing while focusing on movement of the lower portion of the rib cage may facilitate diaphragmatic excursion.²⁸ This technique is particularly important for the patient with a stiff lower rib cage, as is often seen with chronic bronchitis, emphysema, or asthma.⁷

Procedure

- Have the patient begin in a hook-lying position; later progress to a sitting position. Place your hands along the lateral aspect of the lower ribs to direct the patient's attention to the areas where movement is to occur (Figs. 25.11 and 25.12).

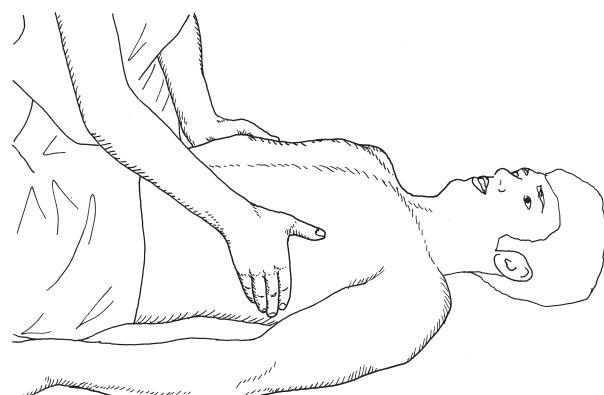

FIGURE 25.11 Bilateral lateral costal expansion—supine.

FIGURE 25.12 Bilateral lateral costal expansion—sitting.

- Ask the patient to breathe out, and feel the rib cage move downward and inward. As the patient breathes out, place pressure into the ribs with the palms of your hands.
- Just prior to inspiration, apply a quick downward and inward stretch to the chest. This places a quick

stretch on the external intercostals to facilitate their contraction.

- Apply *light* manual resistance to the lower ribs to increase sensory awareness as the patient breathes in deeply and the chest expands and ribs flare. Then, as the patient breathes out, assist by gently squeezing the rib cage in a downward and inward direction.
- Teach the patient how to perform the maneuver independently by placing his or her hand(s) over the ribs (Fig. 25.13) or applying resistance with a towel or belt around the lower ribs (Fig. 25.14A&B).

FIGURE 25.13 The patient applies his or her own manual pressure during lateral costal expansion.

Posterior Basal Expansion

Deep breathing emphasizing posterior basal expansion is important for the postsurgical patient who is confined to bed in a semireclining position for an extended period of time because secretions often accumulate in the posterior segments of the lower lobes.

Procedure

Have the patient sit and lean forward on a pillow, slightly bending the hips (see Fig. 25.15). Place your hands over

the posterior aspect of the lower ribs, and follow the same procedure just described for lateral costal expansion.

Pursed-Lip Breathing

Pursed-lip breathing is a strategy that involves lightly pursing the lips together during controlled exhalation. This breathing pattern often is adopted spontaneously by patients with COPD to deal with episodes of dyspnea.^{7,10,28,43,48} Patients with COPD using pursed-lip breathing report a decrease in their perceived level of exertion during activity.¹⁰

However, whether it is beneficial to teach a patient pursed-lip breathing often is debated. Many therapists believe that gentle pursed-lip breathing and controlled expiration is a useful procedure, particularly to relieve dyspnea if it is performed appropriately. It is thought to keep airways open by creating back-pressure in the airways. Studies suggest that pursed-lip breathing decreases the respiratory rate and the work of breathing (oxygen consumption), increases the tidal volume, and improves exercise tolerance.^{15,28,43,48}

PRECAUTION: The use of *forceful* expiration during pursed-lip breathing must be avoided. Forceful expiration while the lips are pursed can increase the turbulence in the airways and cause further restriction of the small bronchioles. Therefore, if a therapist elects to teach this breathing strategy, it is important to emphasize with the patient that expiration should be performed in a controlled manner but not forced.

Procedure

Have the patient assume a comfortable position and relax as much as possible. Have the patient breathe in slowly and deeply through the nose and then breathe out gently through lightly pursed lips as if blowing on and bending the flame of a candle but not blowing it out.⁴³ Explain to

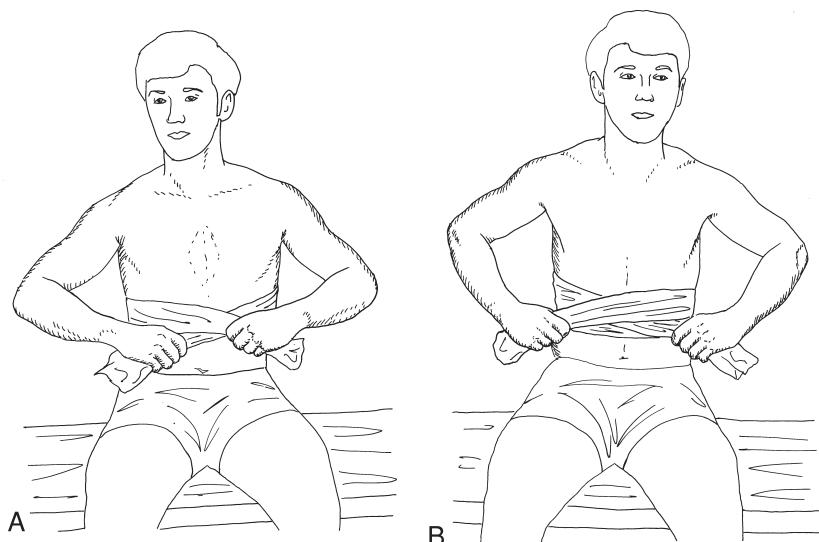

FIGURE 25.14 Belt exercises reinforce lateral costal breathing (A) by applying resistance during inspiration and (B) by assisting with pressure along the rib cage during expiration.

the patient that expiration must be relaxed and that contraction of the abdominals must be avoided. Place your hand over the patient's abdominal muscles to detect any contraction of the abdominals.

Preventing and Relieving Episodes of Dyspnea

Many patients with COPD (e.g., emphysema and asthma) may suffer from periodic episodes of dyspnea (shortness of breath), particularly with physical exertion or when in contact with allergens. Whenever a patient's normal breathing pattern is interrupted, shortness of breath can occur. It is helpful to teach a patient how to monitor his or her level of shortness of breath and to prevent episodes of dyspnea by *controlled breathing techniques, pacing activities*, and becoming aware of what activity or situation precipitates a shortness of breath attack.

Pacing is the performance of functional activities, such as walking, stair climbing, or work-related tasks, within the limits of a patient's ventilatory capacity.¹¹ Although some patients may understand intuitively the limits to which functional activities can be pushed, others must be taught to recognize the early signs of dyspnea. If the patient becomes slightly short of breath, he or she must learn to stop an activity and use controlled, pursed-lip breathing until the dyspnea subsides.

Procedure

- Have the patient assume a relaxed, forward-bent posture (Figs. 25.15 and 25.16; also see Fig. 25.6). A forward-bent position stimulates diaphragmatic breathing (the viscera drop forward and the diaphragm descends more easily). Use bronchodilators as prescribed.
- Have the patient gain control of his or her breathing and reduce the respiratory rate by using pursed-lip breathing during expiration. Have the patient focus on the expiratory phase of breathing while being sure to avoid forceful expiration.

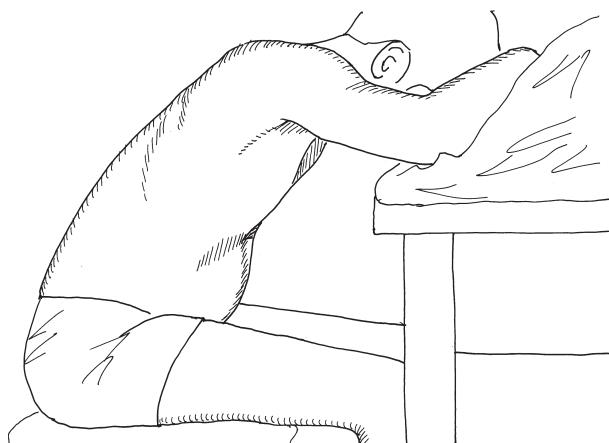

FIGURE 25.15 A patient can sit and lean forward on a pillow to relax and relieve an episode of dyspnea.

FIGURE 25.16 While standing, a patient can lean forward and place some weight on the hands to relieve dyspnea.

- After each pursed-lip expiration, teach the patient to use diaphragmatic breathing and minimize use of accessory muscles during each inspiration.
- Have the patient remain in a forward-bent posture and continue to breathe in a slow, controlled manner until the episode of dyspnea subsides.

Positive Expiratory Pressure Breathing

Positive expiratory pressure breathing is a technique in which resistance to airflow is applied during exhalation, similar to what occurs during pursed-lip breathing, except that the patient breathes through a specially designed mouthpiece or mask that controls resistance to airflow.^{19,20,25} This breathing technique is used to hold airways open during exhalation to mobilize accumulated secretions and improve their clearance. Positive expiratory pressure breathing provides an alternative or adjunct to postural drainage which a patient can perform independently.

Procedure

Positive expiratory pressure breathing is performed in an upright position, preferably seated with the elbows resting on a table. The procedure can be performed against low or high pressure. A low pressure technique involves tidal inspiration and active, but not forced, expiration through a mouthpiece or mask. The patient inhales, holds the inspiration for 2 to 3 seconds, and then exhales, repeating the sequence for approximately 10 to 15 cycles.^{19,20,25} The patient removes the mouthpiece or mask, takes several "huffs" and then coughs to clear the mobilized secretions from the airways. The breathing sequence typically is repeated four to six times with a total treatment session lasting about 15 minutes.

Respiratory Resistance Training

The process of improving the strength or endurance of the muscles of ventilation is known as *respiratory resistance training* (RRT). Other descriptions used to denote this form of breathing exercises are *ventilatory muscle training*, *inspiratory (or expiratory) muscle training*, *inspiratory resistance training*, and *flow-controlled endurance training*. These techniques typically focus on training the muscles of inspiration,^{14,26,32,33,54,65} although expiratory muscle training also has been described.^{32,33} RRT is advocated to improve ventilation in patients with pulmonary dysfunction associated with weakness, atrophy, or inefficiency of the muscles of inspiration or to improve the effectiveness of the cough mechanism in patients with weakness of the abdominal muscles or other expiratory muscles.

With support from animal studies,^{46,62} it has been suggested that the principles of overload and specificity of training apply to skeletal muscles throughout the body, including the muscles of ventilation.* In humans, it is not feasible to use invasive procedures to evaluate morphological or histochemical changes in the diaphragm that may occur as the result of strength or endurance training. Instead, strength or endurance changes must be assessed indirectly. Increases in respiratory muscle strength and endurance are determined by ultrasonographic measurements of the thickness of the diaphragm, maximal voluntary ventilation, and decreased reliance on accessory muscles of inspiration. Respiratory muscle strength (either inspiratory or expiratory) also is evaluated indirectly with measurements of inspiratory capacity, forced expiratory volume, inspiratory mouth pressure using a spirometer, vital capacity, and increased cough effectiveness.

PRECAUTION: Avoid prolonged periods of any form of resistance training for inspiratory muscles. Unlike muscles of the extremities, the diaphragm cannot totally rest to recover from a session of resistance exercises. Use of accessory muscles of inspiration (neck and shoulder muscles) is a sign that the diaphragm is beginning to fatigue.^{3,76}

Inspiratory Resistance Training

Inspiratory resistance training, using pressure- or flow-based devices to provide resistance to airflow, is designed to improve the strength and endurance of the muscles of inspiration and decrease the occurrence of inspiratory muscle fatigue. This technique has been studied in patients with acute and chronic, primary and secondary pulmonary disorders, including COPD,^{1,15,54,64} cystic fibrosis,²⁶ respiratory failure and ventilator dependence (weaning failure),^{2,65} chronic heart failure,¹⁴ and chronic neuromuscular disease.³² Although reviews of the literature have demonstrated that outcomes of inspiratory muscle training programs in patients with pathologies are inconsistent,^{33,50} some positive changes reported after training are increased vital capacity, increased exercise capacity, and fewer episodes of dyspnea.^{14,26,54} Inspiratory muscle training also has been studied and found to be effective (as evidenced by

a decreased respiratory rate) in patients with cervical-level spinal cord lesions.^{24,49,57,74}

Procedure

- The patient inhales through a resistive training device placed in the mouth. These devices are narrow tubes of varying diameters or a mouthpiece and adapter with an adjustable aperture that provide resistance to airflow during inspiration and therefore place resistance on inspiratory muscles. The smaller the diameter of the aperture and the faster the rate of airflow, the greater is the resistance.
- The patient inhales through the device for a specified period of time several times each day. The time is gradually increased to 20 to 30 minutes at each training session to increase inspiratory muscle endurance.

Incentive Respiratory Spirometry

Incentive spirometry is a form of ventilatory training that emphasizes sustained maximum inspirations.^{18,48,60} The patient inhales as deeply as possible through a small, handheld spirometer that provides visual or auditory feedback about whether a target maximum inspiration was reached. Typically, this breathing technique is performed while using a spirometer, but it also may be performed without the equipment.

The purpose of incentive spirometry is to increase the volume of air inspired. It is used primarily to prevent alveolar collapse and atelectasis in postoperative patients. Despite the widespread use of incentive spirometry for patients after surgery, the effectiveness of this technique alone or in addition to general deep breathing and coughing for the prevention of postoperative pulmonary complications is not clear.^{18,40,71}

Procedure

- Have the patient assume a comfortable position (semireclining, if possible) and inhale and exhale three to four times and then exhale maximally with the fourth breath.
- Then have the patient place the spirometer in the mouth, inhale maximally through the mouthpiece to a target setting and hold the inspiration for several seconds.
- This sequence is repeated five to ten times several times per day.

Glossopharyngeal Breathing

Glossopharyngeal breathing is a technique that became known to therapists during the 1950s through patients with severe ventilatory impairment as the result of poliomyelitis. It is a means of increasing the inspiratory capacity when there is severe weakness of the muscles of inspiration.^{28,39,53,75,76} Today, it is used primarily by patients who are ventilator-dependent because of absent or incomplete innervation of the diaphragm as the result of a high cervical-level spinal cord lesion or other neuromuscular disorders. Glossopharyngeal breathing combined with the inspiratory action of the neck musculature can reduce ventilator dependence or can be used as an emergency procedure should a malfunction of a patient's ventilator

* See references 1–3, 15, 26, 32, 33, 44, 46, 54, 57, 62, 65, 71, 76.

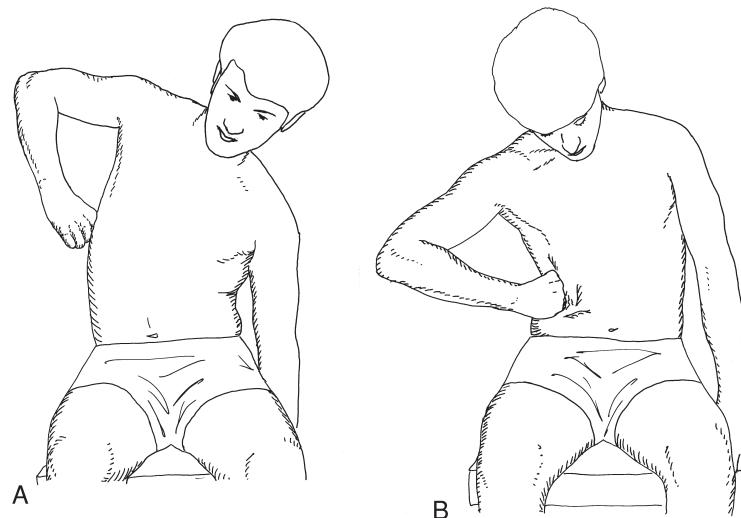

FIGURE 25.17 Chest mobilization during inspiration and expiration. To mobilize the lateral rib cage have the patient (A) bend away from the tight side during inspiration and (B) bend toward the tight side during expiration.

occur.^{3,39,53,75,76} It also can be used to improve the force (and therefore the effectiveness) of a cough or increase the volume of the voice.

Procedure

Glossopharyngeal breathing involves taking several “gulps” of air, usually 6 to 10 gulps in series, to pull air into the lungs when action of the inspiratory muscles is inadequate. After the patient takes several gulps of air, the mouth is closed, and the tongue pushes the air back and traps it in the pharynx. The air is then forced into the lungs when the glottis is opened. This increases the depth of the inspiration and the patient’s inspiratory and vital capacities.^{39,75}

EXERCISES TO MOBILIZE THE CHEST

Chest mobilization exercises are any exercises that combine active movements of the trunk or extremities with deep breathing.^{21,60} They are designed to maintain or improve mobility of the chest wall, trunk, and shoulder girdles when it affects ventilation or postural alignment. For example, a patient with hypomobility of the trunk muscles on one side of the body does not expand that part of the chest fully during inspiration. Exercises that combine stretching of these muscles with deep breathing improve ventilation on that side of the chest.

Chest mobilization exercises also are used to reinforce or emphasize the depth of inspiration or controlled expiration. A patient can reinforce expiration, for example, by leaning forward at the hips or flexing the spine as he or she breathes out. This pushes the viscera superiorly into the diaphragm.

Specific Techniques

To Mobilize One Side of the Chest

- While sitting, have the patient bend away from the tight side to lengthen hypomobile structures and expand that side of the chest during inspiration (Fig. 25.17A).

- Then, have the patient push the fisted hand into the lateral aspect of the chest, bend toward the tight side, and breathe out (Fig. 25.17B).
- Progress by having the patient raise the arm overhead on the tight side of the chest and side-bend away from the tight side. This places an additional stretch on hypomobile tissues.

To Mobilize the Upper Chest and Stretch the Pectoralis Muscles

- While the patient is sitting in a chair with hands clasped behind the head, have him or her horizontally abduct the arms (elongating the pectoralis major) during a deep inspiration (Fig. 25.18A).
- Then instruct the patient to bring the elbows together and bend forward during expiration (Fig. 25.18B).

To Mobilize the Upper Chest and Shoulders

While sitting in a chair, have the patient reach with both arms overhead (180° bilateral shoulder flexion and slight abduction) during inspiration (Fig. 25.19A) and then bend forward at the hips and reach for the floor during expiration (Fig. 25.19B).

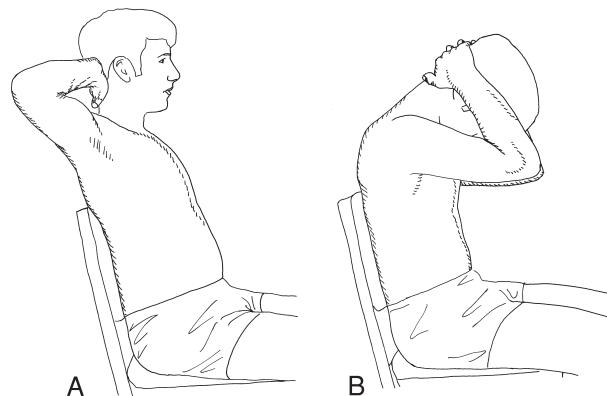

FIGURE 25.18 (A) A stretch is applied to the pectoralis muscles during inspiration, and (B) the patient brings the elbows together to facilitate expiration.

FIGURE 25.19 (A) Chest expansion is increased with bilateral movement of the arms overhead during inspiration. (B) Expiration is then reinforced by reaching the arms toward the floor.

COUGHING

An effective cough is necessary to eliminate respiratory obstructions and keep the lungs clear. Airway clearance is an important part of management of patients with acute or chronic respiratory conditions.^{25,51,60}

The Normal Cough Pump

A cough may be reflexive or voluntary. When a person coughs, a series of actions occurs (Box 25.7).⁴⁷ Under normal conditions, the cough pump is effective to the seventh generation of bronchi. (There are a total of 23 generations of bronchi in the tracheobronchial tree.) Ciliated epithelial cells are present up to the terminal bronchiole and raise secretions from the smaller to the larger airways in the absence of pathology.

Factors that Decrease the Effectiveness of the Cough Mechanism and Cough Pump

The effectiveness of the cough mechanism can be compromised for a number of reasons including the following.^{25,39,51,60,76}

BOX 25.7 The Cough Mechanism

- Deep inspiration occurs.
- Glottis closes, and vocal cords tighten.
- Abdominal muscles contract and the diaphragm elevates, causing an increase in intrathoracic and intra-abdominal pressures.
- Glottis opens.
- Explosive expiration of air occurs.

● **Decreased inspiratory capacity.** Inspiratory capacity can be reduced because of pain due to acute lung disease, rib fracture, trauma to the chest, or recent thoracic or abdominal surgery. Weakness of the diaphragm or accessory muscles of inspiration as a result of a high spinal cord injury or neuropathic or myopathic disease decrease a patient's ability to take in a deep breath. Postoperatively, the respiratory center may be depressed as the result of general anesthesia, pain, or medication.

● **Inability to forcibly expel air.** A spinal cord injury above T12 and myopathic disease, such as muscular dystrophy, cause weakness of the abdominal muscles, which are vital for a strong cough. Excessive fatigue as the result of critical illness and a chest wall or abdominal incision causing pain all contribute to a weak cough. A patient who has had a tracheostomy also has difficulty producing a strong cough, even when the tracheostomy site is covered.

● **Decreased action of the cilia in the bronchial tree.** Action of the ciliated cells may be compromised because of physical interventions such as general anesthesia and intubation or pathologies such as COPD including chronic bronchitis, which is associated with a decreased number of ciliated epithelial cells in the airway. Smoking also depresses the action of the cilia.

● **Increase in the amount or thickness of mucus.** Pathologies (e.g., cystic fibrosis, chronic bronchitis) and pulmonary infections (e.g., pneumonia) are associated with an increase in mucus production and the thickness of the mucus. Intubation irritates the lumen of the airways and causes increased mucus production, whereas dehydration thickens mucus.

Teaching an Effective Cough

Because an effective cough is an integral component of airway clearance, a patient must be taught the importance of an effective cough, how to produce an efficient and controlled voluntary cough, and when to cough. The following sequence and procedures are used when teaching an effective cough.^{25,51,66}

1. Assess the patient's voluntary or reflexive cough.
2. Have the patient assume a relaxed, comfortable position for deep breathing and coughing. Sitting or leaning forward usually is the best position for coughing. The patient's neck should be slightly flexed to make coughing more comfortable.
3. Teach the patient controlled diaphragmatic breathing, emphasizing deep inspirations.
4. Demonstrate a sharp, deep, double cough.
5. Demonstrate the proper muscle action of coughing (contraction of the abdominals). Have the patient place the hands on the abdomen and make three *huffs* with expiration to feel the contraction of the abdominals (see Fig. 25.10). Have the patient practice making a "K" sound to experience tightening of the vocal cords, closing the glottis, and contracting the abdominals.
6. When the patient has put these actions together, instruct the patient to take a deep but relaxed inspiration, fol-

BOX 25.8 Precautions for Teaching an Effective Cough

- Never allow a patient to gasp in air, because this increases the work (energy expenditure) of breathing, causing the patient to fatigue more easily. It also increases turbulence and resistance in the airways, possibly leading to increased bronchospasm and further constriction of airways. A gasping action also may push mucus or a foreign object deep into air passages.
- Avoid uncontrolled coughing spasms (*paroxysmal coughing*).
- Avoid forceful coughing if a patient has a history of a cerebrovascular accident or an aneurysm. Have these patients *huff* several times to clear the airways, rather than cough.
- Be sure that the patient coughs while in a somewhat erect or side-lying posture.

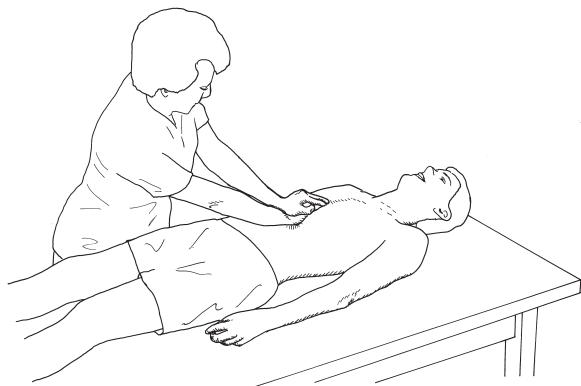

FIGURE 25.20 Therapist-assisted manual cough technique.

FIGURE 25.21 Therapist-assisted or self-assisted manual cough technique.

lowed by a sharp double cough. The second cough during a single expiration is usually more productive.

7. Use an abdominal binder or glossopharyngeal breathing in selected patients with inspiratory or abdominal muscle weakness to enhance the cough, if necessary.

Precautions that should be observed while teaching a patient an effective cough are noted in Box 25.8.

Additional Techniques to Facilitate a Cough and Improve Airway Clearance

To maximize airway clearance, several techniques can be used to stimulate a stronger cough, make coughing more comfortable or improve the clearance of secretions.

Manual-Assisted Cough

If a patient has abdominal weakness (e.g., as the result of a mid-thoracic or cervical spinal cord injury), manual pressure on the abdominal area assists in developing greater intra-abdominal pressure for a more forceful cough. Manual pressure for cough assistance can be applied by the therapist or the patient.^{3,25,39,51,66,76}

Therapist-Assisted Techniques

- With the patient in a supine or semireclining position, the therapist places the heel of one hand on the patient's abdomen at the epigastric area just distal to the xiphoid process. The other hand is placed on top of the first, keeping the fingers open or interlocking them (Fig. 25.20). After the patient inhales as deeply as possible, the therapist manually assists the patient as he or she attempts to cough. The abdomen is compressed with an inward and upward force, which pushes the diaphragm upward to cause a more forceful and effective cough.
- This same maneuver can be performed with the patient in a chair (Fig. 25.21). The therapist or family member can stand in back of the patient and apply manual pressure during expiration.

PRECAUTION: Avoid direct pressure on the xiphoid process during the maneuver.

Self-Assisted Technique

- While in a sitting position, the patient crosses the arms across the abdomen or places the interlocked hands below the xiphoid process (see Fig. 25.21).
- After a deep inspiration, the patient pushes inward and upward on the abdomen with the wrists or forearms and simultaneously leans forward while attempting to cough.

Splinting

If chest wall pain from recent surgery or trauma is restricting the cough, teach the patient to splint over the painful area during coughing.^{25,45,51} Have the patient press the hands or a pillow firmly over the incision to support the painful area with each cough (Fig. 25.22). If the patient cannot reach the painful area, the therapist should assist (Fig. 25.23).

Humidification

If secretions are very thick, work with the patient after humidification therapy or ultrasonic nebulizer therapy, both

FIGURE 25.22 Splinting over an anterior surgical incision.

FIGURE 25.23 Splinting over a posterior lateral incision.

of which enhance the mucociliary transport system and facilitate a productive cough.⁶⁶

Tracheal Stimulation

Tracheal stimulation, sometimes called a *tracheal tickle*, may be used with infants or disoriented patients who cannot cooperate during treatment.⁶⁶ Tracheal stimulation is a somewhat uncomfortable maneuver, performed to elicit a reflexive cough. The therapist places two fingers at the sternal notch and applies a circular motion with pressure downward into the trachea to facilitate a reflexive cough.

Suctioning: Alternative to Coughing

Endotracheal suctioning may be the only means of clearing the airways in patients who are unable to cough or huff voluntarily or after reflex stimulation of the cough mechanism.^{29,60} Suctioning is indicated in all patients with artificial airways. The suctioning procedure clears only the trachea and the mainstem bronchi.

PRECAUTION: Only individuals who have been taught proper suctioning technique should use this alternative means of clearing the airways. Suctioning, if performed incorrectly, can introduce an infection into the airways or damage the delicate mucosal lining of the trachea and bronchi. Improper suctioning also can cause hypoxemia, an abnormal heart rate, and atelectasis. A complete description of the proper endotracheal suctioning technique may be found in other resources.^{29,60}

POSTURAL DRAINAGE

Postural drainage (bronchial drainage), another intervention for airway clearance, is a means of mobilizing secretions in one or more lung segments to the central airways by placing the patient in various positions so gravity assists in the drainage process.^{4,11,25,51,60} When secretions are moved from the smaller to the larger airways, they are then cleared by coughing or endotracheal suctioning. *Postural drainage therapy* also includes the use of manual techniques, such as percussion, shaking, and vibration, coupled with voluntary coughing.

Goals and indications for postural drainage are noted in Box 25.9, and relative contraindications are summarized in Box 25.10.^{4,11,25,51,60} Despite the risks, postural drainage may be necessary in the unstable patient. Modified positioning to avoid head-down or fully horizontal positions typically is necessary for most high-risk patients.

Manual Techniques Used with Postural Drainage Therapy

In addition to the use of body positioning, deep breathing, and an effective cough to facilitate airway clearance, a variety of manual techniques are used in conjunction with postural drainage to maximize the effectiveness of the

BOX 25.9 Goals and Indications for Postural Drainage

Prevent Accumulation of Secretions in Patients at Risk for Pulmonary Complications

- Patients with pulmonary diseases that are associated with increased production or viscosity of mucus, such as chronic bronchitis and cystic fibrosis
- Patients who are on prolonged bed rest
- Patients who have received general anesthesia and who may have painful incisions that restrict deep breathing and coughing postoperatively
- Any patient who is on a ventilator if he or she is stable enough to tolerate the treatment

Remove Accumulated Secretions from the Lungs

- Patients with acute or chronic lung disease, such as pneumonia, atelectasis, acute lung infections, COPD
- Patients who are generally very weak or are elderly
- Patients with artificial airways

BOX 25.10 Relative Contraindications to Postural Drainage

- Severe hemoptysis
- Untreated acute conditions
 - Severe pulmonary edema
 - Congestive heart failure
 - Large pleural effusion
 - Pulmonary embolism
 - Pneumothorax
- Cardiovascular instability
 - Cardiac arrhythmia
 - Severe hypertension or hypotension
 - Recent myocardial infarction
 - Unstable angina
- Recent neurosurgery
 - Head-down positioning may cause increased intracranial pressure; if PD is required, modified positions can be used

mucociliary transport system.^{11,25,51,60,66,72} They include percussion, vibration, shaking, and rib springing. Findings from studies that have been implemented to evaluate the efficacy of these manual techniques as adjuncts to postural drainage are inconclusive.⁶⁶

Percussion

Percussion is used to augment mobilization of secretions by mechanically dislodging viscous or adherent mucus from the airways. Percussion is performed with cupped hands (Fig. 25.24A) over the lung segment being

FIGURE 25.24 (A) Hand position for applying percussion. (B) The therapist alternately percusses over the lung segment being drained.

drained.^{25,67} The therapist's cupped hands strike the patient's chest wall in an alternating, rhythmic manner (Fig. 25.24B). The therapist should try to keep shoulders, elbows, and wrists loose and mobile during the maneuver. Mechanical percussion is an alternative to manual percussion techniques.

Percussion is continued for several minutes or until the patient needs to alter position to cough. This procedure should not be painful or uncomfortable.

PRECAUTIONS: To prevent irritation to sensitive skin, have the patient wear a lightweight gown or shirt. Avoid percussion over breast tissue in women and over bony prominences.

Relative Contraindications to Percussion

Prior to using percussion in a postural drainage program, a therapist must weigh the potential benefits versus potential risks. In most instances, it is prudent to avoid the use of percussion.^{25,67}

- Over fractures, spinal fusion, or osteoporotic bone
- Over tumor area
- If a patient has a pulmonary embolus
- If the patient has a condition in which hemorrhage could easily occur, such as in the presence of a low platelet count, or if the patient is receiving anticoagulation therapy
- If the patient has unstable angina
- If the patient has chest wall pain, for example after thoracic surgery or trauma

Vibration

Vibration, another manual technique, often is used in conjunction with percussion to help move secretions to larger airways. It is applied *only during the expiratory phase* as the patient is deep-breathing.^{25,51,72} Vibration is applied by placing both hands directly on the skin and over the chest wall (or one hand on top of the other) and gently compressing and rapidly vibrating the chest wall as the patient breathes out (Fig. 25.25). Pressure is applied in the same direction as the chest is moving. The vibrating action is achieved by the therapist isometrically contracting (tensing) the muscles of the upper extremities from shoulders to hands.

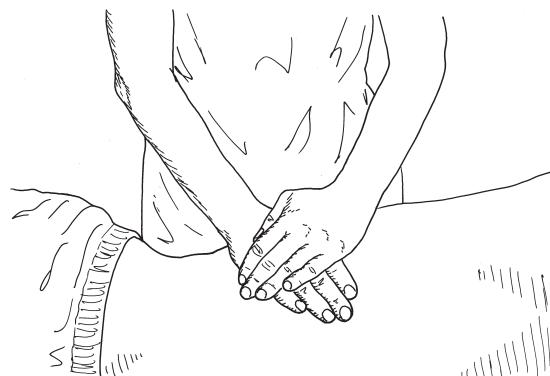

FIGURE 25.25 Hand placement for vibration during postural drainage.

Shaking

Shaking is a more vigorous form of vibration applied during exhalation using an intermittent bouncing maneuver coupled with wide movements of the therapist's hands. The therapist's thumbs are locked together, the open hands are placed directly on the patient's skin, and fingers are wrapped around the chest wall. The therapist simultaneously compresses and shakes the chest wall.^{25,51,72}

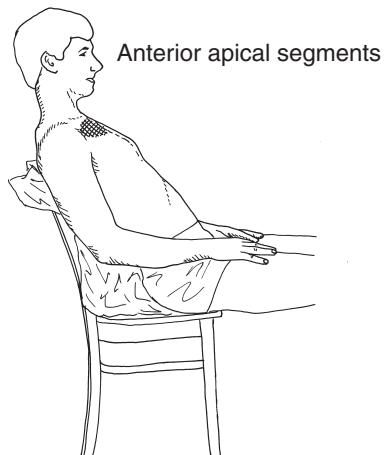

FIGURE 25.26 Percussion is applied directly under the clavicle.

FIGURE 25.28 Percussion is applied bilaterally, directly over the nipple or just above the breast.

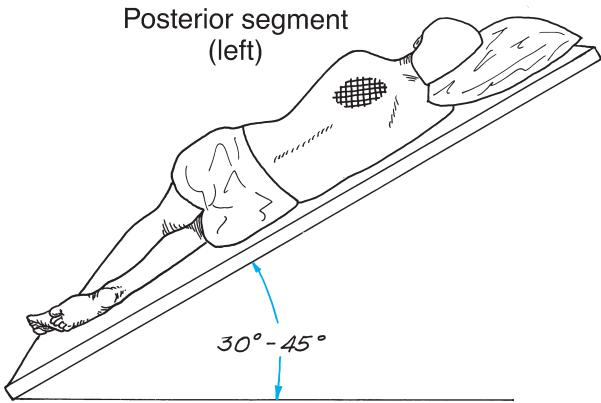

FIGURE 25.29 Patient lies one-quarter turn from prone and rests on the right side. Head and shoulders are elevated 45° or approximately 18 inches if pillows are used. Percussion is applied directly over the left scapula.

Postural Drainage Positions

Positions for postural drainage are based on the anatomy of the lungs and the tracheobronchial tree (see Figs. 25.2 and 25.4). Each segment of each lobe is drained using the positions depicted in Figures 25.26 through 25.37. The shaded area in each illustration indicates the area of the chest wall where percussion or vibration is applied.

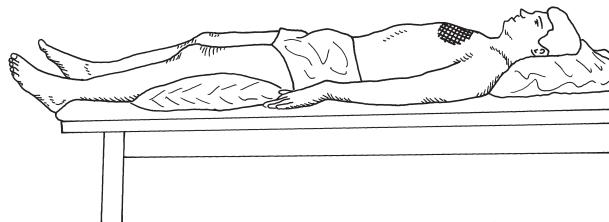

RIGHT AND LEFT UPPER LOBES

Posterior apical segments

FIGURE 25.27 Percussion is applied above the scapulae. Your fingers curve over the top of the shoulders.

Anterior segments

Posterior segment (right)

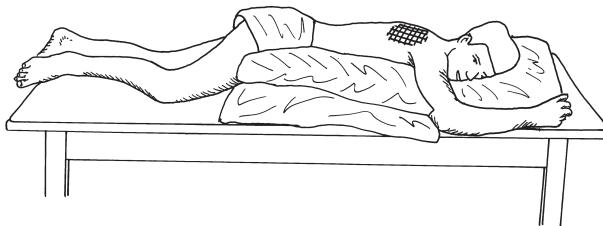

FIGURE 25.30 Patient lies flat and one-quarter turn from prone on the left side. Percussion is applied directly over the right scapula.

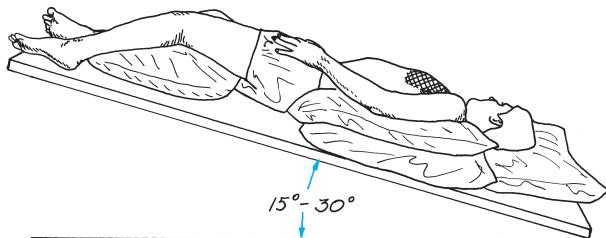

LINGULA

FIGURE 25.31 Patient lies one-quarter turn from supine on the right side, supported with pillows and in a 30° head-down position. Percussion is applied just under the left breast.

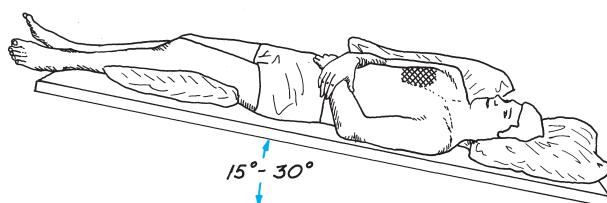

MIDDLE LOBE

FIGURE 25.32 Patient lies one-quarter turn from supine on the left side, supported with pillows behind the back, and in a 30° head-down position. Percussion is applied under the right breast.

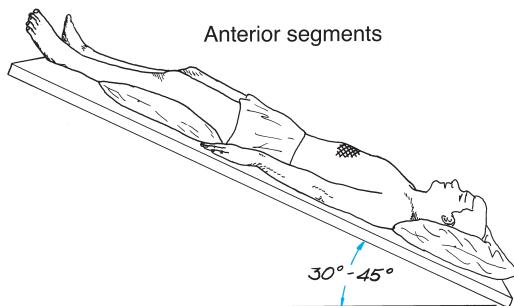

RIGHT AND LEFT LOWER LOBES**Anterior segments**

FIGURE 25.33 Patient lies supine, pillows under knees, in a 45° head-down position. Percussion is applied bilaterally over the lower portion of the ribs.

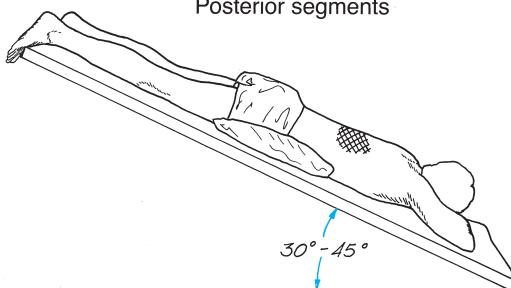

Posterior segments

FIGURE 25.34 Patient lies prone with a pillow under the abdomen in a 45° head-down position. Percussion is applied bilaterally over the lower portion of the ribs.

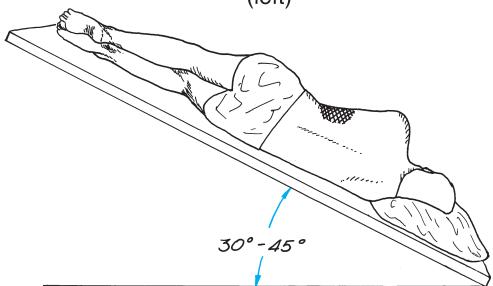

Lateral segment (left)

FIGURE 25.35 Patient lies on the right side in a 45° head-down position. Percussion is applied over the lower lateral aspect of the left rib cage.

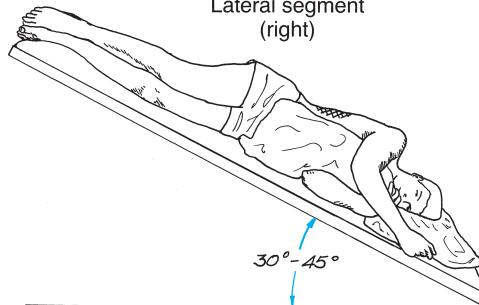

Lateral segment (right)

FIGURE 25.36 Patient lies on the left side in a 45° head-down position. Percussion is applied over the lower lateral aspect of the right rib cage.

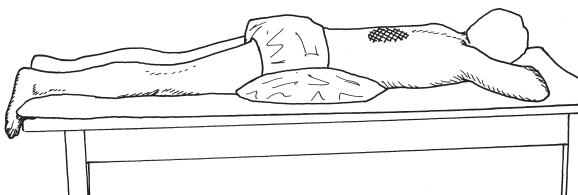

Superior segments

FIGURE 25.37 Patient lies prone with a pillow under the abdomen to flatten the back. Percussion is applied bilaterally, directly below the scapulae.

The patient may be positioned on a postural drainage table that can be elevated at one end, a tilt table, a reinforced padded table with a lift, or a hospital bed. A small child can be positioned on a therapist's or parent's lap.

Guidelines for Implementing Postural Drainage

General Considerations

Time of day. Consider the following when scheduling postural drainage into a patient's day.

- Never administer postural drainage directly after a meal.
- Coordinate treatment with aerosol therapy. Some therapists believe that aerosol therapy combined with humidification prior to postural drainage helps loosen secretions and increases the likelihood of productivity. Others believe that aerosol therapy is best after postural drainage when the patient's lungs are clearer and maximal benefit can be gained from medication administered through aerosol therapy.
- Choose a time (or times) of day likely to be of most benefit to the patient. A patient's cough tends to be highly productive in the early morning because of accumulation of secretions from the night before. Postural drainage in the early evening clears the lungs prior to sleeping and helps the patient rest more easily.

Frequency of treatments. The frequency of postural drainage each day or during the week depends on the type and severity of a patient's pathology. If secretions are thick and copious, two to four times per day may be necessary until the lungs are clear. If a patient is on a maintenance program, the frequency is less, perhaps once a day or only a few days a week.

Preparation for Postural Drainage

- Loosen tight or bulky clothing. It is not necessary to expose the skin. The patient may wear a lightweight shirt or gown.
- Have a sputum cup or tissues available.
- Have sufficient pillows for positioning and comfort.
- Explain the treatment procedure to the patient.
- Teach the patient deep breathing and an effective cough prior to beginning postural drainage.
- If the patient is producing copious amounts of sputum, instruct the patient to cough a few times or have the patient suctioned prior to positioning.
- Make any adjustments of tubes and wires, such as chest tubes, electrocardiography wires, or catheters, so they remain clear during positioning.

Postural Drainage Sequence

- Determine which segments of the lungs should be drained. Some patients with chronic lung diseases, such as cystic fibrosis, need to be drained in all positions. Other patients may require drainage of only a few segments in which secretions have accumulated.

- Check the patient's vital signs and breath sounds.
- Position the patient in the correct position for drainage. See that he or she is as comfortable and relaxed as possible.
- Stand in front of the patient, whenever possible, to observe his or her color.
- Maintain each position for 5 to 10 minutes if the patient can tolerate it or as long as the position is productive.
- Have the patient breathe deeply during drainage but do not allow the patient to hyperventilate or become short of breath. Pursed-lip breathing during expiration is sometimes used.
- Apply percussion over the segment being drained while the patient is in the correct position.
- Encourage the patient to take a deep, sharp, double cough whenever necessary. It may be more comfortable for the patient to momentarily assume a semiupright position (resting on one elbow) and then cough.
- If the patient does not cough spontaneously during positioning with percussion, instruct the patient to take several deep breaths or huff several times in succession as you apply vibration during expiration. This may help elicit a cough.
- If the patient's cough is not productive after 5 to 10 minutes of positioning, go on to the next position. Secretions that have been mobilized during a treatment may not be coughed up by the patient until 30 minutes to 1 hour after treatment.
- The duration of any one treatment should not exceed 45 to 60 minutes, as the procedure is quite fatiguing for the patient.

Concluding a Treatment

- Have the patient sit up slowly and rest for a short while after the treatment. Watch for signs of postural hypotension when the patient rises from a supine position or from a head-down position to sitting.
- Advise the patient that even if the cough was not productive during treatment it may be productive a short while after treatment.
- Evaluate the effectiveness of the treatment by reassessing breath sounds.
- Note the type, color, consistency, and amount of secretions produced.
- Check the patient's vital signs after treatment and note how the patient tolerated the treatment.

Criteria for Discontinuing Postural Drainage

- If the chest radiograph is relatively clear
- If the patient is afebrile for 24 to 48 hours
- If normal or near-normal breath sounds are heard with auscultation
- If the patient is on a regular home program

Modified Postural Drainage

Some patients who require postural drainage cannot assume or cannot tolerate the positions optimal for postural

drainage. For example, a patient with congestive heart failure may exhibit indications of orthopnea (shortness of breath while lying flat). After neurosurgery a patient may not be allowed to assume a head-down (Trendelenburg) position because this position causes increased intracranial pressure. After thoracic surgery a patient may have chest tubes and monitoring wires that limit positioning. Under these circumstances and others, positioning during postural drainage must be modified.^{25,51,60,66} The positions in which postural drainage is undertaken are modified consistent with the patient's medical or surgical problems. This compromise, although not ideal, is better than not administering postural drainage at all.

Home Program of Postural Drainage

Postural drainage may have to be carried out on a regular basis at home for patients with chronic lung disease. Patients need to be shown how to position themselves using inexpensive aids. An adult may place pillows over a hard wedge or stacks of newspapers to achieve the desired head-down positions in bed. A patient also can lean the chest over the edge of a bed, resting with the arms on a chair or stool. A child can be positioned on an ironing board propped up against a sofa or heavy chair. A family member often must be taught proper positioning, percussion or shaking techniques, and precautions to assist the patient.

MANAGEMENT OF PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease is a broad term encompassing a number of chronic pulmonary conditions, all of which obstruct the flow of air in the conducting airways of the lower respiratory tract and alter ventilation and gas exchange.^{6,30,67} Although a variety of pulmonary diseases are classified as obstructive in nature, each disease has its unique features and clinical manifestations and is distinguished by the cause of the obstruction of airflow, the onset of the disease, the location of the obstruction, and the reversibility of the obstruction.

Types of Obstructive Pulmonary Disorders

Typically, *peripheral airway disease*, *chronic bronchitis*, and *emphysema* are classified as COPD; but other obstructive pulmonary diseases that are chronic in nature, such as *asthma*, *bronchiectasis*, *cystic fibrosis*, and *bronchopulmonary dysplasia*, also may be included under this broad descriptor. The focus of discussion and guidelines for management presented in this section of the chapter is on chronic bronchitis and emphysema because patients with these diseases commonly are seen in pulmonary rehabilitation programs.^{6,7,12,37,67}

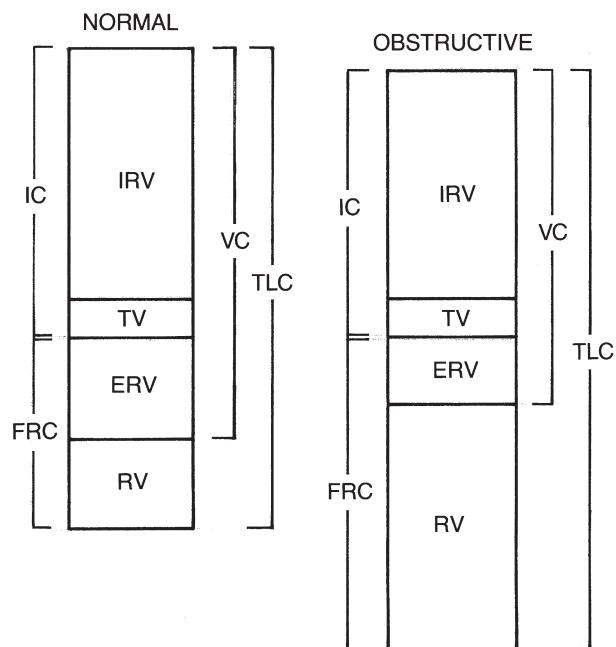

FIGURE 25.38 Normal lung volumes and capacities compared with abnormal lung volumes and capacities found in patients with obstructive pulmonary disease. (From Rothstein, J, Roy, A, Wolf, SL: *The Rehabilitation Specialist's Handbook*, ed. 3. FA Davis, Philadelphia, 2005, p 428, with permission.)

Pathological Changes in the Pulmonary System

Changes in chronic bronchitis and emphysema that occur over time are inflammation of the mucous membranes of the airways; increased production and retention of mucus; narrowing and destruction of airways; and destruction of alveolar and bronchial walls.^{6,30,67} These structural changes are reflected in pulmonary function tests depicted in Figure 25.38. These changes in the patient's pulmonary status predispose the patient to frequent acute respiratory infections.

Impairments and Impact on Function

As a result of the pathophysiology of COPD, many physical impairments develop over time. Patients typically have a chronic, productive cough and are often short of breath. The characteristic impact of COPD on the pulmonary system is the inability to remove air from the lungs effectively, which in turn affects the ability of the respiratory system to transport oxygen into the lungs.

Consequently, functional limitations and eventually disability occur consistent with the disablement process.⁴² Impairments such as increased respiratory rate, decreased vital capacity and forced expiratory volume, increased use of accessory muscles of inspiration, and progressive chest wall stiffness are associated with decreased tolerance to exercise, frequent episodes of dyspnea, decreased walking speed and distance, and eventual inability to perform activities of daily living at home or in the workplace or to remain an active participant in the community.

Management Guidelines: COPD

Lifelong management includes appropriate medical management to lessen disabling symptoms and prevent infection, smoking cessation, and participation in a comprehensive pulmonary rehabilitation program. Important aspects of management include breathing exercises, ongoing, airway clearance, and participation in an individually designed, graded exercise program that includes upper and lower extremity strength training and aerobic conditioning.^{6,7,11,12,37,55,67,70} Common impairments and guidelines for management are described in Box 25.11.

Focus on Evidence

Patients with COPD who appear to benefit most from pulmonary rehabilitation are those with only moderate-level disease and without a substantial number of co-morbidities. A combination of upper and lower extremity exercises have been shown to improve functional status more effectively than either upper or lower extremity exercise alone.⁶

Systematic reviews of the literature of pulmonary rehabilitation programs have demonstrated that the effects of a program of breathing exercises (diaphragmatic and pursed-lip breathing) on respiratory function¹³ and the effects of inspiratory resistance training on exercise capacity⁵⁰ are equivocal. However, peripheral muscle strengthening programs improve physical functioning.⁵⁵

MANAGEMENT OF PATIENTS WITH RESTRICTIVE PULMONARY DISORDERS

Restrictive pulmonary disorders are characterized by the inability of the lungs to expand fully as a result of extrapulmonary and/or pulmonary disease or restriction.^{11,17} In other words, the patient has difficulty taking in a deep breath.

Acute and Chronic Causes of Restrictive Pulmonary Disorders

There are a variety of acute or chronic disorders directly involving structures of the pulmonary system or extrapulmonary disorders that can cause restrictive pulmonary dysfunction.^{11,17}

Pulmonary Causes

- Diseases of the lung parenchyma such as *tumor*, *interstitial pulmonary fibrosis* (e.g., pneumonia, tuberculosis, asbestosis), and *atelectasis*
- Disorders of cardiovascular/pulmonary origin, such as *pulmonary edema* or *pulmonary embolism*
- Inadequate or abnormal pulmonary development (*bronchopulmonary dysplasia*)
- Advanced age

Extrapulmonary Causes

- Chest wall pain secondary to trauma or surgery
- Chest wall stiffness associated with extrapulmonary disease (e.g., scleroderma, ankylosing spondylitis)
- Postural deformities (scoliosis, kyphosis)
- Ventilatory muscle weakness of neuropathic or myopathic origin (e.g., spinal cord injury, cerebral palsy, Parkinson's disease, muscular dystrophy)
- Pleural disease
- Insufficient diaphragmatic excursion because of ascites or obesity

Pathological Changes in the Pulmonary System

Pulmonary function may be altered as a result of pulmonary or extrapulmonary conditions. These alterations in lung volumes and capacities are depicted in Figure 25.39. Cardiopulmonary factors contributing to these changes are decreased pulmonary compliance caused by inflammation or fibrosis (thickening of the alveoli, bronchioles, or pleura), pulmonary congestion, and decreased arterial blood gases (hypoxemia).

Management Guidelines: Post-Thoracic Surgery

Although any number of acute or chronic disorders can be the underlying cause(s) of restrictive lung dysfunction, only management after thoracic surgery is addressed in this section. Patients with cardiac or pulmonary conditions that require surgical interventions are at high risk for restrictive pulmonary complications after surgery. *Thoracotomy*, an incision into the chest wall, is necessary during many types of pulmonary surgery including *lobectomy* (removal of a lobe of a lung), *pneumonectomy* (removal of a lung), or *segmental resection* (removal of a segment of a lobe of a lung).^{17,23,36,40}

Cardiac surgeries, such as coronary artery bypass graft surgery, replacement of one or more valves of the heart, repair of septal defects, or heart transplantation also require thoracotomy.^{17,23,36,40}

NOTE: Patients who undergo upper abdominal surgery also have a high risk of developing postoperative pulmonary complications. Postoperative pain is often greater after upper abdominal surgery than after thoracic surgery.⁷³ This results in hypoventilation (55% decreased vital capacity for the first 24 to 48 hours after surgery) and an ineffective cough, which place the patient at risk for developing pneumonia or atelectasis.^{17,40} A systematic review of the literature revealed that postoperative programs of cardiopulmonary physical therapy have beneficial effects after upper abdominal surgery.⁷³

Factors That Increase the Risk of Pulmonary Complications and Restrictive Lung Dysfunction After Thoracic Surgery

The post-thoracotomy patient experiences considerable chest pain, which leads to chest wall immobility, poor lung

BOX 25.11**MANAGEMENT GUIDELINES—Chronic Obstructive Pulmonary Disease (COPD)****Impairments**

An increase in the amount and viscosity of mucus production

A chronic, often productive cough

Frequent episodes of dyspnea

A labored breathing pattern that results in:

- Increased respiratory rate (tachypnea)
- Use of accessory muscles of inspiration and decreased diaphragmatic excursion
- Upper chest breathing

Inadequate exchange of air in the lower lobes

Most difficulty during expiration; use of pursed-lip breathing

Changes in pulmonary function

- Increased residual volume
- Decreased vital capacity
- Decreased expiratory flow rates

Decreased mobility of the chest wall; a barrel chest deformity develops

Abnormal posture: forward-head and rounded and elevated shoulders

Decreased general endurance during functional activities

Plan of Care

1. Decrease the amount and viscosity of secretions and prevent respiratory infections.

2. Remove or prevent the accumulation of secretions. (This is important if emphysema is associated with chronic bronchitis or if there is an acute respiratory infection.)

3. Promote relaxation of the accessory muscles of inspiration to decrease reliance on upper chest breathing and to decrease muscle tension associated with dyspnea.

4. Improve the patient's breathing pattern and ventilation.

Emphasize diaphragmatic and lateral costal breathing and *relaxed* expiration; decrease the work of breathing, rate of respiration, and use of accessory muscles. Carry over controlled breathing exercises to functional activities.

5. Minimize or prevent episodes of dyspnea.

6. Improve the mobility of the lower thorax.

7. Improve posture.

8. Increase exercise tolerance.

Interventions

1. Administration of bronchodilators, antibiotics, and humidification therapy.

If patient smokes, he or she should be strongly encouraged to stop.

2. Deep and effective cough.

Postural drainage to areas where secretions are identified.

N O T E : Drainage positions may need to be modified if the patient is dyspneic in the head-down position.

3. Positioning for relaxation.

- Relaxed head-up position in bed: trunk, arms, and head are well supported.
- Sitting: leaning forward, resting forearms on thighs or on a table.
- Standing: leaning forward on an object, with hands on the thighs or leaning backward against a wall.

Relaxation exercises for shoulder musculature: active shoulder shrugging followed by relaxation; shoulder and arm circles; horizontal abduction and adduction of the shoulders.

4. Breathing exercises: controlled diaphragmatic breathing with minimal upper chest movement; lateral costal breathing; pursed-lip breathing (careful to *avoid forced* expiration).

Practice controlled breathing during standing, walking, climbing stairs, and other functional activities.

5. Have a patient assume a comfortable position so the upper chest is relaxed and the lower chest is as mobile as possible.

Emphasize controlled diaphragmatic breathing.

Have the patient breathe out as rapidly as possible *without forcing* expiration.

N O T E : Initially, the rate of ventilation is rapid and shallow. As the patient gets control of breathing, he or she slows the rate.

Administer supplemental oxygen during a severe episode, if needed.

6. Exercises for chest mobility, emphasizing movement of the lower rib cage during deep breathing.

7. Exercises and postural training to decrease forward-head and rounded shoulders.

8. Graded endurance and conditioning exercises (see Chapter 4).

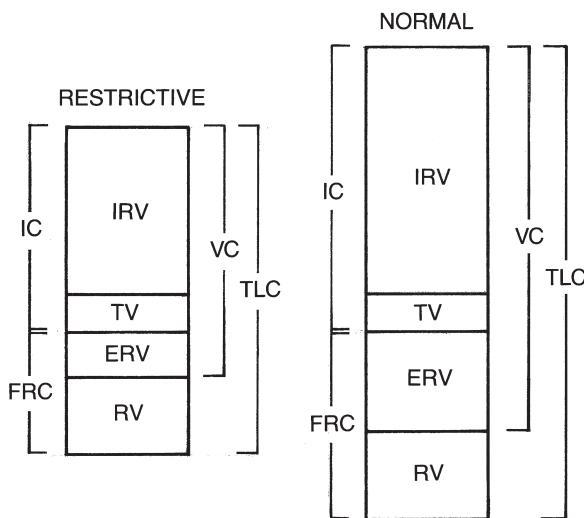

FIGURE 25.39 Normal lung volumes and capacities compared with abnormal lung volumes and capacities found in patients with restrictive pulmonary disorders. (From Rothstein, J, Roy, A, Wolf, SL: *The Rehabilitation Specialist's Handbook*, ed. 3. FA Davis, Philadelphia, 2005, p 428, with permission.)

expansion, and an ineffective cough. In addition, pulmonary secretions are greater than normal after surgery. Therefore, the patient is more likely to accumulate pulmonary secretions and develop secondary pneumonia or atelectasis. Factors that increase the risk of postoperative pulmonary complications are noted in the following sections.^{17,40}

General Anesthesia

- Decreases the normal ciliary action of the tracheobronchial tree
- Depresses the respiratory center of the central nervous system, which causes a shallow respiratory pattern (decreased tidal volume and vital capacity)
- Depresses the cough reflex

Intubation (Insertion of an Endotracheal Tube)

- Causes muscle spasm and immobility of the chest
- Irritates the mucosal lining of the tracheobronchial tree, which causes increased production of mucus
- Decreases the normal action of the cilia in the tracheobronchial tree, which leads to pooling of secretions

Incisional Pain

- Causes muscle splinting and decreases chest wall compliance, which in turn causes a shallow breathing pattern. Consequently, lung expansion is restricted and secretions are not adequately mobilized.
- Restricts a deep and effective cough. The patient usually has a weak, shallow cough that does not effectively mobilize and clear secretions.

Pain Medication

Although pain medication administered postoperatively diminishes incisional pain, it also:

- Depresses the respiratory center of the central nervous system
- Decreases the normal ciliary action in the bronchial tree

General Inactivity, Postoperative Weakness and Fatigue

- Pooling of secretions, particularly in the posterior basilar segments of the lower lobes, because of inactivity
- Decreased effectiveness of the cough pump because of postoperative weakness and fatigue

Other risk factors not directly related to the surgery

- Patient's age (> age 50)
- History of smoking
- History of COPD or restrictive pulmonary disorder because of neuromuscular weakness
- Obesity
- Poor mentation and orientation

Thoracic Surgery: Operative and Postoperative Considerations during Management

Many factors contribute to a patient's postoperative impairments, any one of which influences postoperative management.^{17,23} A patient who has undergone thoracotomy for a pulmonary or cardiac condition typically is hospitalized for a week or less. Postoperative impairments and guidelines for management of a patient who has undergone thoracic surgery are summarized in Box 25.12.^{16,17,23,36,40,41,71} Therapeutic interventions begin on the first postoperative day and include breathing and coughing exercises, shoulder ROM, posture awareness training, and a graded aerobic conditioning program.^{16,23,36,40,41,71}

Co-morbidities and Related Dysfunction

In addition to the primary pulmonary or cardiac pathology (e.g., a malignant tumor, lung abscess, coronary artery disease) the patient also may have related cardiopulmonary conditions, such as angina, congestive heart disease, chronic bronchitis, or emphysema. The patient with a long history of cardiac disease may have preoperative pulmonary dysfunction such as hypoxemia, dyspnea on exertion, orthopnea, or pulmonary congestion. Such co-morbidities and related pulmonary or cardiac dysfunction can complicate postoperative rehabilitation.

Surgical Approach

Pulmonary surgery typically involves a large posterolateral, lateral, or anterolateral chest incision. A standard posterolateral approach (Fig. 25.40), for example, is performed by incising the chest wall along the intercostal space that corresponds to the location of the lung lesion. The incision divides the trapezius and rhomboid muscles posteriorly and the serratus anterior, latissimus dorsi, and external and internal intercostals laterally.

Postoperatively, the incision is painful, and the potential for pulmonary complications is significant. Many patients, quite understandably, complain of a great deal of shoulder soreness on the operated side. Loss of range of shoulder motion and postural deviations are possible because of the disturbance of the large arm and trunk musculature during surgery.

BOX 25.12**MANAGEMENT GUIDELINES—Post-Thoracic Surgery****Impairments**

- Reduced lung expansion or an inability to take a deep inspiration because of incisional pain
- Decreased effectiveness of the cough because of incisional pain and irritation of the throat from intubation
- Possible accumulation of pulmonary secretions either preoperatively or postoperatively
- Decreased chest wall and upper extremity mobility
- Poor postural alignment because of incisional pain or chest tubes
- Increased risk of deep vein thrombosis and pulmonary embolism
- General weakness, fatigue, and disorientation

Plan of Care	Interventions
<ol style="list-style-type: none"> 1. Ascertain the status of the patient before each treatment. 2. Promote relaxation and reduce postoperative pain. 3. Optimize ventilation and re-expand lung tissue to prevent atelectasis and pneumonia. 4. Assist in the removal of secretions. 5. Maintain adequate circulation in the lower extremities to prevent deep vein thrombosis and pulmonary embolism. 6. Regain ROM in the shoulders. 7. Prevent postural impairments. 8. Increase exercise tolerance. 	<ol style="list-style-type: none"> 1. Evaluate orientation, color, respiratory rate, heart rate, breath sounds, sputum drainage into chest tubes. 2. Position the patient in a semi-Fowler's position (head of bed elevated to 30° and hips and knees slightly flexed). This position reduces traction on the thoracic incision. Coordinate treatment with administration of pain medication. 3. Begin deep-breathing exercises on the day of surgery as soon as the patient is conscious; diaphragmatic breathing; segmental expansion. Add incentive spirometry or inspiratory resistance exercises to improve inspiratory capacity. Emphasize a deep inhalation followed by a 3- to 5-second hold and then relaxed exhalation. Continue deep-breathing exercises postoperatively, with six to ten consecutive deep breaths per hour until the patient is ambulatory. 4. Begin deep, effective coughing as soon as the patient is alert and can cooperate. Implement early functional mobility (getting up to a chair, early ambulation). Institute modified postural drainage only if secretions accumulate. 5. Begin active exercises of the lower extremities, with emphasis on ankle pumping exercises on the first day after surgery. Continue leg exercises until the patient is allowed out of bed and is ambulatory. 6. Begin relaxation exercises for the shoulder area on the first postoperative day. These can include shoulder shrugging or shoulder circles. Initiate active-assistive ROM of the shoulders, being careful not to cause pain. Reassure the patient that gentle movements will not disturb the incision. Progress to active shoulder exercises on the succeeding postoperative days to the patient's tolerance until full active ROM has been achieved. 7. Reinforce symmetrical alignment and positioning of the trunk on the first postoperative day when the patient is in bed. NOTE: The patient will tend to lean toward the side of the incision. Instruct the patient in symmetrical sitting posture when he or she is allowed to sit up in a chair or at the side of the bed. 8. Begin a progressive and graded ambulation or stationary cycling program as soon as the chest tubes are removed and the patient is allowed out of bed.

Precautions

- Monitor vital signs throughout treatment.
- Be certain to show the patient how to splint over the incision to minimize incisional pain during coughing.
- Avoid placing traction on chest tubes when moving the patient.
- To prevent dislodging a chest tube for the patient who has a lateral incision, limit shoulder flexion to 90° on the operated side for several days until the chest tube is removed.
- If postural drainage must be implemented, modify positioning to avoid a head-down position.
- Do not use percussion over the incision.
- When turning a patient, use a logroll technique to minimize traction on the incision.

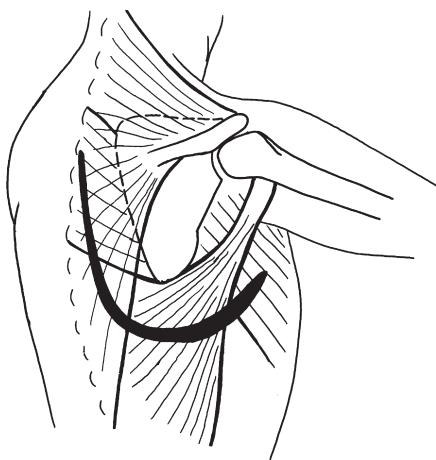

FIGURE 25.40 A posterolateral approach commonly used in thoracic surgery incises and divides the trapezius, rhomboids, latissimus dorsi, serratus anterior, and internal and external intercostal muscles.

The most common incision used with cardiac surgery is a *median sternotomy*. A large incision extends along the anterior chest from the sternal notch to just below the xiphoid. The sternum is then split and retracted so the

chest cavity can be exposed. After completion of the surgical procedure, the sternum is closed with stainless steel sutures. Postoperatively, there is less incisional pain after a median sternotomy than after a posterolateral thoracotomy, but deep breathing and coughing are still painful. After a median sternotomy, a patient tends to exhibit rounded shoulders and is at risk for developing shortened pectoralis muscles bilaterally.

Additional Considerations

After any type of thoracotomy one or two chest drainage tubes are put in place at the time of the surgery to prevent a *pneumothorax* or a *hemothorax*. While these tubes are in place, crimping, clamping, or traction on the tubes must be avoided during postoperative interventions.

Fatigue occurs easily during the first few postoperative days, so treatment sessions should be short but frequent. The duration of treatment sessions should be increased gradually during the patient's hospital stay.

Check the patient's chart regularly to note any day-to-day changes in vital signs or laboratory test results. Always monitor vital signs such as heart rate and rhythm, respiratory rate, and blood pressure prior to, during, and after every treatment session.

INDEPENDENT LEARNING ACTIVITIES

Critical Thinking and Discussion

1. Describe the structure of the lower respiratory tract from the trachea to the alveoli and discuss the impact of pulmonary diseases on those structures and their functions.
2. Describe the thorax and its movements during ventilation and the actions of the primary and accessory muscles of ventilation.
3. Organize a presentation that compares and contrasts the characteristics and management of obstructive and restrictive pulmonary disorders.
4. What factors contribute to placing the post-thoracic surgery patient at risk for the development of postoperative complications?
5. Under what circumstances (types of impairment or pathology) would it be appropriate to try to change a patient's breathing pattern? For what purpose?
6. Analyze how ventilation and coughing are affected by a spinal cord injury at a mid-thoracic level, a C6 level, and a C3 to C4 level.

Laboratory Practice

1. Perform a systematic physical examination of a patient with a year history of chronic bronchitis who has been

referred to your outpatient facility to begin a graded conditioning program.

2. How would you alter or change the focus of your examination of a patient with a traumatic brain injury who is on a ventilator or a patient who is 1 day post-coronary artery bypass graft surgery?
3. Practice auscultation of breath sounds.
4. Practice a complete postural drainage sequence on your laboratory partner. Include manual techniques and cough instruction. Perform the activity for a minimum of 1 to 2 minutes per position to begin to appreciate the endurance needed by the therapist. Then have your partner perform the same sequence with you as the patient to appreciate how it feels from the patient's perspective to undergo postural drainage.
5. What methods of measurement should be used to document improvement in a pulmonary patient's condition as the result of a pulmonary rehabilitation program? Practice those techniques.

Case Study

CASE 1

T.M. is a 62-year-old man who underwent thoracic surgery (right lower lobe lobectomy) yesterday for bronchogenic carcinoma. He has a posterolateral incision. Although his

cough is currently nonproductive, he has had a chronic cough for years. He has also smoked more than a pack of cigarettes a day for 35 years. He is currently febrile with a 99.8°F temperature.

- What current and potential postoperative impairments might you find in your examination?
- Design a comprehensive management program that includes airway clearance, exercise, and functional mobility. How would you progress the program while the patient is hospitalized? What precautions should be built into his plan of care?
- Design a program that the patient can follow when he returns home.

CASE 2

B.A. is a 21-year-old student with a 15-year history of asthma. Her chief complaint is episodes of dyspnea when she is physically active. She wheezes frequently, particularly with physical activity but sometimes at rest. Wheezing also is worse when in contact with household pets at friends' apartments. She is small for her age and underweight but wants to participate in some form of regular physical activity for general health and fitness. What additional signs or symptoms would you expect to find in an examination of this young woman? How would you manage her problems and needs?

Systematic Musculoskeletal Examination Guidelines

APPENDIX

An examination consists of three primary parts: history, systems review, and tests and measures.¹ Details of the history and systems review are described in Chapter 1. Once the history and systems review are complete and determination is made to continue with a musculoskeletal examination, tests are systematically administered in order to define the impairments in terms of which tissues may be interfering with function, identify the resulting functional limitations, and establish a baseline of objective measurements from which progress can be measured.

NOTE: The following information is a suggested sequence for examining a patient with impairments in the musculoskeletal system, along with an explanation of various testing procedures that may be used to establish a diagnosis related to impairments. Specific tests are not described; they are determined by the area being examined and are beyond the scope of this text. All appropriate tests are performed with the patient in one position before moving him or her to another position. Common sequencing of the examination begins with the patient standing, then sitting, then lying down (supine, side-lying on one side, prone, and then side-lying on the other side).

HISTORY

For a discussion on the history, see Chapter 1 and Box 1.8. Information generated from the initial history is summarized in Box A.1 at the end of this appendix.

SYSTEMS REVIEW

For a discussion on the systems review, see Chapter 1 and Table 1.1. An outline of the content of a systems review is summarized in Box A.2 at the end of this appendix.

TESTS AND MEASURES

The following outline of the sequence of tests and measures is summarized in Box A.3 at the end of this appendix.

NOTE: Any tests that were conducted in the systems review are not repeated unless additional clarification is necessary.

Inspection

Observe appearance and basic abilities. Suggestions include the following.

Adaptive or Supportive Aids

Note use of braces, splints, or assistive devices.

Posture

Observe general posture and specific posture or shape of involved body parts such as contour changes, swelling, atrophy, hypertrophy, and asymmetry.

Transitional Activities (Supine–Sit–Stand) and Gait Patterns

Look at general ease of movement, coordination, balance, and ability to maneuver in preparation for the examination. From these observations and the results of the diagnostic testing, more detailed tests can be chosen for documentation of functional limitations and disabilities.

Tests of Provocation (Selective Tension)

Use the principle of selective tension by administering specific tests in a systematic manner to provoke or recreate the symptoms and to minimize or alleviate the symptoms described by the patient during the history. Systematically perform the tests in order to determine whether the lesion is within an inert structure (joint capsules, ligaments, bursae, fasciae, dura mater, and dural sheaths around nerve roots) or a contractile unit (muscle with its tendons and attachments).² Include joint integrity tests to verify problems within the joint.³ From these tests it is possible to identify the forces or stresses that cause or alleviate the patient's symptoms, the stage of healing, and in many cases the tissue or tissues causing the symptoms; that is, identify the impairments(s).

From this information as well as the results of other special tests⁵ and functional tests (described later) attempt to identify a relationship between the tissue impairments and the patient's functional losses. Minimizing and controlling the identified stresses on the involved tissues along with developing or modifying functional activities that can be performed safely to form the foundation when designing an appropriate therapeutic exercise program.

1. Active range of motion (ROM). Ask the patient to move the body parts related to the symptoms through their ROM. From the way the patient moves and the

amount of motion exhibited, determine if the patient is able and willing to move the part. Because both contractile and inert structures are influenced by active motion, specific impairments are not isolated. Note anything abnormal in the movement pattern, any experience of pain, or any changes in sensation.

2. Passive ROM. Repeat the same movements passively; when the end of the available range is reached, apply pressure to get a feel of the resistance of the tissues; the pressure is called overpressure, and the feel is called end-feel. With the muscles relaxed, only inert structures are being stressed. Note whether any of the tests provoke or alleviate the patient's symptoms.
 - Measure the ROM and compare it with the active ROM. Determine whether the limitation follows a pattern of restriction typical for that joint when joint problems exist. These are called capsular patterns^{2,5} and are described for each peripheral joint under the respective sections on joint problems in Chapters 17 through 22.
 - Describe the end-feel, the feel that is experienced at the end of the range when overpressure is applied. Decide whether the feel is:
 - *Soft*—related to compressing or stretching soft tissues.
 - *Firm*—related to stretching joint capsules and ligaments.
 - *Hard*—related to a bony block.
 - *Empty*—no end-feel is detected because the patient does not allow movement to the end of the available range—related to an acutely painful condition in which the patient inhibits motion.
 - Decide if the end-feel is normal or abnormal for that joint. Abnormal end-feels include:
 - *Springy*—intra-articular block such as a torn meniscus or articular cartilage.
 - *Muscle guarding*—involuntary muscle contraction in response to acute pain.
 - *Muscle spasm*—prolonged muscle contraction in response to circulatory and metabolic changes.
 - *Muscle spasticity*—increased tone and contraction in muscle in response to central nervous system influences.
 - Any end-feel that is *different from normal* for that joint or at a *different part of the range* from normal for the joint being tested.
 - Determine the stage of pathology by observing when pain is experienced relative to the ROM. Is the pain or muscle guarding experienced before the end-feel (*acute*), concurrent with the end-feel (*subacute*), or after application of overpressure (*chronic*)?
 - Note whether there is a painful arc, which is pain experienced with either active or passive motion somewhere within the ROM. It indicates that some sensitive structure is being pinched during that part of the range. Sometimes pain-sensitive

structures are pinched at the end of the range. This is not a painful arc, although such pain should be noted.

3. Special joint tests
 - Apply ligament stress tests and special tests for labral and meniscus tears based on joint anatomy.
 - Apply joint play (accessory motion) tests to confirm or rule out joint involvement. Glide, distract, and compress the joint surfaces together to see if there is reproduction of symptoms, alleviation of symptoms, or restricted or excessive motion. Note quality and quantity of joint play. These tests are passive tests used to rule out or confirm articular or capsular impairments. They are performed prior to testing for muscle lesions³ because muscle contraction causes compression and shear forces on the joints,⁴ and therefore pain with muscle contraction could give a false-positive indication of a contractile lesion.
 - Determine the state of hypo- versus hypermobility.
4. Resisted tests. Resist the related muscles so they contract isometrically in midrange to determine whether there is pain or decreased strength in the contractile units. Midrange isometric contractions are used so there is minimal movement or stress to the noncontractile structures around the joint. Initially perform the tests on groups of muscles; then, if pain or weakness is noted, isolate and test each muscle that is potentially involved. Decide if there is a problem in the neuromuscular system. Possible choices include:
 - A *strong, yet painful* contraction indicates a contractile unit problem (assuming joint problems have been ruled out). Palpate along the entire musculotendinous unit to identify the site of injury.
 - A *weak and painless* contraction may suggest a complete muscle tear, a disused muscle, or a neurological problem.
 - A muscle tear has a history of trauma or forceful muscle contraction in the region.
 - A disused muscle usually demonstrates some atrophy and probably is not localized in only one muscle.
 - A neurological problem usually has a pattern of sensory loss as well as weakness in related muscles following a pattern consistent with a nerve root, plexus, or peripheral nerve innervation.
 - A *weak and painful* contraction usually suggests something serious, such as an active lesion, fracture, or inflammation. Relate this finding to information from the history.
 - Document strength with a manual muscle test, tensiometer, or dynamometer test grade. Relate strength to functional limitations.
5. Other tests of muscle performance. Look at other factors influencing muscle function such as endurance,

coordination, stabilizing function, and flexibility (including flexibility of two-joint or multijoint muscles).

Palpation

Palpate, if possible, the structures that are incriminated as the source of the impairments. Usually palpation is best done after the tests of provocation in order not to increase the irritability of the structures prior to testing, although some therapists prefer to palpate earlier in the sequence of testing or in conjunction with the tests of provocation. Palpation can be a confirming test when identifying anatomical structures involved if the tissue that was symptomatic under the selective tension stresses is also symptomatic when palpated. Include the following.

Skin and Subcutaneous Tissue

Note temperature, edema, texture, and mobility.

Muscles, Tendons, and Attachments

Note tone, tenderness, trigger points, tension, and swelling.

Tendon Sheaths and Bursae

Note tenderness, texture, crepitus, and mobility.

Joints and Ligaments

Note effusion, tenderness, changes in position or shape, synovial hypertrophy.

Nerves and Blood Vessels

Note tenderness, change in sensation, neuroma, and pulse.

Neurological Tests

If there are any signs of muscle weakness or change in sensation, perform specific tests to determine nerve, nerve root, or central nervous system involvement. Examine the following.

Key Muscles

Determine strength and reflexes of muscles related to specific spinal levels and peripheral nerve patterns. Strength tests have already been performed in the provocation tests; interpretation of the results based on nerve patterns is considered here for organizational purposes.

Motor Ability

Identify any control, balance, or coordination deficits. Identify abnormal associated reactions, synergies, synkinesis, or postural righting and protective reflexes if indicated.

Sensory Perception

Identify changes in perception of temperature, light touch, deep pressure, two-point discrimination, stereognosis, and proprioception. Relate loss to peripheral nerve or spinal cord patterns or to central nervous system control. If there is central nervous system impairments, test for body awareness of limbs and trunk, spatial awareness, and perception of vertical alignment.

Nerve Mobility

Determine if there are symptoms with stretching or when applying pressure on the peripheral nerves, nerve trunks, or nerve roots.

Cranial Nerve Integrity

Test the cranial nerves if indicated.

Functional Performance Tests

Use standardized and consistently measured tests that focus on the patient's impairments and described limitations. In addition to information gained from self-reports from the patient or from functional limitations described in the history, include examination of the patient's abilities when performing specific functional activities. Suggestions include the following.

Gait Performance

Observe ability to walk on even and uneven surfaces, change directions, speed, distance, and need for assistive devices.

Functional Mobility Performance

Observe ability to climb and descend steps, step over objects, rise up from a chair and sit down, move in and out of a motor vehicle, or other needed activities.

Body Mechanics and Related Abilities

Observe ability to lunge, squat, kneel, and bend over. Observe ability to lift objects of various sizes and weights from various heights and with various techniques.

Upper Extremity Functional Performance

Observe ability to reach, push, pull, grip, and carry objects of various sizes and weights.

Agility and Skill

Observe ability to hop, jump, catch, and throw. Observe eye-hand coordination and ability to manipulate objects with various prehension patterns.

Additional Tests

Cardiovascular/Pulmonary Endurance

Determine level of fitness.

Special Tests

Administer tests unique to specific tissues or functions that have not yet been described.

Adaptability to Environment

Identify barriers, safety, ability for self-care and mobility in the home, job, school, and recreational facilities.

Tests by Other Professionals

Determine if additional medical or other health professional testing should be done to clarify the patient's condition, to receive care beyond the scope of physical therapy, or to receive care by a therapist in an area of specialty other than yours.

BOX A.1. Information Generated from the Initial History**Demographic Data**

- Age, sex, race, ethnicity
- Primary language
- Education

Social History

- Family and caregiver resources
- Cultural background
- Social interactions/support systems

Occupation/Leisure

- Current and previous employment (Job/school-related activities)
- Recreational, community activities/tasks

Growth and Development

- Developmental history
- Hand and foot dominance

Living Environment

- Current living environment
- Expected destination after discharge
- Community accessibility

General Health Status and Lifestyle Habits and Behaviors Past/Present (based on self or family report)

- Perception of health/disability
- Lifestyle health risks (smoking, substance abuse, diet, exercise, sleep habits)

Medical/Surgical/Psychological History**Medications: Current and Past****Family History**

- Health risk factors
- Family illnesses

Cognitive/Social/Emotional Status

- Orientation, memory
- Communication
- Social/emotional interactions

Current Conditions/Chief Complaints/Concerns

- Conditions, reasons PT services sought
- Patient's perceived level of disability
- Patient's needs, goals
- History, onset (date and course), mechanism of injury, pattern and behavior of symptoms
- Family or caregiver needs, goals, perception of patient's problems
- Current or past therapeutic interventions
- Previous outcome of chief complaint(s)

Functional Status and Activity Level

- Current/prior functional status: basic ADL, IADL related to self-care and home
- Current/prior functional status in work, school, community-related IADL

Other Laboratory and Diagnostic Tests**BOX A.2. Areas of Screening for the Systems Review****Cardiovascular/Pulmonary**

- Heart rate, respiratory rate, and blood pressure
- Pain or heaviness in the chest or pulsating pain
- Light-headedness; peripheral edema

Integumentary

- Skin temperature, color, texture
- Skin integrity
- Scars, lumps, growths

Musculoskeletal

- Height, weight
- Symmetry
- Gross ROM and strength

Neuromuscular

- General aspects of motor control (balance, locomotion, coordination)
- Sensation, changes in hearing or vision; severe headaches

Gastrointestinal/Genitourinary

- Heartburn, diarrhea, vomiting, severe abdominal pain
- Problems with swallowing
- Problems with bladder function
- Unusual menstrual cycles, pregnancy

Cognitive and Social/Emotional

- Communication abilities (expressive and receptive)
- Cognition, affect
- Level of arousal, orientation, ability to follow directions or learn
- Behavioral/emotional stressors and responses

General/Miscellaneous

- Persistent fatigue, malaise
- Unexplained weight gain or loss
- Fever, chills, sweats

BOX A.3. Systematic Musculoskeletal Examination

1. History (see Box A.1)
2. Systems review (see Box A.2)
3. Tests and measures

Inspection

- Use of adaptive or supportive aids
- Posture
- Transitional activities and gait

Tests of Provocation (Selective Tension)

- Active ROM
- Passive ROM
- Special joint tests
- Resisted tests
- Other tests of muscle performance

Palpation

- Skin and subcutaneous tissue
- Muscles, tendons, and attachments
- Tendon sheaths and bursae
- Joints and ligaments
- Nerves and blood vessels

Neurological Tests

- Key muscles
- Motor ability
- Sensory perception
- Nerve mobility
- Cranial nerve integrity

Functional Performance Tests

- Gait performance
- Functional mobility performance
- Body mechanics and related abilities
- Upper extremity functional performance
- Agility and skill

Additional Tests

- Cardiovascular endurance
- Special tests
- Adaptability to environment
- Tests by other professionals

Glossary

A

- abruptio placentae** Premature detachment of the placenta from the uterus
- accessory movement** Movement within a joint and surrounding soft tissues that is necessary for normal range of motion but cannot be voluntarily performed
- accommodating resistance exercise** A term used synonymously with **isokinetic exercise**
- active inhibition** A type of stretching exercise in which there is reflex inhibition and subsequent elongation of the contractile elements of muscles
- adaptation** The ability of an organism to change over time in response to a stimulus
- adenosine triphosphate (ATP)** A high-energy compound from which the body derives energy
- adhesions** Abnormal adherence of collagen fibers to surrounding structures during immobilization, following trauma, or as a complication of surgery, which restricts normal elasticity of the structures involved
- aerobic exercise** Submaximal, rhythmic, repetitive exercise of large muscle groups, during which the needed energy is supplied by inspired oxygen
- aerobic system** An aerobic energy system in which ATP is manufactured when food is broken down
- airway clearance techniques** Therapeutic procedures to improve mucociliary transport; includes coughing, postural drainage, manual techniques (percussion, vibration, shaking) and deep breathing exercise
- airway resistance** Resistance to the flow of air in the lungs offered by the bronchioles
- amniotic fluid** Liquid contained in the amniotic sac. The fetus floats in the fluid, which serves as a cushion against injury and helps maintain a constant fetal body temperature
- anaerobic exercise** Exercise that occurs without the presence of inspired oxygen
- anaerobic glycolytic system (lactic acid system)** Anaerobic energy system in which ATP is manufactured when glucose is broken down to lactic acid
- apnea** Cessation of breathing
- apneusis** Cessation of breathing during the inspiratory phase of respiration

arteriosclerosis obliterans (ASO) See **arteriosclerotic vascular disease**

arteriosclerotic vascular disease (ASVD) Progressive narrowing, loss of elasticity, fibrosis, and eventual occlusion of the large and middle-sized arteries, usually in the lower extremities

arteriovenous oxygen difference ($a-\bar{v}O_2$ difference) The difference between the oxygen content of arterial and venous blood

arthritis Inflammation of the structures of a joint

arthrodesis Surgical fusion of bony surfaces of a joint with internal fixation such as pins, nails, plates, and bone grafts; usually done in cases of severe joint pain and instability in which mobility of the joint is a lesser concern

arthroplasty Any reconstructive joint procedure, with or without a joint implant, designed to relieve pain and/or restore joint motion

arthroscopy Examination of the internal structures of a joint by means of an endoscopic viewing apparatus inserted into the joint

arthrotomy Surgical incision into a joint

asthma An obstructive lung disease seen in young patients, associated with a hypersensitivity to specific allergens and resulting in bronchospasm and difficulty breathing

atelectasis Collapse or incomplete expansion of the lung

ATP-PC system Anaerobic energy system in which adenosine triphosphate (ATP) is manufactured when phosphocreatine (PC) is broken down

atrophy Wasting or reduction of the size of cells, tissues, organs, or body parts

auscultation Listening to heart or lung sounds within the body, usually with a stethoscope

B

balance Ability to maintain the body's center of gravity over the base of support

bradypnea Slow rate of respiration; depth either shallow or normal

bronchiectasis A chronic obstructive lung disease characterized by dilation and repeated infection of medium-sized bronchioles

bursitis Inflammation of a bursa

C

capsular pattern Pattern of limitation, characteristic for a given joint, that indicates that a problem exists with that joint

cardiac output Volume of blood pumped from a ventricle of the heart per unit of time; the product of heart rate and stroke volume

cardiopulmonary endurance Ability of the lungs and heart to take in and transport adequate amounts of oxygen to the working muscle, allowing activities that involve large muscle masses to be performed over long periods of time

chondromalacia patellae Deterioration of the articular cartilage at the posterior aspect of the patella

chondroplasty Débridement procedure to repair joint cartilage, usually at the patellofemoral joint; also called abrasion arthroplasty

chronic bronchitis Inflammation of the bronchi that causes an irritating, productive cough that lasts up to 3 months and recurs over at least two consecutive years

chronic obstructive pulmonary disease (COPD) Term used to describe a variety of chronic lung conditions such as chronic bronchitis, emphysema, and peripheral airway disease

chronic pain syndrome Used to describe patients with long-standing low back pain who have developed illness behavior and hopelessness. There is no longer a direct relationship between the pain and the apparent disability, and treatment of the painful symptoms usually does not change the condition. The patient may require psychological and sociological intervention and behavior modification techniques

circuit training Training program that uses selected exercises or activities performed in sequence

closed-chain exercise Exercise in which the distal end of the segment is fixed to a supporting surface as the trunk and proximal segments move over the fixed part. This includes functional exercises, especially for the lower extremities, in which the foot is stabilized on the ground and the muscles control the hips, knees, and ankles in activities such as squatting, climbing steps, and getting in and out of a chair

clubbing, digital Broadening or thickening of the soft tissues of the terminal phalanges of the fingers and toes; often seen in persons with chronic pulmonary disease

co-contraction Simultaneous contraction of muscles on opposite sides of a joint; source of dynamic stability of a joint

comparable sign Test procedure that can be repeated following a therapeutic maneuver to determine the effectiveness of the maneuver

compression dressing Sterile bandage applied around or over a new surgical incision to compress the wound site and control swelling

concentric exercise Overall shortening of the muscle occurs as it generates tension and contracts against resistance

conditioning Augmentation of the energy capacity of the muscle through an exercise program

continuous training Training program that uses exercise over a given duration without rest periods

contracture Shortening or hypomobility of the skin, fascia, muscle, or joint capsule that prevents normal mobility or flexibility of that structure

contusion Bruising from a direct blow, resulting in capillary rupture

coordination Using the right muscles at the right time with correct intensity. Coordination is the basis of smooth and efficient movement, which often occurs automatically

crackles Fine or coarse lung sounds heard with a stethoscope primarily during inspiration and caused by movement of secretions in the small airways of the lungs; formerly referred to as **rales**

cumulative trauma disorder Musculoskeletal symptoms from excessive or repetitive motion causing connective tissue or bony breakdown. Initially, the inflammatory response from the microtrauma is subthreshold but eventually builds to the point of perceived pain and resulting dysfunction. Syndromes include shin splints, carpal tunnel, bursitis, tendinitis, cervical tension, thoracic outlet, tennis elbow, and marching fracture. Also known as cumulative trauma syndrome, repetitive strain injury, and **overuse syndrome**

cyanosis Bluish appearance of skin and mucous membranes due to insufficient oxygenation of the blood

cystic fibrosis Genetically based disease that involves malfunction of the exocrine glands and leads to chronic lung infections and pancreatic dysfunction

D

deconditioning Change that takes place in cardiovascular, neuromuscular, and metabolic functions as a result of prolonged bed rest or inactivity

decongestive lymphatic therapy Comprehensive approach to management of lymphedema that combines elevation, compression, exercise, massage, and skin care

degenerative joint disease (DJD) See **osteoarthritis**

delayed-onset muscle soreness (DOMS) Exercise-induced muscle tenderness or stiffness that occurs 24 to 48 hours after vigorous exercise

derangement (disk protrusion) Any change in the shape of the nucleus pulposus of the intervertebral disk that causes it to protrude beyond its normal limits

disability Inability to undertake normal activities of daily living (ADL) as a result of physical, mental, social, or emotional impairments

diagnosis Recognition or determination of the cause and nature of a pathological condition

diastasis recti Separation of the rectus abdominis muscle in the midline at the linea alba; continuity of the abdominal wall is disrupted

dislocation Displacement of a part, usually the bony partners within a joint

distensibility Ability of an organ or tissue to be stretched out or enlarged

distraction Pulling apart or separation of joint surfaces

- dorsal clearance** Surgical removal of diseased synovium from the extensor tendons of the fingers and wrist
- dynamic stabilization** Isometric or stabilizing contraction of trunk or proximal girdle muscles to maintain control of the functional position in response to imposed fluctuating forces through the moving extremities
- dynamometer** Device that quantitatively measures muscle strength
- dysfunction** Loss of function as a result of adaptive shortening of soft tissues and loss of mobility
- dyspnea** Shortness of breath; labored, distressed breathing

E

- eccentric exercise** Overall lengthening of the muscle occurs as it develops tension and contracts to control motion against the resistance of an outside force; negative work is done
- efficiency** Ratio of work output to work input
- elasticity** Ability of soft tissue to return to its original length after a stretch force has been released
- embolus** Thrombus or clot of material that has been dislodged and transported in the bloodstream from a larger to a smaller vessel, resulting in occlusion of the vessel
- emphysema** A chronic obstructive pulmonary disease characterized by inflammation, thickening, and deterioration of the respiratory bronchioles and alveoli
- end-feel** Quality of feel the evaluator experiences when passively applying pressure at the end of the available range of motion
- endurance** Ability to resist fatigue
- endurance, general (total body)** Ability of an individual to sustain low-intensity exercises, such as walking, jogging, or climbing, over an extended period
- endurance, muscular** Ability of a muscle to perform repeated contractions over a prolonged period
- energy systems** Metabolic systems involving a series of chemical reactions resulting in the formation of waste products and the manufacture of adenosine triphosphate (ATP). The systems include the ATP-PC (adenosine triphosphate-phosphocreatine) system, the anaerobic glycolytic system, and the aerobic system
- ergometer** Apparatus, such as a stationary bicycle or treadmill, used to quantitatively measure the physiological effects of exercise
- exercise bouts** Number of sets of a repetition maximum performed during each exercise session
- exercise duration** Total number of days, weeks, or months during which an exercise program is performed
- exercise frequency** Number of times exercise is performed within a day or within a week
- exercise load** Amount of weight used as resistance during an exercise
- exercise prescription** Individualized exercise program involving the duration, frequency, intensity, and mode of exercise
- expiratory flow rate** Volume of air exhaled per unit of time

- expiratory reserve volume (ERV)** Maximum amount of air an individual can exhale after a normal, relaxed expiration
- extension bias** Describes the preferred position of spinal extension (lordosis) in which the patient's symptoms are decreased. Usually the symptoms increase in spinal flexion
- extensor lag** The range of active extension is less than the range of passive extension of a joint; in the knee, usually the result of inhibition or dysfunction of the quadriceps mechanism; synonymous with **quadriceps lag**; in the fingers, usually the result of adhesions restricting mobility of the extensor tendons

- extrapment** Tissue trapped on the outside of a structure unable to assume its normal relationship. When a meniscoid tissue becomes trapped outside a zygapophyseal joint as the surfaces slide together, the motion is blocked and tension is placed on the capsular tissue
- extrusion** Protrusion of the nucleus pulposus of the intervertebral disk in which the nuclear material ruptures through the outer annulus and lies under the posterior longitudinal ligament

F

- fast-twitch (FT) fiber** Skeletal muscle fiber with a fast reaction time that has a high anaerobic capacity and is suited for phasic muscle activity
- fatigue, general (total body)** Diminished response of a person during prolonged physical activity, such as walking or jogging, that may be due to a decrease in blood sugar (glucose) levels, decrease in glycogen stores in muscle and liver, or depletion of potassium, especially in the elderly
- fatigue, local (muscle)** Diminished response of the muscle due to a decrease in energy stores, insufficient oxygen, and buildup of lactic acid; protective influences from the central nervous system; or a decrease in the conduction of impulses at the myoneural junction
- fetus** Developing embryo in the uterus from 7 to 8 weeks after fertilization until birth
- fitness** General term indicating a level of cardiovascular functioning that results in heightened energy reserves for optimum performance and well-being
- flat low-back posture** Posture characterized by decreased lumbosacral angle, decreased lumbar lordosis, and posterior tilting of the pelvis
- flexibility** Ability of muscle and other soft tissue to yield to a stretch force
- flexibility exercise** General term used to describe exercises performed by a person to passively or actively elongate soft tissues without the assistance of a therapist
- flexion bias** Position of spinal flexion in which the patient's symptoms are lessened. Usually the symptoms are provoked in spinal extension
- forward head posture** Posture characterized by increased flexion of the lower cervical and upper thoracic regions, increased extension of the occiput on the first cervical vertebra, and increased extension of the upper cervical vertebrae

fremitus, vocal or tactile Vibration that can be felt on the chest wall as a person speaks

functional excursion Distance a muscle can shorten after it has been stretched to its maximum length

functional exercise Exercise that mimics functional activities but is performed in a controlled manner or environment

functional limitation Limitation due to an impairment that is not disabling yet interferes with normal function

functional position Position or range of motion in which the patient experiences the greatest comfort or least amount of stress on the tissues in the region. It may also be referred to as the **resting position** or neutral position. The position is not static and may change as the patient's condition changes

functional residual capacity Amount of air remaining in the lungs after a resting expiration

functional skills Motor skills that are necessary to perform activities or tasks of daily living independently: refined movements requiring coordination, agility, balance, and timing

G

ganglion (pl., ganglia) Ballooning of the wall of a joint capsule or tendon sheath

gestation Period of development from the time of fertilization to birth (pregnancy)

glossopharyngeal breathing Type of breathing exercise used to increase a patient's inspiratory capacity by gulping in air

glycogen Storage form of carbohydrates in the body, found predominantly in the muscles and the liver

H

handicap Social disadvantage resulting from an impairment or disability that prevents or limits persons in their occupation, environment, or social setting

hemarthrosis Bleeding into a joint, usually from severe trauma

hemoptysis Expectoration of blood or blood-streaked sputum from the bronchial tree and lungs

hemothorax Collection or effusion of blood in the pleural cavity

herniation Abnormal protrusion of an organ or other body structure through a defect or natural opening in a covering membrane, muscle, or bone

hyperplasia Increase in the number of fibers or cells

hypertrophy Increase in the cross-sectional size of a fiber or cell

hyperventilation Increase in the rate and depth of respiration above a level necessary for normal ventilatory function

I

impairment Any loss or abnormality of psychological, physiological, or anatomical structure or function that limits or changes an individual's ability to perform a task or activity

incentive spirometry Form of inspiratory muscle training in which the patient inhales maximally and sustains the inspiration

incontinence, urinary or fecal Involuntary loss of bladder or bowel contents; often a result of both neuromuscular and musculoskeletal impairments; may occur in combination with prolapse of the uterus

inspiratory capacity Amount of air a person can inhale after a resting expiration

inspiratory reserve volume (IRV) Maximum amount of air a person can inhale after a relaxed inspiration

inspiratory resistance training Method of strengthening the muscles of inspiration

intermittent claudication Cramping of muscles after short periods of exercise; often seen in patients with occlusive arterial disorders

intermittent traction Traction force that is alternately applied and released at frequent intervals, usually in a rhythmic pattern

interval training Training program that alternates bouts of heavy work with periods of rest or light work

intrinsic muscle spasm Prolonged contraction of a muscle in response to the local circulatory and metabolic changes that occur when a muscle is in a continued state of contraction

intubation Insertion of a tube, such as an endotracheal or nasogastric tube, into the body

involution Progressive contraction of the uterus following childbirth, returning the organ to near its prepregnant size

isokinetic exercise Form of active-resistive exercise in which the speed of movement of the limb is controlled by a preset rate-limiting device

isometric (static) exercise Form of exercise in which tension develops in the muscle but no mechanical work is performed. There is no appreciable joint movement, and the overall length of the muscle remains the same

J

joint mobilization/manipulation Passive traction and/or gliding movements applied to joint surfaces that maintain or restore the joint play normally allowed by the capsule, so the normal roll-slide joint mechanics can occur as a person moves

joint play Capsular laxity or elasticity that allows movements of the joint surfaces. The movements include distraction, sliding, compression, rolling, and spinning

K

kypholordotic posture Posture characterized by an exaggerated thoracic kyphosis and lumbar lordosis and usually forward head

kyphosis Posterior convexity in the spinal column. A posterior curve is primary because it is present at birth and remains in the thoracic and sacral regions of the spine

kyphotic posture Posture characterized by an exaggerated posterior curvature of the thoracic spine; syn: **hump-back, round back**

L

labor Physiological process by which the uterus contracts and expels the products of conception after 20 or more weeks of gestation

load-resisting exercise Any exercise in which a load or a weight-producing external force resists the internal force generated by a muscle as it contracts

lobectomy Surgical removal of a lobe of a lung

lordosis Anterior convexity in the spinal column. An anterior curve is secondary or compensatory and occurs in the cervical and lumbar spinal regions as the spine of a young child adapts to the upright position

lordotic posture Posture characterized by an increase in the lumbosacral angle, causing increased lumbar lordosis, anterior pelvic tilt, and hip flexion

lung compliance Distensibility or elastic recoil of lung tissue

lymphedema Excessive accumulation of extravascular and extracellular fluid in tissue spaces

M

manipulation/mobilization Passive, skilled manual therapy techniques applied to joints and related soft tissues at varying speeds and amplitudes using physiological or accessory motions, for therapeutic purposes

mastectomy Removal of a breast

maximal aerobic power (max VO₂) Maximum volume of oxygen consumed per unit of time

maximal heart rate reserve (HRR) Difference between the resting heart rate and the maximum heart rate

mediastinal shift Asymmetrical positioning of the trachea, palpable at the suprasternal notch

meniscectomy Intra-articular procedure at the knee by which the meniscus (fibrocartilage) is removed surgically

metabolic equivalent (MET) Amount of oxygen required per minute under quiet resting conditions; equal to 3.5 mL of oxygen consumed per kilogram of body weight per minute

mobilization See **manipulation**

multiple-angle isometrics Application of resistance at multiple points in the ROM to isometric muscle contractions

muscle-setting exercise Form of isometric exercise but one not performed against any appreciable resistance; gentle static muscle contractions used to maintain mobility between muscle fibers and to decrease muscle spasm and pain

muscle soreness, acute Pain or tenderness in muscle that occurs during strenuous exercise as the muscle fatigues

muscle soreness, delayed-onset See **delayed-onset muscle soreness**

muscle spasm See **intrinsic muscle spasm**

N

non-weight-bearing bias Preferred position in which the patient's symptoms are lessened when in non-weight-bearing positions such as lying down or in traction or when reducing spinal pressure by leaning on the upper extremities (using arm rests to unweight the trunk), by

leaning the trunk against a support, or while in a pool. The condition is considered gravity sensitive because the symptoms are worsened during standing, walking, running, coughing, or similar activities that increase spinal pressure

O

occlusion Closure or obstruction of a vessel such as an artery or vein

open-chain exercise Exercise in which a distal segment of the body moves freely in space

orthopnea Difficulty breathing while lying supine

osteoarthritis (degenerative joint disease) Chronic degenerative disorder primarily affecting the articular cartilage with eventual bony over-growth at the margins of the joints

osteoporosis (bone atrophy) Condition of bone that leads to loss of bone mass, narrowing of the bone shaft, and widening of the medullary canal

osteotomy Surgical cutting and realignment of bone to correct deformity and reduce pain

outcome measure Activity that is objectively documented and is part of the goal for therapeutic intervention

overload Stressing the body or parts of the body to levels above that normally experienced

overpressure Stretch force applied to soft tissues at the end of the ROM

overstretch Stretch beyond the normal range of motion of a joint and the surrounding soft tissues

overtraining Synonymous with **overwork overuse syndromes** See **cumulative trauma disorders**

overwork Phenomenon that causes temporary or permanent deterioration of strength as a result of exercise, most often observed clinically in patients with nonprogressive lower motor neuron diseases who participate in excessively vigorous resistance exercise programs. Also known as overwork weakness or **overtraining**

oxygen deficit Time period during exercise in which the level of oxygen consumption is below that necessary to supply all the ATP required for the exercise

oxygen transport system Composed of stroke volume, heart rate, and arterial-mixed venous oxygen difference

P

pacing Performance of functional activities within the available cardiopulmonary capacity

pallor Chalky white appearance or blanching of the skin

paresthesia Abnormal sensation perceived as burning, tingling, or prickling

pathological fracture Fracture resulting from minor stresses to bone already weakened by disease (osteoporosis)

pendulum (Codman's) exercises Self-mobilization techniques that use the effects of gravity to distract the humerus from the glenoid fossa and gentle pendulum motions to move the joint surfaces

percussion Technique used with postural drainage to mobilize secretions by mechanically dislodging viscous or adherent secretions in the lungs

percussion, mediate Technique used to assess the air-to-solids ratio in the lungs

peripheral airway disease Early form of obstructive lung disease characterized by inflammation, fibrosis, and narrowing of the small airways

perturbation Displacement or disturbance of the body. Anterior/posterior and medial/lateral movement of a person, or the supporting surface under the person, is used to test and develop balance and postural reactions

phlebitis Inflammation of a vein

phosphocreatine (PC) Creatine phosphate; an energy-rich compound that plays a critical role in providing energy for muscular contraction

physiological movement Movement a person normally can carry out, such as flexion, extension, rotation, abduction, and adduction

plasticity The quality of soft tissue that allows it to maintain a lengthened state after a stretch force has been removed

pleural effusion Presence of fluid in the pleural cavity

pleurectomy Incision into the pleura

plyometric training High-intensity, high-velocity resistance exercise characterized by a resisted eccentric muscle contraction followed by a rapid concentric contraction and designed to increase muscular power and coordination; also known as **stretch-shortening drills**

pneumectomy Surgical excision of lung tissue. In some instances, the term denotes removal of an entire lung

pneumonia An inflammation of the lungs characterized by consolidation and exudation; often caused by a bacterial or viral infection

pneumothorax Presence or accumulation of air in the pleural cavity

postural drainage Means of clearing the airways of secretions by placing the patient in various positions so gravity assists in the flow of mucus

postural dysfunction Faulty posture in which adaptive shortening of soft tissues and muscle weakness has occurred

postural fault (postural pain syndrome) Posture that deviates from normal alignment but has no structural limitations

posture Position or attitude of the body, the relative arrangement of body parts for a specific activity, or a characteristic manner of bearing one's body

power Work per unit of time ($\text{force} \times \text{distance/time}$) or $\text{force} \times \text{velocity}$

progressive resistance exercise (PRE) Approach to exercise whereby the load or resistance to the muscle is applied by some mechanical means and is quantitatively and progressively increased over time

pulmonary edema Infiltration of fluid (serum) in the lungs

pumping exercises Active repetitive exercises, usually of the ankles or wrists, performed to maintain or improve circulation in the extremities

Q

Q angle Angle formed by intersecting lines drawn from the anterior-superior iliac spine through the midportion of

the patella and from the anterior tibial tuberosity through the mid-patella. The norm is 15°.

quadriceps lag Synonymous with **extensor lag** of the knee

R

rales Synonymous with **crackles**

range of motion (ROM) Amount of angular motion allowed at the joint between any two bony levers

range of motion, active (AROM) Movement within the unrestricted ROM for a segment that is produced by active contraction of the muscles crossing that joint

range of motion, active-assistive (A-AROM) Type of active ROM in which assistance is provided by an outside force, either manually or mechanically, because the prime-mover muscles need assistance to complete the motion

range of motion, passive (PROM) Movement within the unrestricted ROM for a segment produced entirely by an external force. There is no voluntary muscle contraction

Raynaud's disease Functional vasospasm of the small arteries, particularly in the hands, caused by an abnormality of the sympathetic nervous system

reflex muscle guarding Prolonged contraction of a muscle in response to a painful stimulus. Guarding ceases when the pain is relieved but may progress to muscle spasm

reflux Backward or return flow of urine toward the kidneys from the bladder

relaxation Conscious effort to relieve tension in muscles

relaxed (slouched) posture Also called **sway back posture**. A posture characterized by shifting of the pelvic segment anteriorly, resulting in hip extension, and shifting of the thoracic segment posteriorly, resulting in flexion of the thorax on the upper lumbar spine. Increased lordosis in the lower lumbar region, increased kyphosis in the thoracic region, and a forward head are usually observed with relaxed posture

repetition maximum (RM) Greatest amount of weight a muscle can move through the range of motion a specific number of times in a load-resisting exercise routine

residual volume (RV) Amount of air left in the lungs after a maximum expiration

resistance exercise Any form of active exercise in which a dynamic or static muscular contraction is resisted by an outside force

resistance exercise, manual Type of active exercise in which resistance is provided by a therapist or other health professional to a dynamic or a static muscular contraction

resistance exercise, mechanical Type of active exercise in which resistance is applied through the use of equipment or mechanical apparatus

resistance exercise, variable Form of dynamic exercise carried out using equipment that varies the resistance to the contracting muscle throughout the ROM

respiration, external Exchange of gas at the alveolar capillary membrane and the pulmonary capillaries

respiration, internal Exchange of gas between the pulmonary capillaries and the cells of the surrounding tissues

respiratory resistance training Use of resistance to improve the strength or endurance of the muscles of ventilation; used interchangeably with ventilatory muscle training and inspiratory or expiratory resistance training.

resting position Position of the joint in which there is maximum laxity in the capsule and surrounding structures

rheumatoid arthritis A chronic connective tissue disease that is often systemic; characterized by inflammation of synovial joints with periods of exacerbation and remission

rhonchi Formerly used to describe **wheezes**

rhythmic stabilization Form of isometric exercise in which manual resistance is applied to one side of a proximal joint, then to the other; no movement occurs as the individual stabilizes against the antagonistic forces

round-back posture Posture characterized by an increased thoracic curve, protracted scapulae, and a forward head

rubor Redness of the skin associated with inflammation

S

sacaption Elevation of the humerus in the plane of the scapula that is 30° to 45° anterior to the frontal plane; also called **scapular plane abduction**

scoliosis Abnormal lateral curvature of the vertebral column

scoliosis, functional Nonstructural reversible lateral curvature of the spine; also called **nonstructural or postural scoliosis**

scoliosis, structural Irreversible lateral curvature of the spine with fixed rotation of the vertebrae

selective tension Administration of specific tests in a systematic manner to determine whether the site of a lesion is in an inert structure (joint capsule, ligament, bursa, fascia, dura mater, or dural sheath around nerve roots) or in a contractile unit (muscle with its tendons and attachments)

self-mobilizing Techniques whereby the patient is taught to apply joint mobilization techniques to restricted joints using proper gliding techniques

self-stretching Techniques whereby the patient is taught to stretch a joint or soft tissue passively by using another part of the body for applying the stretch force

setting exercise See **muscle-setting exercise**

short-arc extension (terminal extension) exercise Active or active-resisted extension of a joint through the final degrees of its range of motion; most often applied to the knee from 35° flexion to full extension

slow-twitch (ST) fiber Skeletal muscle fiber with a slow reaction time and high aerobic capacity, suitable for tonic muscle activity

specificity of training Principle underlying the development of a training program for a specific activity or skill and the primary energy systems involved during performance

sprain Severe stress, stretch, or tear of soft tissues such as the joint capsule, ligament, tendon, or muscle

stability Synergistic coordination of muscle contractions around a joint that provides a stable base for movement

stabilization exercise Form of exercise designed to develop control of proximal areas of the body in a stable, symp-

tom-free position in response to fluctuating resistance loads. Exercises begin with easy ones so control is maintained; then they progress in duration, intensity, speed, and variety. Often called **dynamic stabilization** exercise

static traction Steady traction force applied and maintained for an extended time interval. It may be continuous (prolonged) or sustained

steady state Pertaining to the time period during which a physiological function remains at a constant value

strain Overstretching, overexertion, overuse of soft tissue; tends to be less severe than a sprain; results from slight trauma or unaccustomed repeated trauma of a minor degree. It also refers to the amount of deformation that occurs in tissues when a stress is applied

strength Force output of a contracting muscle. It is directly related to the amount of tension a contracting muscle can produce

stress Load or force applied to tissues per unit area

stress testing Multistage test that determines the cardiovascular functional capacity of the individual

stretch-shortening drills Synonymous with **plyometric training**

stretch weakness Weakening of muscles that are habitually kept in a stretched position beyond their physiological resting length

stretching Any therapeutic maneuver designed to lengthen (elongate) pathologically shortened soft tissue structures, thereby increasing the range of motion

stretching, cyclic Repeated passive stretch usually applied by a mechanical device

stretching, passive Type of mobility exercise in which manual, mechanical, or positional stretch is applied to soft tissues and in which the force is applied opposite to the direction of shortening

stretching, selective Process of stretching some muscle groups while selectively allowing others to adaptively shorten to improve function in a patient with paralysis

stretching, self See **self-stretching**

stroke volume Amount of blood pumped out of the ventricles with each contraction (systole)

subluxation An incomplete or partial dislocation that often involves secondary trauma to surrounding soft tissue

sway-back posture See **relaxed (slouched) posture**

synovectomy Surgical removal of the synovium (lining of the joint) in patients with chronic joint swelling

synovitis Inflammation of a synovial membrane; an excess of normal synovial tissue and fluid within a joint or tendon sheath

T

target heart rate Predetermined heart rate to be obtained during exercise

tendinitis Scarring or calcium deposits in a tendon

tendinosis Degeneration of a tendon from repetitive microtrauma; collagen degeneration without inflammation

tendon-gliding exercises Exercises designed to maintain or develop mobility between the multijoint–musculotendinous units and other connective tissue structures in the

wrist and hand; also used to develop neuromuscular control and coordinated movement

tenosynectomy Surgical removal of proliferated synovium from tendon sheaths

tenosynovitis Inflammation of the synovial sheath covering a tendon

tenovaginitis Thickening of a tendon sheath

terminal extension See **short-arc extension**

thoracotomy Any surgical cutting of the chest wall

thromboangiitis obliterans (Buerger's disease) Inflammatory reaction and subsequent vasospasm of the arteries as a result of exposure to nicotine

thrombophlebitis Inflammatory occlusion of a deep or superficial vein with a thrombus

thrombosis Formation of a clot in a blood vessel

thrombus Blood clot

tidal volume (TV) Amount of air a person breathes in and breathes out during relaxed inspiration and expiration

total lung capacity (TLC) Total amount of air in the lungs; vital capacity plus residual volume

traction Process of drawing or pulling

transfer of training Carryover of the effects of an exercise program from one mode of exercise or performance to another. Also known as **cross-training**

transitional stabilization Stabilization technique whereby the functional position of the spine is stabilized by the

trunk muscles while the body moves from one position to another. It requires graded contractions and adjustments between the trunk flexor and extensor muscles

V

Valsalva maneuver Expiratory effort against a closed glottis

vasoconstriction Narrowing of a blood vessel because of contraction of smooth muscle in the walls of the vessels, resulting in decreased blood flow

velocity spectrum rehabilitation Isokinetic exercises performed over a wide range of exercise speeds

ventilation Movement or mass exchange of air in and out of the body

ventilatory muscle training (VMT) Process of improving the strength or endurance of the muscles of ventilation, usually the inspiratory muscles

vibration Technique of rapid shaking with small amplitude used with postural drainage to mobilize secretions

vital capacity (VC) Greatest amount of air a person can inspire and expire

W

wheezes Abnormal breath sounds heard during exhalation characterized by high- or low-pitched sounds or musical tones; formerly called **rhonchi**

- Forward-bending leg lifts, 677
- Forward-bending test, 413

- Forward-head posture, 891
 axial extension technique for decreasing, 399, 399f
 faulty scapular posture and, 485, 485f
 round back with, 394f, 395–396
 shoulder impingement syndromes and, 505
 temporomandibular dysfunction and, 434
- Fracture(s), 320–325**
 bone healing after, 322–323
 causes and types of, 321f, 322, 322t
 complications of, 323
 hand and wrist, 596
 hip, 664–670
 management of, 323–325
 immobilization period, 323, 324
 postimmobilization period, 323–325
 open reduction and internal fixation of, 344, 344f
 hip fracture, 665–670, 665f
 osteoporotic, 318–320, 319f
 pathological, 185, 186, 893
 radial
 Colles' fracture, 563
 displaced fracture of radial head, 564, 565–567
 signs and symptoms of, 322
 FRC (functional residual capacity), 856, 856f, 892
- Free weights, 213–215**
 advantages and disadvantages of, 215
 characteristics of, 214–215, 214f–215f
 for elbow exercises, 581, 581f
 for forearm pronator/supinator exercises, 581, 582f
 types of, 213, 213f
 for wrist exercises, 582, 582f, 636, 636f
- Fremittus, 859, 892**
- Frequency of exercise, 22, 891**
 aerobic exercise, 239
 plyometric activities, 210
 resistance exercise, 163
 stretching, 80, 81–82
- Friction massage, 69, 93**
- Frozen shoulder, 489**
- Full-arc exercise, 165**
- “Full can” exercise, 547, 547f
- Full fist position, 631f, 632**
- Functional activities**
 ankle and foot, 791
 elbow, 583
 to improve forearm pronation/supination, 581–582
 in overuse syndromes, 577
 after total elbow arthroplasty, 572
- hip
 after hip fracture, 669–670
 after total hip arthroplasty, 660
- knee
 after anterior cruciate ligament reconstruction, 734
 exercises to simulate, 750–751, 751f
 in patellofemoral pain syndrome, 714
 after total knee arthroplasty, 710–711
- shoulder, 549–550, 550f
 after shoulder replacement arthroplasty, 500
- for spinal rehabilitation, 421, 423, 440, 442, 442t, 451f, 473–476, 475f
 intermediate to advanced exercises, 477–478
- wrist and hand, 598, 638
- after carpometacarpal arthroplasty of thumb, 612
 after metacarpophalangeal implant arthroplasty, 607
 after proximal interphalangeal arthroplasty, 610
 after wrist arthroplasty, 602

 exercises for lymphedema, 846
 joint mobilization for, 696
 manual resistance exercise for, 194, 194f
 manual stretching techniques for, 102–103,
 102f, 743
 muscle function for, 692
 neuromuscular inhibition techniques for, 743
 open-chain exercises for, 747, 747f
 range of motion for hip flexion combined
 with, 52, 52f
 self-stretching techniques for, 743–744, 744f
 after total knee arthroplasty, 707, 708

Knee-to-chest movements, 673

 for lymphedema, 845, 846, 847
 in pregnancy and postpartum, 816, 817

Kypholordotic posture, 395, 892

Kyphosis, 384, 505, 876, 892

L

Labor, 893
 cervical effacement and dilation during,
 798–799, 799f
 premature, 812, 819
 preparation for, 821

relaxation and breathing exercises during,
 815–816

stages of, 798–799, 799f

Larynx, 854

Lateral (radial) collateral ligament of elbow,
 559, 559f

Lateral (femoral) collateral ligament of knee,
 688, 722

Lateral costal (basal) expansion, 863–864,
 863f–864f

Lateral epicondylitis, 563, 575–577, 577f, 584

Lateral flexibility in spine, 448–449, 449f–450f

Lateral retinacular release (LRR), 716–718, 717t
 complications of, 716

 indications for, 716

 outcomes of, 718

 postoperative management and exercise after,
 716–718, 717t

 procedures for, 716

Lateral shift, correction of
 extension techniques for, 426–427, 426f
 flexion techniques for, 430, 430f

Latissimus dorsi muscle

 manual stretching of, 533–534

 self-stretching of, 400, 534

 strengthening exercises for, 547

“Lawnmower pull,” 549, 583, 583f

Lawton Instrumental Activities of Daily Living
Scale, 261t

Leg, 760

Leg length asymmetry, 647

 after surgery for hip fracture, 667

 after total hip arthroplasty, 656–657

Leg lifting style, 257, 258f

Leg lifts, 470, 677, 677f

Leg-lowering exercises, 746

 bilateral, 469

 in pregnancy and postpartum, 813

Leg sliding, 813

Legg-Calvé-Perthes disease, 344

Levator ani muscle, 802f, 802t

Levator costarum muscle, 391f

Levator scapulae muscle, 389t, 535f

 manual stretching of, 535, 535f

 self-stretching of, 400, 536, 536f

Lifting, 751

 balance during, 256–258, 256f–258f

 load position for, 477

 lumbar spine position for, 476–477

 repetitive, 477–478

 after total elbow arthroplasty, 572, 573

Ligament(s). *See also specific ligaments.*

adaptations to resistance exercise, 158t,
 159

of ankle and foot, 761–762, 761f

 injuries of, 777–782

of elbow, 559, 559f

of hip, 644–645, 645f

of knee, 688, 688f

 injuries of, 722–737

 longitudinal, 409

 palpation of, 885

of shoulder, 482, 482f, 484f

spinal, 386t

 stress tests for, 884

 surgical repair/reconstruction of, 337–338

 synthetic, 336

Ligamentous injuries of ankle and foot,

 777–782

nonoperative management of, 777–778

 surgery for, 779–782, 779f

Ligamentous injuries of ankle and foot
(Continued)
 exercise after, 780–781
 outcomes of, 782
 postoperative management for, 780
 preventing re-injury after, 781–782
 procedures for, 779–780

Ligamentous injuries of knee, 722–737
 in female athletes, 722–723
 impairments and functional limitations/disabilities due to, 723
 mechanisms of, 722
 nonoperative management of, 723–725, 724t
 surgery for, 725–737
 anterior cruciate ligament reconstruction, 726–735, 729t–730t
 posterior cruciate ligament reconstruction, 735–737
 types of, 725

Ligamentum patellae, 690

Limb loading
 for cervical stabilization exercises, 456–458, 456f–458f, 457t–458t
 for lumbar stabilization exercises, 456–458, 456f–458f, 457t–458t

Limb volumetric measurements, 836

Limits of stability, 251–252, 252f

Literature reviews, 12

Load-resisting exercise, 212, 893

Lobectomy, 876, 893

Longus colli muscle, 389t, 391–392, 392f

Lordosis, 893

Lordotic posture, 384, 394–395, 394f, 893

Lower extremity. *See also specific structures.*
 ankle and foot, 759–791
 aquatic exercises for
 independent strengthening exercises, 288–289, 288f
 manual stretching, 281–282, 281f
 self-stretching, 282–283, 282f
 strengthening, 286–287, 286f
 D_1 extension pattern, 196t, 200–201, 200f
 D_1 flexion pattern, 196t, 200, 200f
 D_2 extension pattern, 196t, 201–202, 201f
 D_2 flexion pattern, 196t, 201, 201f
 frontal plane deviations from asymmetries of, 397–398, 397f
 functional performance tests for, 885
 hip, 643–682
 intermittent claudication in, 826–827, 828
 knee, 687–752
 leg length asymmetry, 647
 lymphatic drainage exercises for, 844–845, 846–847, 846f–847f
 manual resistance exercises for, 192–195, 192f–195f
 manual stretching techniques for, 99–104, 99f–103f
 neural testing and mobilization techniques for, 368–369, 369f
 plyometric activities for, 209
 PNF diagonal patterns for, 196t, 200–202, 200f–201f
 range of motion techniques for, 52–55, 52f–55f

thrombophlebitis and deep vein thrombosis in, 334, 656, 705, 707, 716, 719, 831–833
 veins of, 831f

LRR. *See Lateral retinacular release (LRR).*

Lumbar plexus, 358, 359f

Lumbar region
 core muscle activation and training in, 387–390, 387t, 388t, 421, 431, 440, 454–456
 abdominal bracing, 454f, 455
 drawing-in maneuver for transversus abdominis activation, 390, 421, 452, 454–455, 455f
 multifidus activation, 455–456, 456f
 posterior pelvic tilt, 454f, 455

global muscle stabilization exercises in, 460–465
 progression to dynamic exercises, 465
 with progressive limb loading, 460–463, 460f–462f, 460t, 462t
 quadratus lumborum, 465, 465f
 variations and progressions in, 463–464, 463f–465f

isometric and dynamic exercises for, 467–471, 468f–472f
 soft tissue injuries in, 432–433

Lumbar spine
 aquatic exercises for
 independent strengthening, 289
 manual stretching, 280, 280f
 facet joint orientation in, 386t
 lifting style to reduce load on, 257
 mobilization of, 431–432, 432f
 muscle control in, 387–391, 387t, 388t, 389f–391f
 objective findings of intervertebral disk
 lesions in, 413–414, 413f
 passive positioning of, 421, 443
 position for lifting, 476–477
 position of symptom relief in, 443
 range of motion techniques for, 55–56, 56f
 self-stretching of to increase extension of, 448, 448f
 techniques for lesions with extension bias in, 425–428, 426f, 427f
 techniques for lesions with flexion bias in, 429
 techniques to increase flexion of, 447–448
 assisted stretching, 447, 447f
 self-stretching, 447–448
 techniques to increase lateral flexibility, 448–449, 449f–450f
 traction applied to, 427–428, 450, 450f

Lumbar strain, 416

Lumbar support, 477

Lumbopelvic rhythm, 646–647

Lumbosacral angle, 394–395, 394f

Lumbosacral trunk, 359f

Lumbricales muscles of foot, 362f

Lumbricales muscles of hand, 356, 356f, 357f, 592, 592f, 593f
 self-stretching of, 635, 635f
 strengthening exercises for, 637

Lunate, 131, 131f, 590, 590f

Lung(s). *See also Pulmonary disorders; Respiratory system.*
 breath sounds, 859–861, 860f
 in chronic obstructive pulmonary disease, 875, 875f

compliance of, 854, 893
 in restrictive pulmonary disorders, 876–880
 structure of, 855–856, 855f
 surgical procedures for, 877
 volumes and capacities of, 856, 856f

Lunges, 679–680, 680f, 750
 partial, 476, 697, 708, 750

Lymphadenectomy, 835, 839

Lymphadenitis, 835

Lymphadenopathy, 835

Lymphangitis, 835

Lymphatic drainage exercises, 842–847, 845f–847f

Lymphatic system, 834
 disorders of, 834–847
 causes of, 835
 clinical manifestations of, 835–836
 examination and evaluation of, 836
 vessels of, 835f

Lymphedema, 834, 893
 after breast cancer surgery, 839, 842
 exercises for, 837, 842–847, 845f–847f
 location and severity of, 835–836
 management of, 836–838
 prevention of, 836, 837
 primary and secondary, 835
 types of, 835

M

Magnetic resonance angiography, 828

Magnuson-Stack procedure, 522

Mallet finger deformity, 625

Mandible, 391, 391f

Manipulation, 893

Manipulation under anesthesia, 110
 glenohumeral joint, 493

Manual-assisted cough technique, 869, 869f

Manual resistance exercise, 21f, 165, 167–168, 186–195, 894
 advantages and disadvantages of, 187
 application of resistance and stabilization for, 187
 aquatic, 283–287, 283f–287f
 body mechanics of therapist for, 187
 lower extremity, 192–195
 ankle, 194–195, 195f
 hip, 192–194, 192f–193f
 knee, 194, 194f
 repetitions, sets, and rest intervals for, 187–188
 techniques for, 188–195
 upper extremity, 188–191
 elbow, 190, 190f–191f
 fingers and thumb, 191, 191f–192f
 forearm, 191, 191f
 scapula, 190, 190f
 shoulder, 188–190, 188f–190f
 wrist, 191, 191f
 verbal commands for, 187

Manual stretching techniques, 66, 68, 82–83
 in anatomical planes of motion, 94–104
 application of, 89–90
 for aquatic exercise, 279–282, 279f–281f
 in combined, diagonal patterns, 94
 for lower extremity, 99–104
 ankle and foot, 103–104, 103f
 hip, 99–102, 99f–102f
 knee, 102–103, 102f–103f
 stabilization for, 94

for upper extremity, 94–99
 elbow and forearm, 97–98, 97f, 563, 576, 578
 shoulder, 94–96, 94f–96f, 492
 wrist and hand, 98–99, 98f
Manubrium, 121f, 482f, 484f
Marching, 681
Massage, 93, 185
 friction (cross-fiber), 69, 93
 in ankle/foot overuse syndromes, 777
 around cesarean incision site, 819
 in elbow overuse syndromes, 576
myofascial, 93
 to relieve postural stress, 402
 during stages of soft tissue injury and healing, 299–300, 302
Mastectomy, 838, 893
Maximal loading, 161
McMurray grinding test, 737
MCP joints. *See Metacarpophalangeal (MCP) joints.*
Mechanical resistance exercise, 165, 168, 203–206, 894. *See also Strengthening exercises.*
 advantages and disadvantages of, 204
 for children, 205, 205f
 circuit weight training, 207–208
 in conditioning programs, 204
 for older adults, 205–206
 in rehabilitation, 204
 for strengthening hand muscles, 637–638
Mechanical stretching, 68, 84–85, 84f, 89, 94, 578
Medial (ulnar) collateral ligament of elbow, 559, 559f
Medial (tibial) collateral ligament of knee, 688, 689, 722, 724t, 727
Medial epicondylitis, 563, 575–577
Median nerve, 353, 353f, 355, 356f, 561
 compression in carpal tunnel, 373–377, 374f, 594
 entrapment at elbow, 561
 injury of, 354t, 355–356
 mobility of, 351
 testing and mobilization techniques for, 351, 367–368, 368f, 371, 375, 375f
Median sternotomy, 880
Mediastinal shift, 859, 893
Medications, falls related to, 260, 265
MedRisk Instrument for Measuring Patient Satisfaction (MRPS), 23
Meniscectomy, 738, 742, 893
Meniscus(i) (knee), 137f, 688f, 689
 tears of, 737–742
 nonoperative management of, 738, 738f
 partial meniscectomy for, 738, 742
 surgical repair of, 699, 738–742
 complications of, 739
 exercise after, 740–741
 indications and contraindications for, 738–739
 outcomes of, 741–742
 postoperative management and immobilization after, 739–740
 procedures for, 739
 vascularity and healing of, 738, 738f
 transplantation of, 738, 742
Metabolic adaptations to resistance exercise, 158t, 159

Metabolic changes with training, 242
Metabolic equivalents (METs), 234, 893
Metacarpal bones, 131f, 590, 590f
Metacarpophalangeal (MCP) implant arthroplasty, 603–608
 complications of, 607–608
 exercise after, 605–607
 implants for, 603–604, 603f
 indications for, 603
 outcomes of, 607
 postoperative management and immobilization after, 604–605, 605f
 procedures for, 604
Metacarpophalangeal (MCP) joints, 131f, 590f, 591–592
 arthrokinematics of, 591, 592
 of digits 2–5, 591–592
 in extensor tendon exercises, 629, 630, 632–633, 633f
 in flexor tendon exercises, 622–623, 631–632, 631f–632f
 isolated extension of, 633
 isolated flexion of, 632
 mobilization techniques for, 135
 distraction, 135, 135f
 glides and progression, 135, 135f
 mobilization with movement of, 598
 range of motion techniques for, 51, 51f
 in rheumatoid arthritis, 310
 exercises after extensor tendon repair, 614–615
 stretching techniques for, 99
 of thumb, 592
 arthrodesis of, 343t
Metatarsal bones, 141f, 760, 760f
 subluxation of, in rheumatoid arthritis, 311f
Metatarsophalangeal (MTP) joints, 763
 arthrokinematics of, 762
 flexion and extension exercises for, 788
 of great toe
 arthrodesis of, 774
 extension of, 788
 gout in, 766
 hypomobility of, 766
 range of motion techniques for, 55, 55f
 in rheumatoid arthritis, 310, 311f
METs (metabolic equivalents), 234, 893
Microfracture technique, 340, 652
 at hip, 652
 at knee, 698, 699
Midcarpal joint, 131f, 590, 590f
Military press, 546–547, 546f, 584
“Mini-open” procedures, 336
 rotator cuff repair, 512–513
Mini-squats, 476, 680, 680f, 697, 708, 714, 748–749, 749f
Mini-trampolines, 220
Minimum active tension
 after extensor tendon repair, 629
 after flexor tendon repair, 621
Mobility
 active, 66
 definition of, 2, 2f, 65
 elbow, 562–563
 excessive, 69
 functional, 65, 87–88
 treatment sequence for enhancement of, 119–120

impaired, 65–66, 67t
 interventions to increase, 68–69
 joint mobilization for limitations of, 114
 of nerves, 350–351, 366
 impairment of, 366–370 (*See also Neural tension disorders*)
 passive, 66
 resistance training and, 166
shoulder
 after closed reduction of shoulder dislocation, 520
 after glenohumeral joint stabilization, 526–527
 after rotator cuff repair, 515, 516
 after shoulder replacement arthroplasty, 499, 500
 after subacromial decompression, 510
 spinal, 441, 442t, 444–450
 terms related to, 65–69
 wrist and hand, 598
Mobilization, 893. *See also Joint mobilization; Spinal mobilization.*
Mobilization with movement (MWM), 110, 120–121
 for ankle and foot hypomobility, 768, 768f
 for deQuervain’s disease, 616
 for elbow hypomobility, 563, 564f
 for elbow overuse syndromes, 576, 577f
